The own investigations confirmed the proposal of Lam and Teng (2003) to work with a reduction factor. In nearly all cases, the reached rupture strain of the used CFRP systems was considerably smaller than ultimate tensile strain found from flat coupon tensile tests. An example is given with Figure 5. In this case, the obtained values of k_ε for SikaWrap 200C fibers are shown.

An average value of 0.69 for k_ε has been found. This value is considerably higher than the value investigated by Lam and Teng (2003). The statistical evaluation also revealed a strong spreading during tests. In this case, the standard deviation was 0.126. Hence, the characteristic value or 5-percentile value obtained from the test results was 0.486. While Lam and Teng (2003) suggested a common reduction factor for CFRP systems, the own experiments showed that there are strong differences between the used carbon fibers. As an example, the average value for Tenax fibers was considerably smaller in comparison to Sika fibers. In this case, the average value was 0.50 only. It means that the efficiency factor depends on the CFRP material, and it should be investigated carefully.

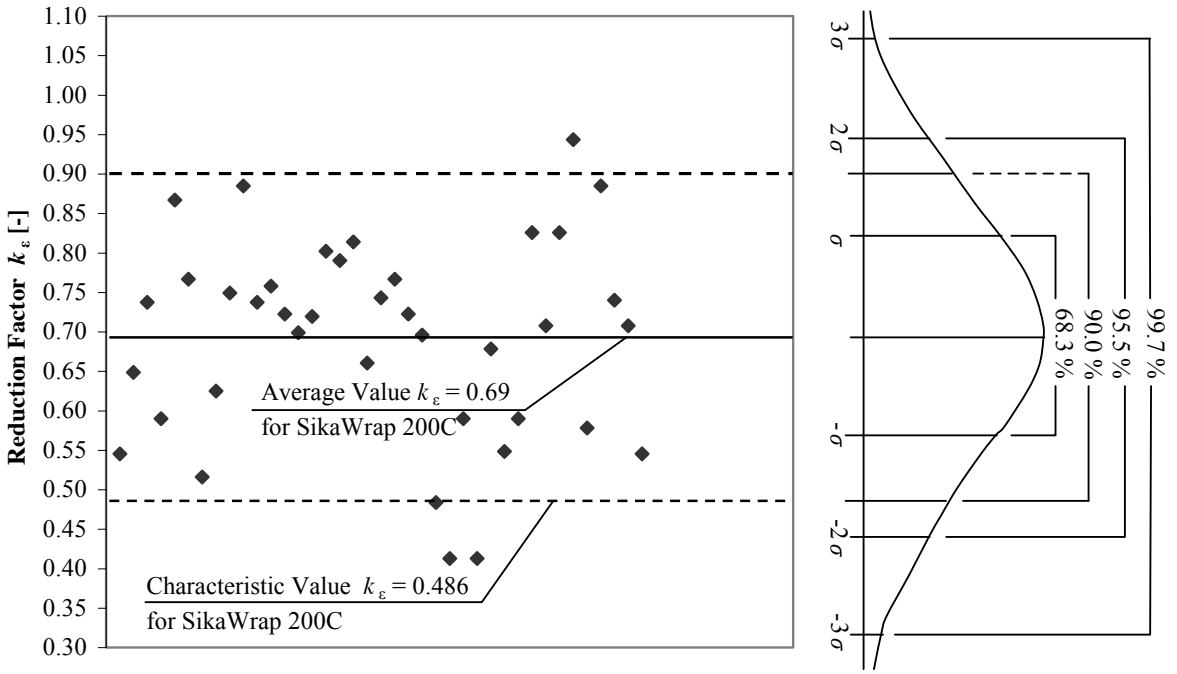

Figure 5 Statistical distribution of the reduction factor k_ε for SikaWrap 200C fibers

CFRP confined reinforced concrete

This section describes the results on confined reinforced concrete. Thereby, the effect of a dual confinement (consisting of transverse steel reinforcement and CFRP confinement) was the point of interest. Dual confinement strongly increases the load bearing capacity in general. In doing so, it is possible to summarize the shares of the confinement pressures of CFRP and steel confinement.

$$f_{l(\mathrm{FRP,steel})} = \frac{1}{2}\rho_j \cdot E_j \cdot \varepsilon_{ju} + \frac{1}{2}\rho_{st} \cdot f_y \cdot k_e \tag{5}$$

Where ρ_{st} = transverse steel volumetric ratio, f_y = yield stress, and k_e = coefficient of lateral and vertical efficiency of transverse steel reinforcement (cf. Mander et al. 1988).

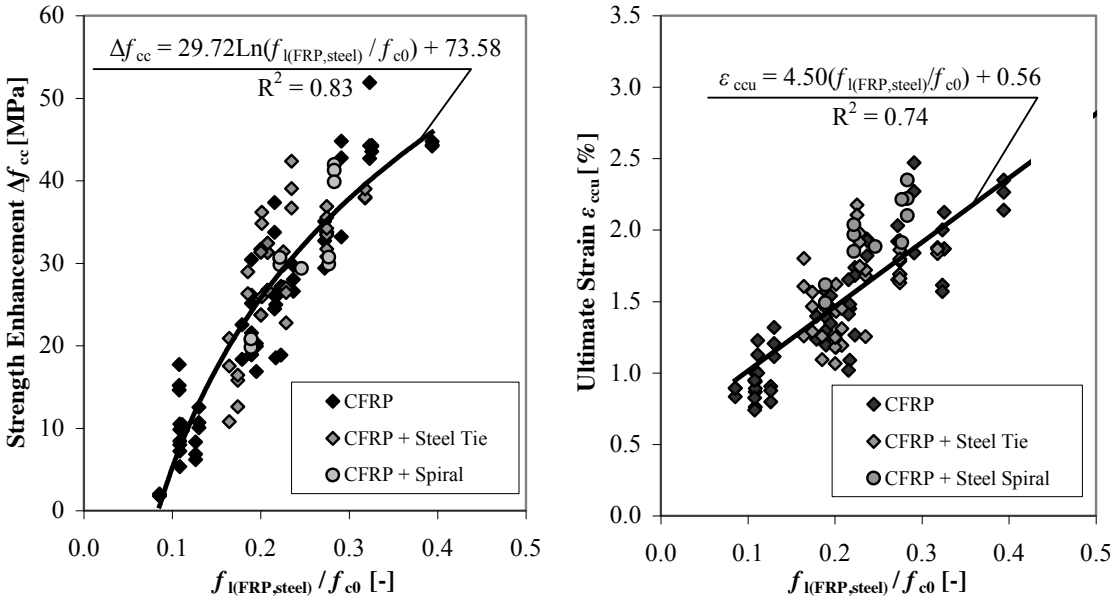

Figure 6 f_{cc} and ε_{ccu} as functions of relationship between $f_{l(\mathrm{FRP.steel})}$ and f_{c0}

In the diagrams of Figure 6, the strength enhancement as well as the ultimate strain reached for the confined plain concrete columns and of the reinforced ones are shown as functions of the ratio between $f_{l(FRP,steel)}$ and f_{c0}. Again, it is possible to find common regression curves for mathematical interpretation.

Concerning the material behavior of reinforced specimens in the axial direction, an analogy is obvious, where continuous decrease of specimens' axial rigidity occurs. However, this transition zone is more prolonged and smooth than plain FRP confined specimens showed.

Figure 7 describes the differences in the material behavior with a comparison between a CFRP confined concrete specimen and a column dual confined by spiral and CFRP jacket. In this case, a CFRP confined (2 layers) specimen with a diameter of 300 mm and a spiral ($Ø$ = 10 mm, s = 55 mm) is compared with a specimen of the same diameter and confinement but without reinforcement. As explained in Equation 7, it is assumed that for the case of steel transverse reinforcement a constant confining pressure can be expected when the steel is yielding and the stress-strain relationships of steel-confined concrete gradually decrease after the yielding of the steel. The following second modulus is similar to the E_2 observed in confined plain concrete. The reason is that a further strength enhancement only depends on the CFRP action now.

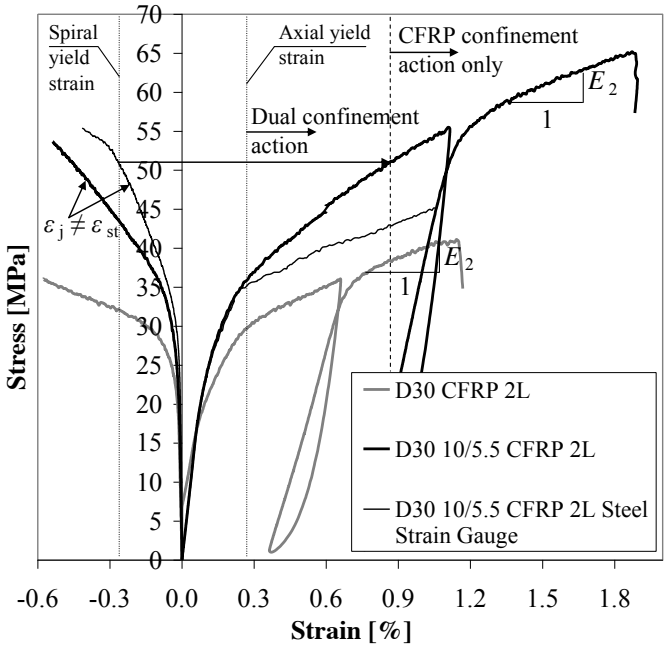

Figure 7 Comparison between a confined concrete specimen (D30 CFRP 2L) and a reinforced concrete specimen (D30 10/5.5 CFRP 2L)

Likewise, Figure 7 reveals that the strain development in CFRP jacket and transverse reinforcement is different. After leaving the elastic range of the concrete material, the obtained strain of the deployed transverse reinforcement ε_{st} increased slowly compared to the strain determined in the CFRP jacket ε_j. This behavior is in sharp contrast to the assumption in different material models, for instance Hu *et al*. (2012) and Eid and Paultre (2008), that ε_j is equal to ε_{st}.

Impact of longitudinal reinforcement on CFRP rupture strain

It has already been pointed out above that the rupture strain of carbon fibers used for confinement is considerably smaller if compared with ultimate strain received from flat coupon test. Furthermore, some research groups (Pellegrino and Modena (2010)) propose that the longitudinal reinforcement has an impact on k_ε. This is due to the fact that external FRP confinement in columns provides additional restraining for vertical steel bars, postponing buckling especially when steel stirrups are poorly stepped. Pellegrino and Modena (2010) propose that this results in further strain concentrations, mainly near the location of the vertical steel bars, and causes a further decrease of k_ε. During their investigations, they recognized a strong impact of the longitudinal steel ratio. Thereby, the influence is stronger on CFRP confinement as on GFRP. The diagram on the left in Figure 8 describes the proposal of Pellegrino and Modena (2010) to predict the reduction factor k_ε. In this example, the confinement materials (CFRP, GFRP) and the confinement ratios were varied.

The own investigations with CFRP confined reinforced specimens did not confirm the assumption of Pellegrino and Modena (2010). The longitudinal reinforcement remained without impact. Evidence can be given with the diagram on the right of Figure 8. Therein, CFRP confined specimens with a diameter of 200 mm and the same tie configuration (Ø = 6 mm, s = 100 mm) but with different amount of longitudinal bars (Ø = 12 mm) are compared.

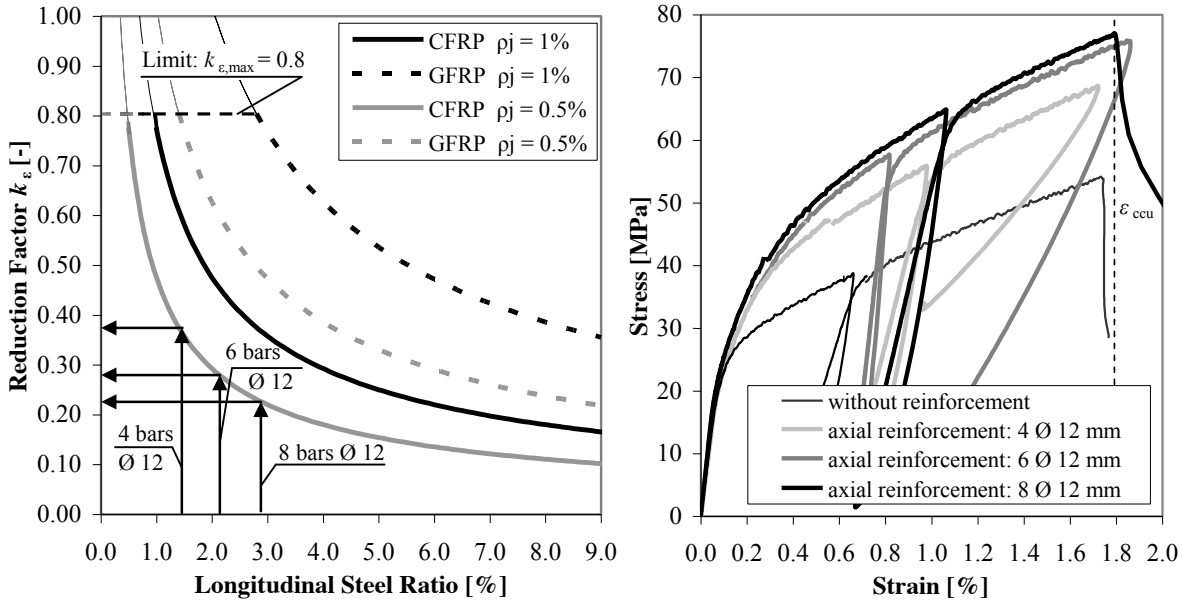

Figure 8 Left: Proposal of Pellegrino and Modena (2010) concerning k_ε; Right: Comparison between confined reinforced concrete specimens with a different amount of longitudinal bars

Thereby, the number of bars differed between 4 and 8. It is obvious that in all cases nearly the same maximum axial strain ε_{ccu} was reached. A strong impact of the longitudinal reinforcement on ε_{ju} should influence the confinement pressure f_l. Because of this circumstance, the diagram on the left of Figure 8 also explains the determination of k_ε for the three longitudinal bar configurations by using the proposal of Pellegrino and Modena (2010). With increasing numbers of bars k_ε should get smaller. Hence, this should reduce ε_{ccu}, but such a behavior could not be observed. The reduction factor k_ε remains the same whether longitudinal reinforcement is deployed or not.

COMPARISON WITH EXPERIMENTAL RESULTS OF OTHER RESEARCH GROUPS

Our own results for CFRP confined plain concrete were compared with the test results of Xiao and Wu (2003), Lee *et al*. (2004), Eid *et al*. (2009), and Lam and Teng (2004). Because of this procedure, we were able to enlarge our own data base significantly. Figure 9 includes a sample. The diagram on the left describes the obtained results for the strength enhancement Δf_{cc} of confined plain concrete columns as functions of the ratio between f_l and f_{c0}.

The diagram on the right compares our own results for confined reinforced concrete with the test results of Lee *et al*. (2004), Eid *et al*. (2009), Ilki *et al*. (2008), and Matthys *et al*. (2005). These references offered sufficient data concerning deployed CFRP system and transverse reinforcement as well as information with respect to reached f_{cc} and ε_{ccu}. Hence, a sum of our own experimental experience and the results of other research groups were aspired to obtain proper regression curves to predict f_{cc} and ε_{ccu}. The diagram on the right provides a sample. It describes the dependency of Δf_{cc} on the ratio between total confinement pressure $f_{l(FRP,steel)}$ and unconfined concrete strength f_{c0}.

Both diagrams prove a very good agreement between the different test series. It is possible to find proper common regression curves despite the fact that different testing machines, test setups, and raw materials (for concrete and CFRP confinement) were deployed. In both cases, it is possible to find very good and common regression curves for mathematical interpretation.

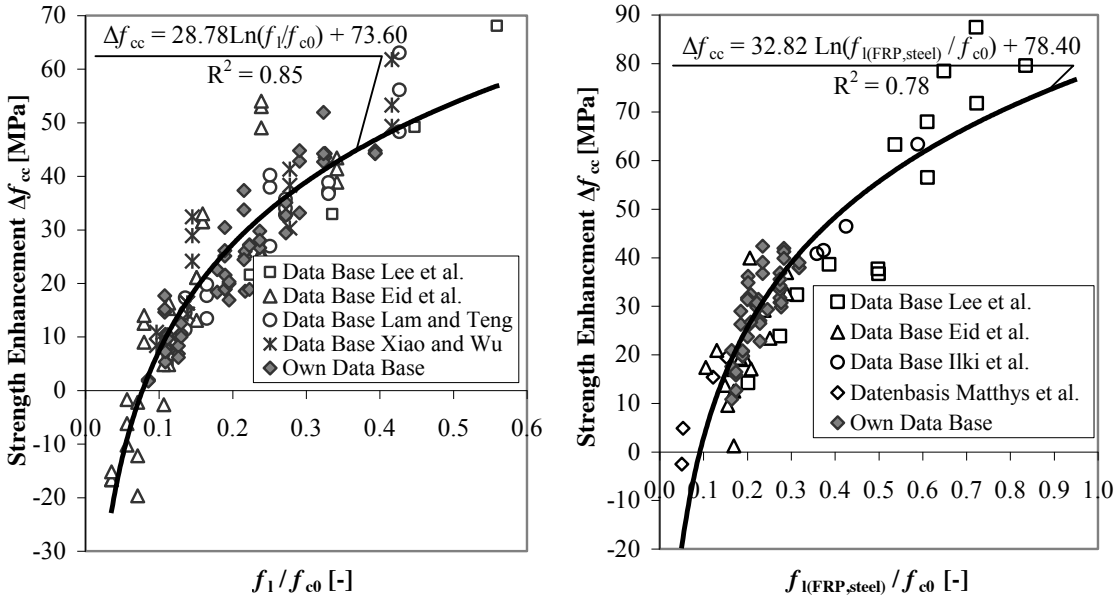

Figure 9 f_{cc} as function of relationship between f_l or $f_{l(FRP.steel)}$ and f_{c0}

COMMON REGRESSION CURVES FOR CONFINED PLAIN AND REINFORCED CONCRETE

In a last step, all results concerning f_{cc} and ε_{ccu}, for CFRP confined plain concrete specimens as well as CFRP confined reinforced concrete specimens, are described in one regression analysis. This is possible if the portion for the transverse reinforcement in Eq. 5 is zeroed for specimens without transverse reinforcement. Figure 10 presents the results. A very good accordance is obvious if the total confinement pressure is deployed for regression analysis.

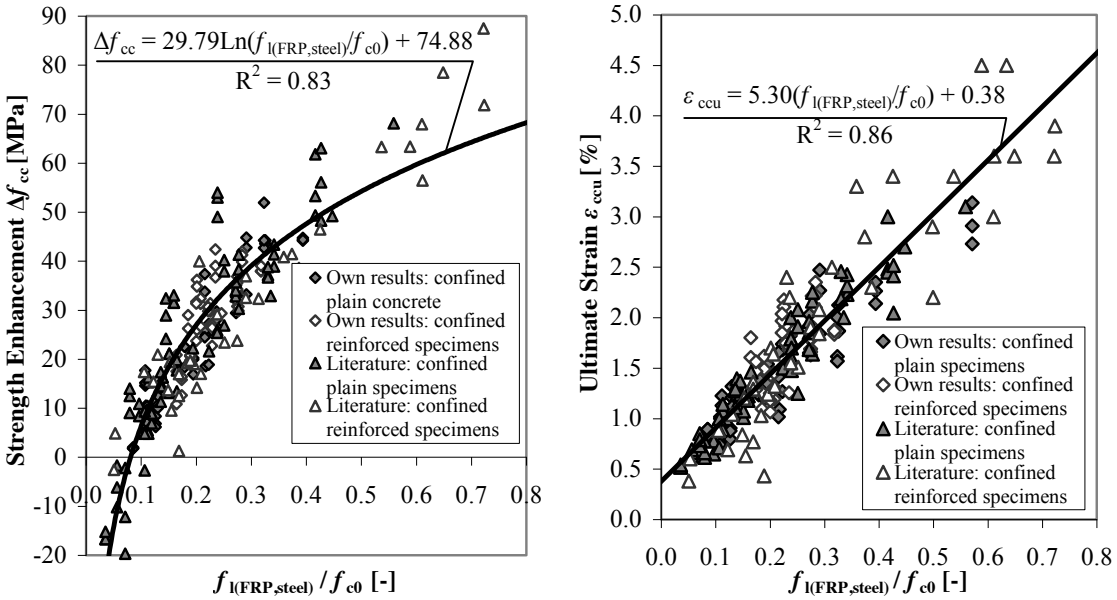

Figure 10 f_{cc} and ε_{ccu} as functions of relationship between $f_{l(FRP.steel)}$ and f_{c0}

At last, we are able to propose common equations for predicting f_{cc} and ε_{ccu}.

$$f_{cc} = f_{c0} + 30 \cdot \ln\left(\frac{f_{l(FRP,steel)}}{f_{c0}}\right) + 75 \tag{6}$$

$$\varepsilon_{ccu} = \varepsilon_{c0} \cdot 1.75 + 0.05 \cdot \frac{f_{l(FRP,steel)}}{f_{c0}} \tag{7}$$

It should be ensured that $f_{l(FRP,steel)}/f_{c0}$ is more than or equal to 0.1. This approach avoids the usage of low level confinement which is not able to provide sufficient confinement pressure. For receiving the complete material behavior, our own investigations suggest that it seems to be sufficient to adopt Eq. 3 and Eq. 4 to develop entire stress-strain curves.

CONCLUSIONS

A FRP confinement can increase the strength and the ductility of concrete and reinforced concrete significantly. The present study confirms the bilinear stress-strain model by Lam and Teng (2003) for confined plain and reinforced concrete. The proposal of Xiao and Wu (2003) to work with the ratio between confinement modulus E_{jl} and unconfined concrete strength f_{c0} could also be confirmed. The rupture strain of the used carbon fibers is considerably smaller if compared with the ultimate strain obtained from flat coupon tests. It is suitable to work with an efficiency factor k_ε to consider this phenomenon, but k_ε varies for every CFRP material. It should be investigated carefully. The dual confinement effect of steel and CFRP confinement resulted as the total of transverse steel reinforcement and CFRP jacket. Thereby, it is possible to find regression curves in order to explain mathematically the influence of the confinement pressure, which is provided by CFRP and steel confinement, on the stress-strain behavior of wrapped concrete. New equations for predicting f_{cc} an ε_{ccu} were presented in this paper.

ABSTRACT

Beam-column joints are critical members in a moment-resisting structure to maintain the stability of the whole structure. Failure of beam-column joints is likely to cause the collapse of the structure. Many methods have been proposed to strengthen reinforced concrete beam-column joints. Among others, relocation of plastic hinges away from beam-column joints has been proved to be effective. However, there exist limited studies on numerical simulation of seismic performance of beam-column joints failed with the formation of plastic hinges at end of beams. This paper examines modeling of this type of beam-column joints using OpenSees. It is recognized that rotation due to the strain penetration of longitudinal reinforcements at the end of a plastic hinge has a substantial effect on the overall response of a beam-column joint. Omission of this effect will result in an overestimation of the hysteretic behavior. To simulate the behavior of a beam-column joint failed with the formation of plastic hinge, a numerical model based on a macro joint element combined with bond-slip zero-length element or moment-rotation spring element to account for the effect of strain penetration is proposed. This model has been successfully implemented into OpenSees for representing beam-column joints strengthened by ferrocement jackets with chamfers. It has been shown that accuracy of the numerical predictions is significantly improved by taking into account the rotation induced by strain penetration.

INTRODUCTION

In moment-resisting structures, beam-column joints have been recognized as critical members for transferring forces and moments among the beams and the columns. Under seismic action, beam-column joints transfer higher shear forces as compared with the adjoining members due to the moment reversal across the joints. Thus, beam-column joints should be designed to have sufficient shear strength in order to maintain the stability and integrity of the structures.

Buildings in areas of low to moderate seismic risk, such as those in Hong Kong, were traditionally designed without seismic provisions, i.e. designed to gravity load and wind load only (Lam et al. 2002). Beam-column joints designed without seismic provision or detailing are normally in lack of transverse reinforcements or without adequate confinement in the joint cores. Figure 1 shows examples of standard method of detailing reinforced concrete beam-column joints (IStructE 1989). Transverse reinforcements are not provided in the joint. Horizontal load to be considered is only wind loading. Concerning low- to medium-rise buildings, wind effect is very small as compared with possible earthquake effect. As a result, buildings performing well under conventional load cases may suffer some degrees of damage under earthquake, which depends on the intensity of the earthquake. Proper strengthening is required to enhance seismic performance of non-seismically designed structures. More seriously, failure of beam-column joints in moment-resisting structures may cause catastrophic collapse of buildings (Kam et al. 2011). Strengthening is necessary and preferable to improve seismic behavior of non-seismically designed beam-column joints (Algirdas 2002).

Proper consideration of joint flexibility in frame structures is essential to capture the overall performance of a structure under earthquake action. Previous studies have demonstrated the importance of joint flexibility for assessment of reinforced concrete structures. Ghobarah and Biddah (1999) performed dynamic analyses of RC frames with flexible joint or rigid joint. It was concluded that incorporation of inelastic shear deformation in the joints had a significant influence on the seismic performance of structure. Overall displacement response of the frame increased when including joint flexibility. Karayannis et al. (2011) investigated the influence of strength and stiffness degradation in exterior joints on the local and global failure mechanisms of RC structures.

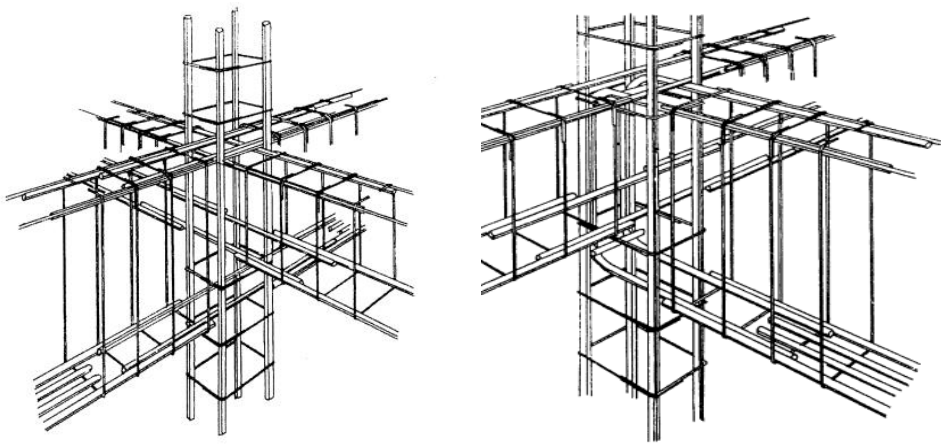

Figure 1 Traditional beam-column joints in Hong Kong (IStructE 1989)

Response of the structures with and without joint degradation demonstrated that neglecting the possible local damage of exterior joints may lead to erroneous assessment of seismic behavior. Park and Mosalam (2013) compared the nonlinear dynamic response of three hypothetical non-ductile RC buildings considering or ignoring joint flexibility. It revealed a significant difference in spectral accelerations at 2.0% drift for building structures with and without joint flexibility. Conventional ways of modelling a frame structure, however, rarely incorporate joint flexibility and consider the joints as rigid elements. A reliable, practical approach for modelling various types of beam-column joints is needed.

This paper presents a study on numerical simulation of beam-column joints strengthened by ferrocement jackets, especially for those failed with the formation of plastic hinges in the beam. This type of failure is beneficial to resist earthquake for a frame structure. A numerical model based on macro joint element and bond-slip zero-length element or moment-rotation spring element is proposed. Details of the proposed beam-column joint model and some of the results obtained using the proposed model are presented. The model has been implemented into OpenSees as zero-length sectional element or spring element at the end of a plastic hinge. Finally, results obtained from the numerical simulation are compared with the test results.

SIMULATION OF BEAM-COLUMN JOINTS

Simulation is conducted on reinforced concrete beam-column joints using OpenSees (2009). OpenSees is an object-oriented, open-source software framework for simulating the seismic response of structural and geotechnical members and systems. A macro joint element proposed by Lowes et al. (2003) is adopted to simulate the behavior of joint core. Beam-column joints with and without strengthening tested by the authors are selected for simulation (Li et al. 2015). Figure 2 shows the strengthened exterior beam-column joints. Boundary conditions are identical to those used in the tests. Constant axial load is first applied. Subsequently, horizontal load is applied at the beam tip using displacement control.

Macro Joint Element

A macro model available in OpenSees (2009) is employed to simulate the response of RC beam-column joints under cyclic loading. As shown in Figure 3, the element ("BeamColumnJoint" element) consists of one shear panel element, eight bar-slip springs and four interface-shear springs. Shear panel elements are used to simulate strength and stiffness degradation due to failure of the joint core. Bar-slip springs simulate stiffness and strength degradation due to anchorage-zone damage. Interface shear spring simulates the reduced capacity of shear transfer at the joint perimeter due to crack opening.

Generally, cross-section of un-strengthened joint is divided into confined concrete core and unconfined concrete cover with consideration of confinement provided by transverse reinforcements. For a beam-column joint strengthened by ferrocement jacket, the cross-section is discretized into confined concrete core, confined mortar and unconfined mortar. Stress-strain relationship of confined concrete is determined according to modified Kent-Park model (Scott et al. 1982). "Concrete02" available in OpenSees is adopted to represent concrete and mortar fibers. For simplicity, "Steel02" model with a bilinear monotonic stress-strain curve is used for reinforcing steel and wire mesh. Envelop of shear stress-strain relationship for shear panel zone is determined

based on the test results (Li et al. 2015) and is implanted using "pinching4". Other parameters related to unloading and reloading are defined as follows. rDispP and rDipsN are equal to 0.25. rForceP and rForceN are set to be 0.3. To include P-Δ effect, different values are used for uForceP and uForceN at various axial loads. In this study, uForceP (or uForceN) is -0.2 for the specimens under $0.2f_c'A_g$ axial load.

Figure 2 Exterior beam-column joint strengthened by ferrocement jackets with chamfers

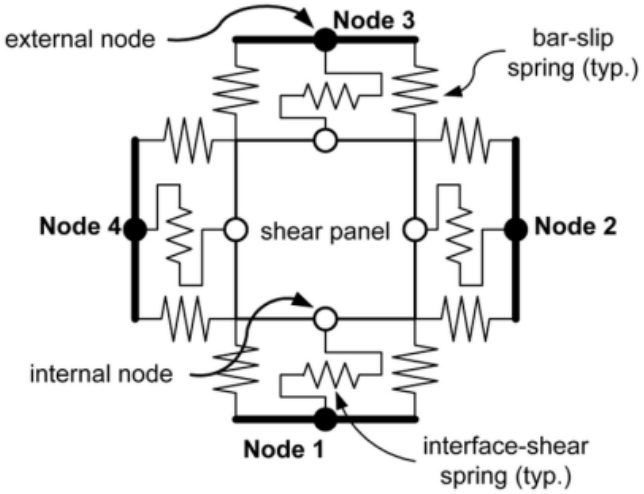

Figure 3 Macro beam-column joint element (Lowes et al. 2003)

Beam-Column Joints

Two exterior beam-column joints (Specimens JC0 and JS2) in the authors' study (Li et al. 2015) are selected. They represent two types of failure mechanisms: joint-shear failure and beam-flexural failure. Details of specimens can be referred to Li et al. (2015). A schematic view of the beam–column joint model and discretization of cross-section in the control specimen is given in Figure 4. For specimen JS2, joint core is enlarged after installing chamfers at beam-column corners. In the simulation, joint core is divided into two parts, including joint shear panel considered in "BeamColumnJoint" element and "Beamcolumn" element with varying cross section. Here, chamfer region is modeled by four "Beamcolumn" elements with the cross-section reduced linearly with depth, from 500 mm to 200 mm. Besides, ferrocement jackets are also included by specifying appropriate sectional properties. A schematic model for a beam-column joint strengthened by ferrocement jacket with chamfers is given in Figure 5. "BeamwithHinges" element is adopted to model possible plastic hinge zone.

Extent of plasticity for the specimen failed in beam-flexural is controlled by the length of plastic hinge. Scott and Fenves (2006) compared two methods of computing the length of plastic hinge: 0.216L based on Paulay and Priestley (1992) (i.e. based on equations (1) to (3) from Priestley et al. 2007) and 0.226L by Coleman and

Spacone (2001). Here, L is the length of a member. It was concluded that close agreement was attained using the two methods for global load-displacement response and local moment-curvature response of a reinforced concrete bridge pier. Thus, an empirical method for calculating length of plastic hinge is adopted (Priestley et al. 2007) using in the following equations.

$$L_p = kL_c + L_{sp} \geq 2L_{sp} \tag{1}$$

$$k = 0.2\left(\frac{f_u}{f_y} - 1\right) \leq 0.08 \tag{2}$$

$$L_{sp} = 0.022 f_y d_b \tag{3}$$

where L_p, L_{sp} and L_c are the plastic hinge length, the strain penetration length and the cantilever member length respectively (in mm); f_y and f_u are yield strength and ultimate stress of longitudinal reinforcements respectively (in MPa). d_b is the diameter of longitudinal reinforcement (in mm). Calculated plastic hinge length for this study is about 175 mm.

RESULTS AND DISCUSSIONS

Shear-Failure Specimen

Figure 6 compares simulation with test results for specimen JC0. The tested and predicted lateral loads are 25.5 kN and 26.3 kN respectively. In the negative direction, the tested and predicted lateral loads are 23.6 kN and 26.2 kN respectively. Lateral load in positive direction is well predicted while that in negative direction is overestimated. This is attributed to the use of symmetrical constitutive material model for shear panel zone. Furthermore, post-peak load at beam tip is overestimated. This is attributed to in lack of consideration in concrete spalling at the advanced stage of loading (Panagiotakos and Fardis 2001). Generally, main characteristics of hysteretic load-displacement curve are captured in the simulation of specimen JC0.

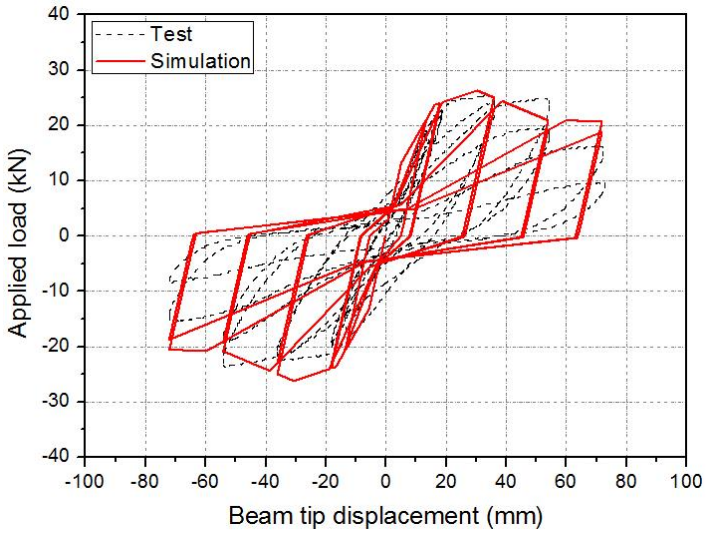

Figure 6 Comparison of simulation with test result for specimen JC0

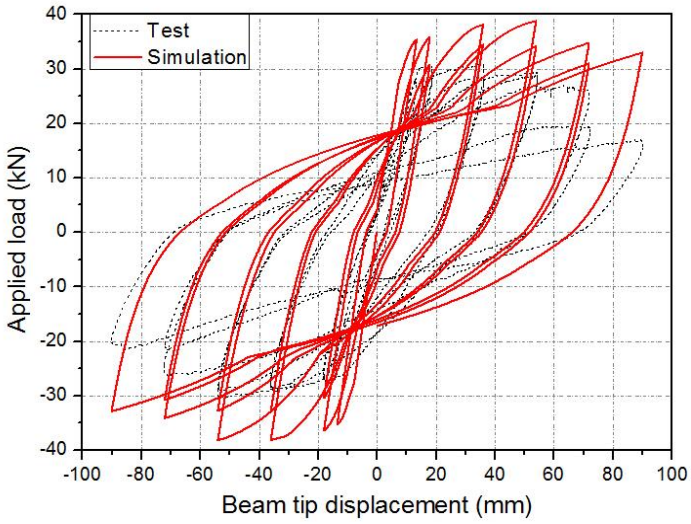

Figure 7 Comparison of simulation with test result for specimen JS2 without consideration on strain penetration

Flexural-Failure Specimen

Figure 7 shows the comparison of simulation with test result for specimen JS2 without consideration on strain penetration at end of plastic hinge. The tested lateral loads in push and pull directions are 30.9 kN and 30.3 kN respectively. Applied load at beam tip is overestimated at 38.8 kN in push direction and 38.2 kN in pull direction in the simulation. This may be attributed to possible error in considering plastic hinge in the beam.

Stain penetration normally occurs at the end of plastic hinge. Simulation of RC columns has demonstrated that without considering strain penetration effect may significantly overestimate post-peak strength. Besides, fixed-end rotation contributed approximately 25%-40% of the total horizontal displacement for both RC circular columns and rectangular columns (Lehman and Moehle 2000; Sezen and Moehle 2006; Feng 2013). In this study, strain penetration is observed with cracking at chamfers in the strengthened joints. However, fiber section beam-column elements do not take into account fixed-end rotation due to the strain penetration of longitudinal reinforcements. A joint failed in beam flexural has similar support condition as a cantilever column. Thus, modeling of beam-column joints should include strain penetration at plastic hinge zones. Two approaches for considering strain penetration are examined, including the use of a zero-length section element with bond slip behavior and a zero-length spring element with moment-rotation relationship.

Bond-slip at interface

Strain penetration at the end of plastic hinge is introduced by including a bond-slip relationship for longitudinal reinforcements. As shown in Figure 8, a zero-length fiber section containing bond-slip relationship is inserted at the interface between strengthened and un-strengthened area. This sectional element has the same reinforcement detail for which the constitutive relationship is defined by a hysteretic stress-slip model containing strain penetration effect. Zhao and Sritharan (2007) proposed a material model "Bond_SP01" to reflect stress-slip relationship of longitudinal reinforcements. They highlighted that the model is applicable to fully anchored reinforcement. This is consistence with beam reinforcement detail in the strengthened joint.

Comparison of simulation using a model with zero-length fiber section and test data for specimen JS2 is shown in Figure 9. Prediction in terms of applied load versus displacement at beam tip agrees with test result in terms of peak load, displacement corresponding to peak strength and strength degradation. The predicted lateral loads in push and pull directions are reduced to 31.9 kN and 32.1 kN respectively. Furthermore, descending segment in load-displacement curve is captured in the simulation. It is noted that non-symmetrical response in push and pull direction is not considered in the simulation. The main deficiency in the simulation is at the advanced stage of loading in that load increases gradually as displacement increases. This may be attributed to the spalling of concrete and buckling of longitudinal reinforcements (Panagiotakos and Fardis 2001). Such phenomenon is observed in the test but not considered in the simulation.

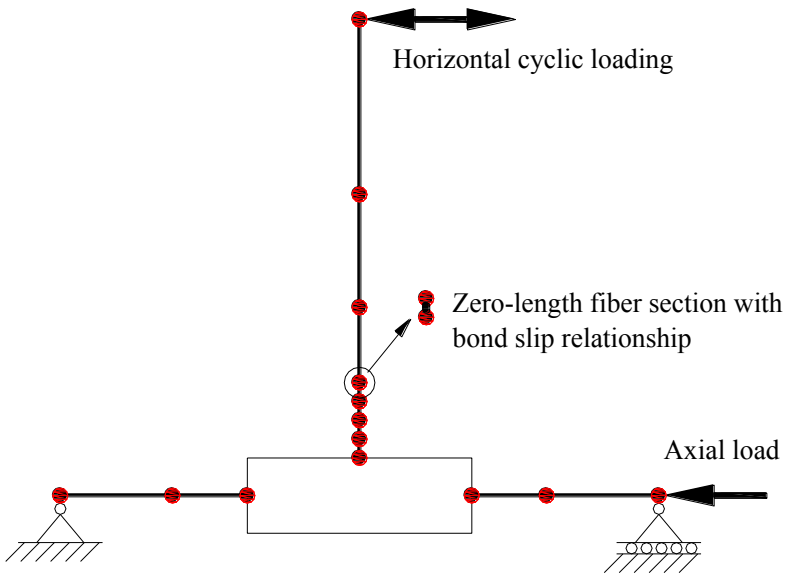

Figure 8 Numerical model of ferrocement-strengthened joint with zero-length fiber section

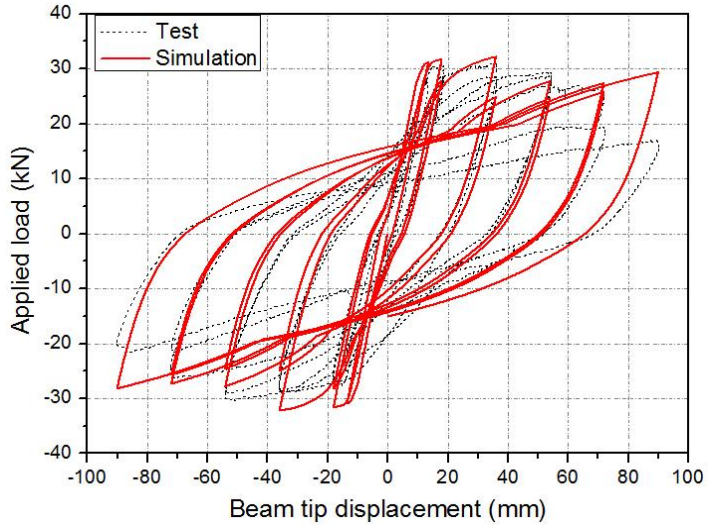

Figure 9 Comparison of simulation with test result for specimen JS2 with strain penetration using zero-length fiber section

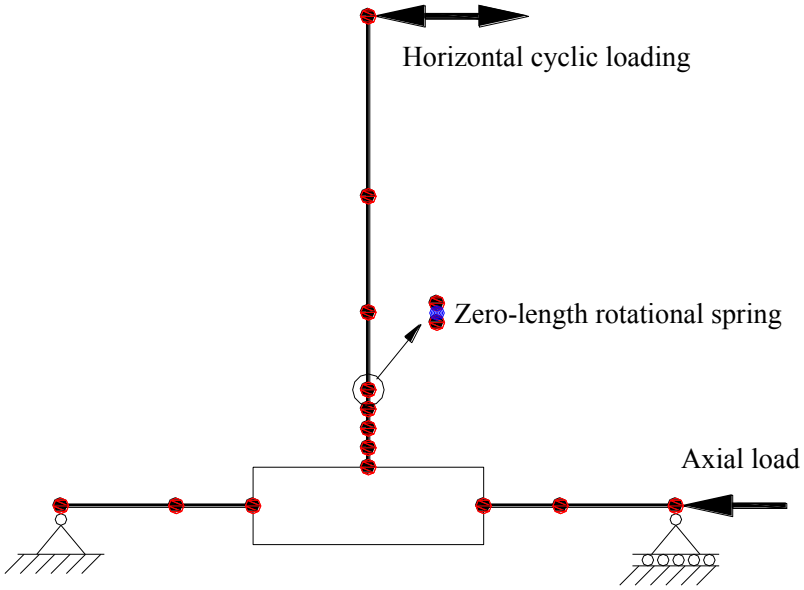

Figure 10 Numerical model of ferrocement-strengthened joint with zero length rotation spring element

Rotational spring

Strain penetration at the end of plastic hinge is also modeled through a rotational spring. The rotational spring reflects total moment-rotation relationship at end of plastic hinge. Thus, a zero-length spring element is added at the interface of strengthening area to un-strengthening area as shown in Figure 10. Constitutive model for rotational spring is defined and discussed as follows.

There are a number of hysteretic models for simulating cyclic deterioration in strength and stiffness of RC members (Otani 1981; Sivaselvan and Reinhorn 2000; Ibarra et al. 2005). Among others, modified Ibarra-Medina-Krawinkler (IMK) model is adopted to simulate constitutive relationship for rotational spring in this study. This model is able to simulate strength deterioration with a descending slope after reaching the load bearing capacity of a structural member. This is one of the key features of the IMK model as compared with traditional models, such as simple bilinear models. The IMK model simulates up to four modes of cyclic deterioration including strength degradation, post-peak strain softening, unloading stiffness degradation, and accelerated reloading stiffness deterioration (Ibarra et al. 2005). Cyclic deterioration is based on normalized energy dissipation capacity and an exponent factor that describes the rate of cyclic deterioration against

accumulation of damage (Ibarra et al. 2005). This model is implemented in OpenSees as shown in Figure 11.

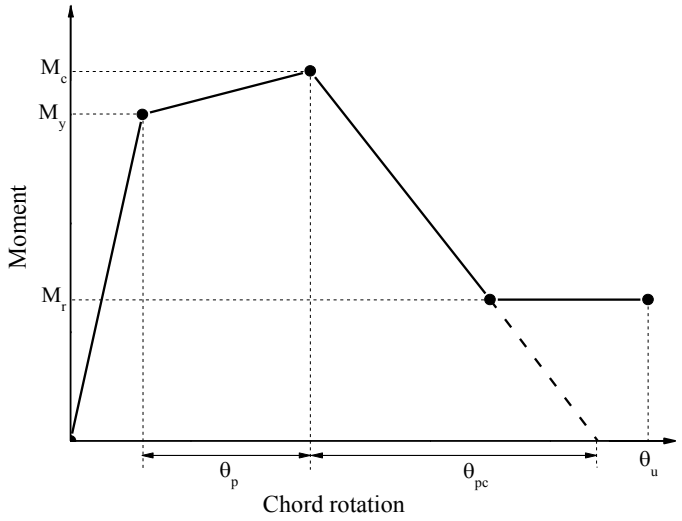

Figure 11 Envelop of IMK model

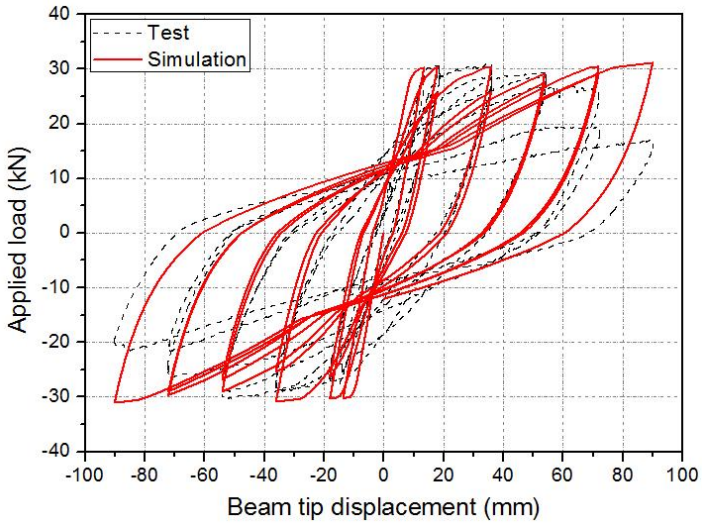

Figure 12 Comparison of simulation using rotational spring with test result for specimen JS2

Seven parameters are required to control the monotonic and cyclic performance of the IMK model. There are yield moment, chord rotation at yield, chord rotation at peak moment, hardening stiffness ratio, post-capping stiffness, normalized hysteretic energy dissipation index and an exponent term to model the rate of deterioration. Haselton et al. (2008) calibrated IMK model using 255 RC columns and considered the influence of axial load, transverse reinforcement ratio, arrangement of transverse reinforcement and concrete. Based on database, prediction formulas for determining parameters in IMK model were proposed in equations (4) to (8).

Flexural strength at yielding is determined according to the prediction proposed by Panagiotakos and Fardis (2001). It has been proved to provide adequate accuracy in predicting flexural strength. Predictive equations proposed by Haselton et al. (2008) are adopted to define the parameters in IMK model as shown in Equations (4) to (8). Equation (4) is the secant stiffness. Equation (5) illustrates strain hardening ratio for positive (negative) loading direction. Cyclic deterioration parameters for strength, post-capping strength, reloading stiffness and unloading stiffness are predicted using Equation (6). Pre-capping chord rotation and post capping chord rotation for positive (negative) loading direction are calculated using Equations (7) and (8) respectively. It is worth noticing that rate of deterioration for each parameter is equal to default value at 1.0.

$$\frac{EI_y}{EI_g} = 0.065 + 1.05v \quad 0.2 \le \frac{EI_y}{EI_g} \le 0.6 \tag{4}$$

$$M_c / M_y = (1.25)(0.89)^n (0.91)^{0.01 f_c'} \tag{5}$$

$$\lambda = (170.7)(0.27)^n (0.10)^{s/d} \tag{6}$$

$$\theta_p = 0.13(1 + 0.55\alpha_{sl})(0.13)^n (0.02 + 40\rho_{sh})^{0.65} (0.57)^{0.01 f_c'} \tag{7}$$

$$\theta_{pc} = (0.76)(0.031)^n (0.02 + 40\rho_{sh})^{1.02} \tag{8}$$

where EI_y and EI_g are the effective cross-sectional moment of inertia and the gross cross-sectional moment of inertia respectively. M_c and M_y are the capping moment capacity and the yielding moment respectively; n is the axial load ratio of the member; s/d is the ratio of stirrup spacing and the depth of the section; ρ_{sh} is the area ratio of transverse reinforcement in the plastic hinge region. α_{sl} is the bond-slip indicator (equal to 1.0 where bond-slip is possible and equal to 0 where bond-slip is not possible).

Using the model with rotational spring element, predicted result of specimen JS2 is plotted in Figure 12 and is compared with test result as shown in dash line. Hysteretic load-displacement curve is accurately predicted. The predicted lateral load is 30.3 kN in push direction and 30.8 kN in pull direction. Similar to the simulation with zero-length fiber section, the applied load is overestimated at final stage of loading. This may be attributed to that buckling of longitudinal reinforcement and spalling of concrete are not taken into account in the simulation (Panagiotakos and Fardis 2001). Generally, parameters of IMK model are obtained from regression analysis.

CONCLUSIONS

Numerical simulation of reinforced concrete exterior beam-column joints with and without strengthening is developed using OpenSees. Response of non-seismically designed beam-column joints can be predicted when proper constitutive relationship is defined for joint shear panel. Numerical simulation on the strengthened joint is focused on modeling the plastic hinge as the joint failed in beam-flexural. Two methods are used to represent strain penetration effect at the end of plastic hinge, including adopting bond-slip relationship and moment-rotation spring element. The methods improve the predictions for beam-column joints failed in beam-flexural. However, overestimation of loading is found in both models at the advanced stage of loading. This may be attributed to the lack of considerations in buckling of longitudinal reinforcements and spalling of concrete. Further studies are needed to refine the material models for reinforcing steel. In addition, determination of parameters in “Pinching4” and “IMK” necessaries further study as most of them are obtained empirically.

ABSTRACT

Cracking of concrete is one of the most complicated phenomena in reinforced concrete analysis and is one of the key aspects governing serviceability analysis of RC structures. Current methods for investigating cracking rely on empirical approaches that give unreliable results with errors of multiple times the real value. A new non-empirical method based on the combination of the stress-transfer and the smeared approaches is proposed for deriving crack spacing models. The stress-transfer approach governs the strain distribution of the reinforcement between the consecutive cracks whereas the smeared approach allows for the estimation of the mean strain of the element. The suggested method introduces the concept of damage zones: the bond in the area adjacent to the normal cracks is considered to be fully damaged, thus bond behaviour is non-uniform in the segment between cracks. Crack spacing models were derived using the load-strain analysis method presented in the Eurocode 2 and were shown to give results that are in good agreement with the crack spacing values taken from available experimental data.

KEYWORDS

Crack spacing, stress-transfer approach, smeared crack, RC tie, compatible model

INTRODUCTION

In general practice, design of reinforced concrete (RC) structures is often based on the assumption of perfect bond between concrete and reinforcement, i.e. no physical slip is allowed. This simplification might be reasonable in load capacity analysis of structures with proper reinforcement detailing and anchorage; however it becomes unreasonable when serviceability (cracking and deformation) of RC structures is considered. Neglecting bond-slip leads to significant inaccuracies in the assessment of serviceability performance of structures (Oehlers *et al*. 2012). Existing serviceability models are conflicting with each other, thus crack analyses are commonly carried out separately to general deformation analyses. Previous studies have shown that deflection predictions by different code techniques may vary up to 100%, whereas variability of crack width predictions was of even higher order (Gribniak *et al*. 2013, Balazs *et al*. 2013).

Cracking is considered to be one of the most complicated issues in the research of RC structures. Some of the key aspects affecting the cracking behaviour are the interaction between concrete and reinforcement, crack propagation along the boundary of larger aggregate particles at micro level, stress relief and stress redistribution after every new crack appears. The mentioned factors contribute to the highly non-linear nature of concrete and partly explain why cracks are of various orientations, shapes and lengths (normal, diagonal or longitudinal as well as major and secondary cracks). Cracks make the stress-strain state in the tensile zone highly unpredictable and it is known that classical theories often provide inaccurate crack width and crack spacing predictions.

In general structural design practice there are two prevailing approaches in crack analysis of RC structures that enable the estimation of maximum allowable crack widths in serviceability checks:

1. The classical and most common approach in the design codes, which is based on the bond between reinforcement and concrete (Beeby 2005). Where the crack width is estimated using a generalized equation:

$$w = k \cdot \frac{\emptyset_s}{\rho} \cdot \varepsilon \tag{1}$$

where k is an empirical coefficient, $\emptyset_s$ is the bar diameter, ρ is the reinforcement ratio, ε is mean strain value of tension reinforcement between cracks. Bond stresses are assumed to be constant when deriving Eq.1 in order to simplify the reinforcement-concrete interaction; however, this simplification introduces empirical parameters.

2. Concrete cover approach, in which crack spacing is directly related only to the concrete cover of the reinforcement (Broms 1965):

$$w = k_1 \cdot c \tag{2}$$

where k_1 is the empirical coefficient and c is the concrete cover. These models have to be calibrated to specific experimental elements and therefore may be inaccurate for other scenarios of reinforcement arrangements.

There are variations of both approaches, which mostly alter the empirical coefficient values (Borosnyoi and Balazs 2005). Despite the extensive experimental and analytical investigations, errors in crack width predictions are still significantly scattered and yield unreliable results in the structural analysis of RC structures (Perez 2013).

This paper proposes a new methodology for deriving crack spacing models for RC ties at the stage of stabilised cracking. The study advances a new concept of combining the stress-transfer and the smeared crack approaches. The former approach governs the strain distribution of the reinforcement between the consecutive cracks whereas the latter takes the advantage of knowledge about the mean strain of the member. An important part of the modelling approach is the introduction of the so called *damage zones* located in the vicinity of the major cracks. It has been assumed that the bond between concrete and reinforcement bar is damaged in these zones and the bond-slip behaviour differs from the areas outside the damage zones. Based on the experimental strain profiles of RC ties, it has been found that the length of the damage zone depends on the diameter of the bar and load level. The proposed new method presented in this paper relies on these findings to derive crack spacing models.

BEHAVIOUR OF A REINFORCED CONCRETE TIE

A RC element tie shown in Figure 1 is used to illustrate the interaction of cracking, deformation and bond behaviour in RC structures. Such elements are often chosen due to their simplicity and reasonably good representation of the stress and strain states of the tensile zone in RC structures (Fantilli 2007).

During the initial loading stage (OA), the deformation behaviour of the tensile member is almost linearly elastic, as shown in Figure 1(a). Composite action and compatibility of reinforcement and concrete strains are attained in the element with discontinuities due to slip occurring only in small regions at the loaded ends (refer to Figure 2(a)). Bond stresses are directly related to slip and therefore develop only in regions with non-zero slippage. The bond stresses increase together with the value of slip, whereas at the ends of segments the bond stresses diminish until they reach zero at the location of the cracks, where the slip changes direction and the absolute value of it is the largest. This effect can be explained by the presence of localized concrete damage near the crack plane, which significantly reduces the bond action (Ruiz 2007).

With increasing load, strains in the reinforcement as well as in the concrete grow until a certain limit of concrete cracking is reached. The first crack appears in the section where stresses in concrete transferred through bond action reach its tensile strength. This causes an immediate redistribution of stresses in the cracked section: concrete stresses and strains drop to zero at the location of the crack, thus the entire tensile force is transferred only through the reinforcement bar. Further away from the crack, part of the force is transferred to the concrete through the bond action. Stresses and strains in the concrete increase over distance until the tensile strength of the concrete is reached and a new crack may form again. The distance, required to reach the tensile strength of the concrete is often called the *transfer length* and is the most influencing factor in cracking analysis (Beeby 2005). Distribution of strains, slip and bond stresses after formation of the first cracks is shown schematically in Figure 1b. The cracking phenomena also cause a sudden drop in stiffness of an element which is evident from the force versus average strain diagram.

After the first crack has occurred, any further increase of the load creates new cracks, and the RC element proceeds to the crack formation phase (stage 2 and part AB in the diagram). It should be noted that the local effect of bond deterioration near the crack plane becomes more significant with increasing number of cracks. After the crack formation stage, the so called stabilized cracking phase is reached and the RC member becomes separated into a

number of concrete blocks (see Figure 1(c)). During this stage the tensile stresses are still transferred to the concrete over the reinforcement due to the bond action but the length of these blocks is insufficient to allow the stresses in the concrete to reach the tensile strength. The length of all blocks falls into a specific interval $l_{tr} \leq l_{cr} \leq 2l_{tr}$, where l_{tr} is the transfer length. From available published data (Bigaj 1999; Borosnyoi and Balazs 2005) it was determined that an average block length (crack spacing) could be in the range of $1.3l_{tr}$-$1.5l_{tr}$. The concept of stabilized cracking is controversial, formation of new cracks in this phase is very limited and has an insignificant influence on the final crack pattern (Perez 2013) The deformation behaviour with a usually stable number of cracks continues until the reinforcement yields (stage 3 and part BC in the diagram).

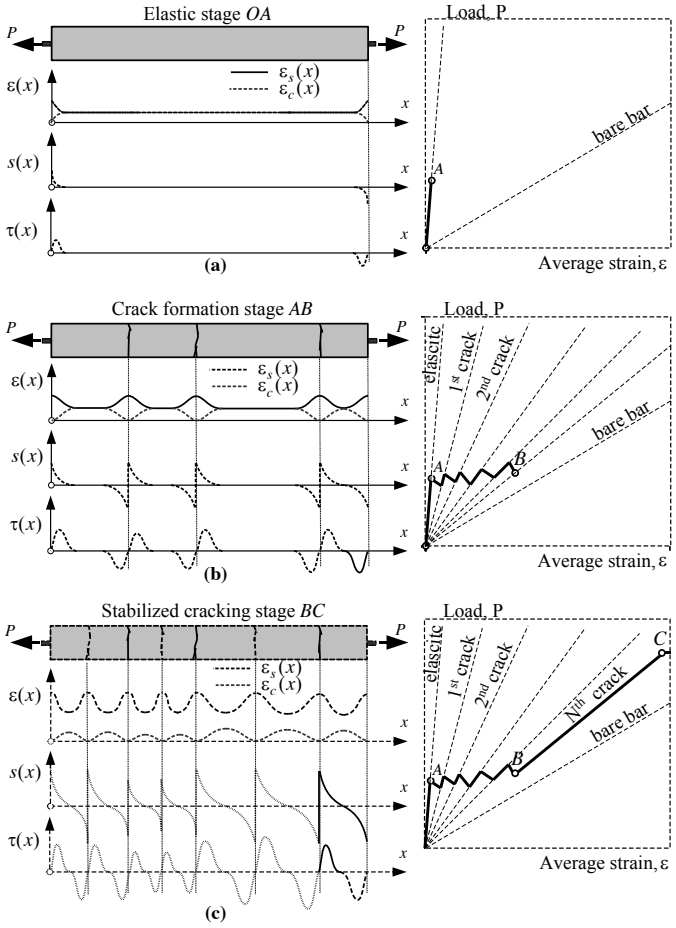

Figure 1 Behaviour of a RC tie: a) the elastic, b) crack formation and c) stabilized cracking stages

The behaviour of a RC tie between two consecutive cracks has been experimentally investigated by Houde (1974) Scott and Gill (1987) and Kankam (1997). Figure 2(a) shows the reinforcement strain distribution along a 200mm length bar at various load stages as reported by Kankam (1997). It can be observed that the variation of the reinforcement strains in the middle part of the bar can be well approximated by a first order (linear) polynomial equation for higher load levels and a second order (parabolic) polynomial for lower load levels:

$$\varepsilon_s(x) = \varepsilon_0 + a_1 x \tag{3}$$

$$\varepsilon_s(x) = \varepsilon_0 + a_1 x^2 \tag{4}$$

where a_1 is the shape function coefficient and ε_0 is the minimum reinforcement strain at the centre between cracks.

The use of a linear approximation Eq. (3) yields a reasonably good match with experimental results, particularly in the final loading stages, with coefficient of determination in the range of 0.9-0.95. Approximation of the experimental strain curves by a second order polynomial Eq. (4) also provided results with good agreement, with

coefficient of determination ranging from 0.92 to 0.95 at earlier loading stages and from 0.88 to 0.9 for the later loading stages as can be seen from Figure 2(b). A number of other experimental results were also analysed (Houde 1974, Kankam 1997), proving that linear or parabolic approximation of strain curves may be used in the mid part of an element.

DERIVATION OF CRACK SPACING MODELS

This section describes the procedure for deriving the crack spacing model in detail. The suggested approach is developed for the stabilized cracking stage and relies on the assumption that the bond behaviour in the central area of the block between adjacent cracks is different from that near the normal cracks. The concrete close to the cracks is considered to be damaged and therefore the strains follow a different law in the vicinity of the cracks. The change in the strain distribution implies that the bond-slip relationships in the middle section between cracks and in the areas close to the cracks are different. This effect is clearly visible in the strain diagrams presented in Figure 2(a). This locally damaged concrete zone is further defined as the damage zone and the length of this zone is denoted by l_d. To keep the naming consistent, the central part of the concrete block between these damage zones is called the effective zone and is further denoted by l_{ef}. To simplify the proposed concept, it is assumed that the bond in the damage zones is fully damaged. This implies that the bond stresses in this zone are equal to zero and thus the reinforcement strains are constant and equal to the strains at the location of the crack. The distance between cracks can be expressed through the lengths of the damage and effective zones:

$$l_{cr} = l_{ef} + 2l_d \tag{5}$$

Tests results of Houde (1973) were further investigated to provide a quantitative expression for the damage zone (refer to Figure 3(a)). In this case, the effective zone is assumed to follow a parabolic law while the damage zones have fully degraded bond. The lengths of each zone were estimated by equating the integrals of the experimental and fitted curves with an additional assumption that the minimum strains ε_0 of the curves coincide. The evolution of the damage zone with increasing load is obtained from this approach. The same procedure was applied to additional tests of Kankam (1997) and is summarized in Figure 3(b). A simple linear equation is suggested from the analysis of the experimental results to evaluate the damage zone length in relation to the load level:

$$l_d = 1000\varepsilon_s\phi_s \tag{6}$$

where ϕ_s is the bar diameter and ε_s is the reinforcement strains at the location of the crack.

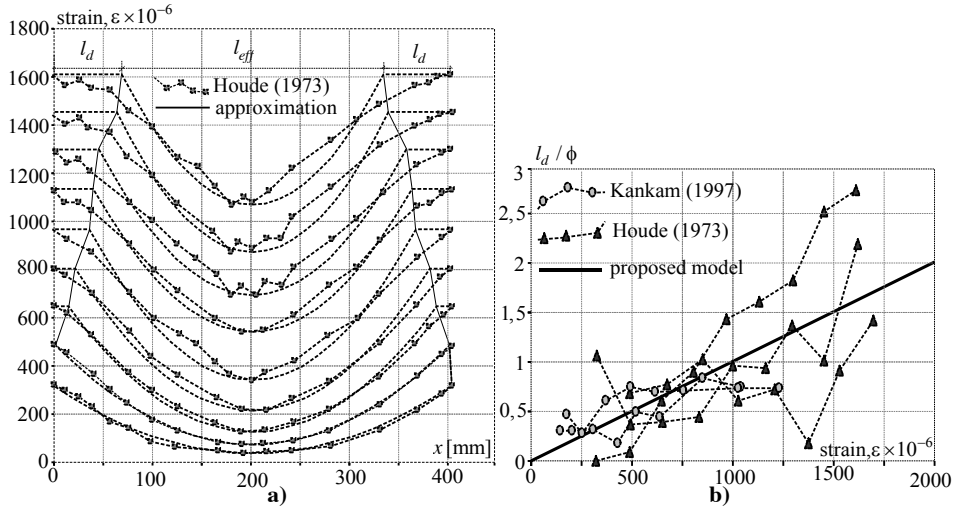

Figure 3 Effective and damage zones: a) distribution of steel strains; b) development of the damage zone

The other condition is to maintain identical bond-slip relationship for the effective area without the reinforcement ratio as a variable parameter. A way to achieve this is by applying the same reinforcement strain function $\varepsilon(x)$ for all the RC ties. The same strain and slip rate can be ensured by keeping the minimal reinforcement strains ε_0 identical in the middle section of each RC tie. An important aspect in this concept is the independence of the final crack spacing from concrete compressive strength, which had been shown to be the case by Farra (1993) and is also confirmed in the current study.

The described technique of calculating the effective and damage zones enables the derivation of crack spacing models, consistent with the assumed average strain model. All the equations are presented with symmetry conditions, for one half of the crack spacing length. It is important to note that the suggested method depends on the reference element. The reinforcement bar diameter and reinforcement ratio values of this chosen element are hence referred to as reference values. Another key reference value is the crack spacing l_{cr} of the chosen element. The benefit of this method is that in order to develop a crack spacing model only a single data point is required, i.e. the reference value l_{cr}, which can be obtained either from experimental data or estimated by empirical or numerical methods. This ensures the simplicity of this algorithm.

Procedure for the linear shape function

1. For a given load P_i, with reference diameter $Ø_{ref}$ and reference reinforcement ratio ρ_{ref}, the average deformation ε_{mi} of an RC element is calculated according to the Eurocode 2 (or other design codes). The maximum reinforcement steel strains ε_i are also known for the load level and are considered to be constant over the damage zone length.

2. The average distance between cracks l_{cr} is assumed to be known, thus the effective and damage zone lengths can be determined from Eq. (5) and (6).

3. Substituting the known values into Eq. (3) provides the shape function of the reinforcement strains over the effective length:

$$\varepsilon_0 + a_1\left(0.5 l_{ef}\right) = \varepsilon_i \tag{7}$$

4. Since the minimum strains and the shape function coefficient are unknown, an additional equation is required. The average and maximum deformation values ε_{mi} and ε_i have been already determined, along with the lengths of the effective and damage zones, thus the minimum deformation ε_0 and coefficient a_1 can also be found by integrating strains over the crack spacing length. Since the shape function only applies to the strains over the effective zone length and the maximum deformation in the damage zones is constant, the integral can be expressed as:

$$\varepsilon_i \cdot l_d + \int_0^{0.5l_{ef}} \varepsilon_s(x) = \varepsilon_{mi} \cdot 0.5l_{cr} \tag{8}$$

5. The shape function coefficient and the minimum strain can now be obtained by solving the following system of equations:

$$\begin{cases} \varepsilon_0 + a_1\left(0.5l_{ef}\right) = \varepsilon_i \\ a_1 \cdot \frac{\left(0.5l_{ef}\right)^2}{2} + \varepsilon_0\left(0.5l_{ef}\right) + \varepsilon_i l_d = \varepsilon_{mi} \cdot (0.5l_{cr}) \end{cases} \tag{9}$$

The obtained coefficient a_1 value is constant for the same reinforcement diameter regardless of the reinforcement ratio.

6. After the shape coefficient and the minimum strain are determined, bond stresses can be expressed by differentiating the strain shape function:

$$\tau(x) = \frac{E_s\phi_s}{4}\frac{d\varepsilon_s}{dx} = a_1\frac{E_s\phi_s}{4} \tag{10}$$

Note: the bond stresses for a linear shape function are constant.

7. Following the previously discussed condition of fixing the minimum strains for all other RC ties and ensuring identical bond, the shape function coefficient for different reinforcement diameters can thus be evaluated from the bond equation:

$$a_1 = \frac{4\tau}{E_s\phi_s} \tag{11}$$

8. After obtaining the shape function coefficient, the length of the effective zone and thus the crack spacing are obtained by rearranging the initial shape function expression Eq. (7) :

$$l_{ef} = \frac{\varepsilon_i - \varepsilon_0}{0.5a_1} \tag{12}$$

Since the load level is known, the damage zone length and the crack spacing are easily found from Eqs. (5) and (6). Having the shape function coefficients for chosen reinforcement diameters, the crack spacing values can be found for any other reinforcement ratio value of interest to the designer.

Procedure for the parabolic shape function

The procedure for the parabolic shape function requires slight changes and further steps to obtain a crack spacing model. The initial steps and assumptions are the same as those described for the linear case. The difference is the nature of the shape function, for which the initial steps produces the following system of equation in order to find the coefficient and minimum strain values:

$$\begin{cases} \varepsilon_0 + a_1\left(0.5l_{ef}\right)^2 = \varepsilon_i \\ a_1 \cdot \frac{\left(0.5l_{ef}\right)^3}{3} + \varepsilon_0\left(0.5l_{ef}\right) + \varepsilon_i l_d = \varepsilon_{mi} \cdot (0.5l_{cr}) \end{cases} \tag{13}$$

1. The bond stresses are not constant for the second order polynomial shape function and are equal to:

$$\tau(x) = \frac{E_s\phi_s}{4}\frac{d\varepsilon_s}{dx} = 2a_1x\frac{E_s\phi_s}{4} \tag{14}$$

2. The main difference between the procedures for the linear and parabolic shape functions is that the latter depends on the distance from the centre of the investigated section. In this case it is not possible to find the coefficients for other bar diameters directly and further steps are necessary. To keep the bond identical between investigated RC ties, the distribution of slip between reinforcement and concrete over the effective length is required. This distribution is found by integrating the reinforcement strain shape function. For simplicity, concrete strains are neglected:

$$s(x) = \int \varepsilon_s(x)dx = \varepsilon_0 x + \frac{1}{3}a_1x^3 \tag{15}$$

3. Since both the bond and slip distributions vary with distance, a unique bond-slip relationship $\tau(s)$ can be derived by equating Eqs. (14) and (15). The steps for a parabolic shape function are summarized in Figure 4.

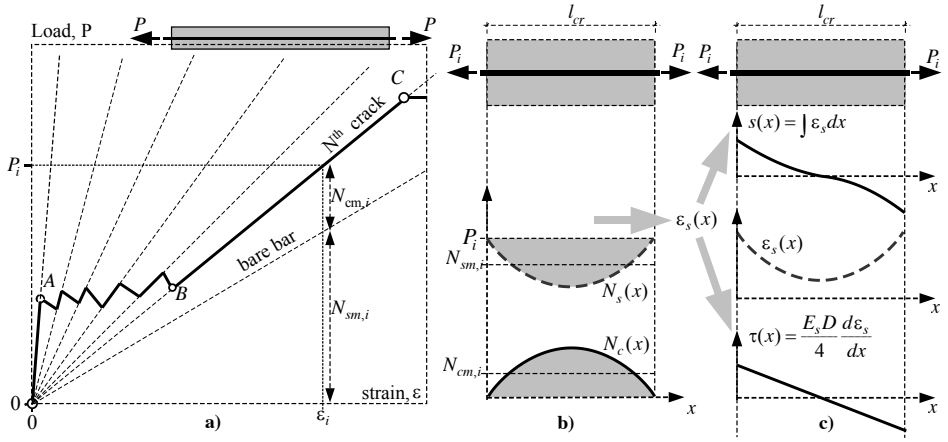

Figure 4 The proposed bond modelling method: a) average concrete and steel forces; b) shape functions; c) calculation of slip and bond stress distribution

4. In contrast to the linear shape function, the coefficients and the effective, damage zone and thus crack spacing lengths are found numerically by using the stress transfer approach and applying the obtained bond-slip relationship $\tau(s)$. With the obtained shape function coefficients for other RC ties, same as for the linear case, average distance between cracks l_{cr} can now be obtained.

RESULTS OF CRACK SPACING ANALYSIS

Reinforced concrete ties with identical material properties were further investigated using the linear and parabolic strain shape functions following the procedures described above. The concrete section was taken as a square with side dimensions determined from the investigated reinforcement diameters and ratios. The reference element for all further analyses was a 100mm by 100mm cross-section RC element, with Ø14mm reinforcement, 1.54% reinforcement ratio and crack spacing l_{cr} = 161.2mm, which is the mean crack spacing value from available experimental data for a bar diameter of 14mm. Concrete compressive strength was taken as 28MPa and the tensile strength was 2MPa. The load level was taken as a pseudo service load equal to 300MPa induced stress in the reinforcement, which has a yield strength of 500MPa. The external force P_i was assumed to be applied directly to the reinforcement bar. A comparison of the distribution of strains obtained for several selected reinforcement diameters and reinforcement ratios is presented in Figure 5. The different behaviour is clearly visible between the linear and parabolic shape functions. One important aspect to note is the different minimum reinforcement strains. The constant deformations represent the damage zone, for which the assumption of a fully damaged bond was made.

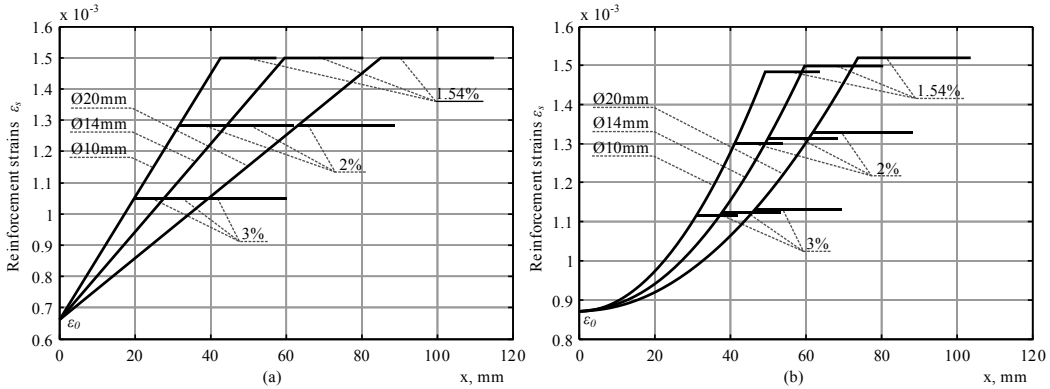

Figure 5 Distribution of strains for the a) linear and b) parabolic strain shape functions

The average distances between cracks obtained by the linear and second order polynomial models are presented in Figure 6. The results are plotted against available published experimental data. The experimental results in the literature exhibit considerable scattering, and the experimental mean of this data is shown for comparison purposes. The numerical analyses results represent a RC tie of 100mm by 100mm dimensions with varying reinforcement ratio. A reinforcement bar diameter $Ø_{ref}$ =14mm and reinforcement ratio ρ_{ref} = 1.54% was chosen as the reference case for which the crack spacing value was assumed to be known and equal to l_{cr} = 161.2mm. Both proposed approaches yield favourable results but with a slightly different behaviour. The parabolic model coincides very well with the mean experimental data for larger reinforcement diameters and is acceptable for smaller diameters. The linear model behaviour is noticeably different and does not coincide as well as the parabolic one but it has the advantage of being a simpler approach, which is easier to apply for predicting cracks.

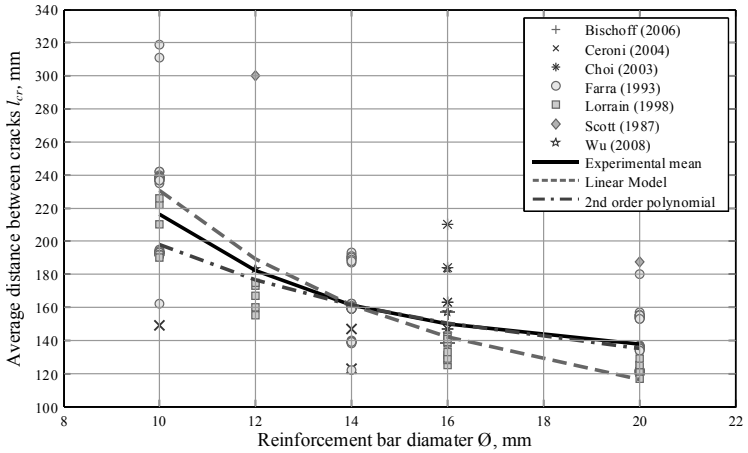

Figure 6 Average distance between cracks obtained by the linear and parabolic models compared against experimental results

Crack spacing models were derived for both shape function cases. Following the steps described above, two equations were derived for the linear and parabolic shape functions, respectively, to estimate the crack spacing of RC ties:

$$l_{cr,linear} = 17.8Ø \cdot \rho^{-1.026} + e^{0.454\rho} \tag{16}$$

$$l_{cr,parabolic} = 10.55Ø \cdot \rho^{-0.6} + e^{4.16\rho^{-0.181}} \tag{17}$$

It should be noted that the derived models are valid for the specific chosen reference element, changing the reference element properties would provide a different crack spacing model.

PARAMETRIC STUDY

A parametric study was carried out in order to demonstrate the influence of concrete tensile strength and load level on the average crack spacing. The basic properties and parameters are kept the same as in the previous section. In the study, both the linear and parabolic models were investigated. The concrete tensile strength f_{ct} was fixed at 2MPa when varying the load level, while a load level of 300MPa was used as the base when exploring the impact of varying tensile strength. The findings clearly show that both of the tested variables influence the crack spacing but the tensile strength of the concrete does not have a significant impact on the results when compared to varying the load level. The effect of different load levels is more pronounced and is more visible for reinforcement bars of larger diameter. In contrast to the curves obtained by varying the tensile strength of concrete, where a larger spread is visible with smaller diameter bars. It is important to note, that certain combinations of variables like material

properties, load levels, average strains and the initial assumption of crack spacing for the reference element lead to cases where results cannot be obtained due to the inability to find coefficients for the shape functions that are physically viable. This is the case with concrete tensile strength greater than 2.5MPa and 3.0MPa for linear and parabolic models respectively. Figure 7 summarizes the findings of the parametric study.

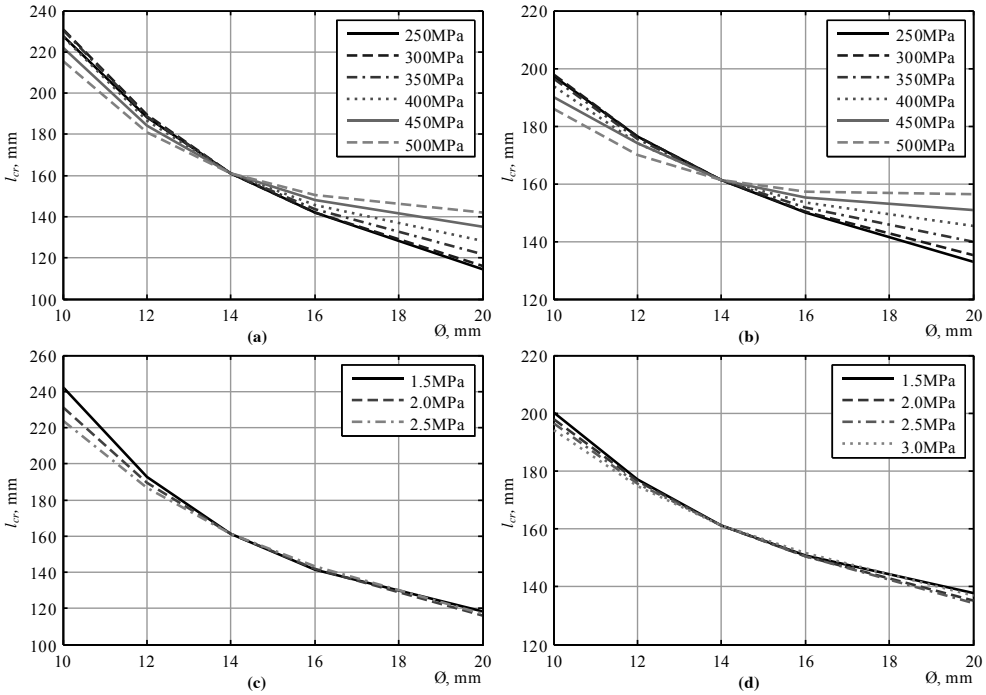

Figure 7 Results of parametric analysis for linear and polynomial models: a) linear model with a varying load level, b) parabolic model with varying load, c) linear model with varying concrete tensile strength, and d) parabolic model with varying concrete tensile strength

CONCLUSIONS

A new method for developing crack spacing models based on compatibility of the smeared crack and stress transfer approaches has been proposed. The concept relies on the average deformations of the element at a chosen loading level within the stabilized cracking stage, which can be obtained by any smeared crack approach, while further calculations rely on the stress transfer concept to attain the deformation shape function. The new approach has many benefits that are important to the field of structural engineering. The proposed approach combines bond-slip relationship, cracking and deformation models to develop the crack spacing model. The suggested method is transparent, particularly for the linear shape function case which requires few steps and consists of simple calculations that also conveys the physical meaning in a clear way. Very little initial data is required, essentially parameters of only one key element with a reference diameter, reinforcement ratio and crack spacing are needed in order to derive the crack spacing model for RC ties with other geometrical and reinforcement configurations. This method allows the user to develop unique models based on custom requirements, by introducing additional assumptions such as changing the shape functions and the damage zone models. Therefore the proposed concept can act as a very flexible base platform for further crack spacing investigations of RC ties and can be potentially modified and applied to elements with unconventional reinforcement.

ABSTRACT

A generalised stress-strain tension-stiffening relationship conforming to the Chinese Code for Design of Concrete Structures GB 50010-2010 is proposed. Based on the provisions in GB 50010-2010 for rigidity and curvature calculations of reinforced concrete flexural members, tension-stiffening relationships were derived from moment-curvature relations by means of the inverse technique for deformation analysis. A parameterized stress block for tension-stiffening was suggested. The proposed tension-stiffening model was applied to nonlinear finite element analysis of reinforced concrete beams. Good agreement between the analysis results based on the proposed model and those based on the codified formulas in GB 50010-2010 was achieved. The proposed model will be able to serve as a design aid for serviceability evaluation of concrete beams in general.

KEYWORDS

Chinese code, moment-curvature relation, reinforced concrete design, tensile stress block, tension-stiffening.

INTRODUCTION

In reinforced concrete design practice, deformation and cracking control are key aspects in serviceability limit state (SLS) so as to ensure the stiffness, integrity, human comfort, durability, and aesthetics of the structures. The Chinese Code for Design of Concrete Structures GB 50010-2010 (MOHURD 2010) stipulates requirements in satisfying the SLS of structures, and the code contains provisions for crack width calculation and deflection checking. When conducting checking against SLS in structural design, the load combinations for SLS shall be composed, where the load factors should be determined in accordance with the requirements in the Load Code for the Design of Building Structures GB 50009-2012 (MOHURD 2012) based on the functional use of structure, the type of loading, the persistency of loading, and relevant site-specific conditions. Pertaining to the load combination, the structural actions should be determined, and checking of crack width and deflection should be performed.

A limitation with the use of codified formulations is that their range of applications is confined to relatively regular structures. For the design of irregular or complex structures, the formulations might not be directly applicable, and alternative methodology such as the use of sophisticated numerical techniques would be necessary. With the advent of high-strength concrete and high-performance concrete, long-span concrete structures have been gaining increasing popularity. The serviceability criterion of long-span members is often the governing condition of the design, and deflection control of concrete flexural members has become a critical issue under the SLS. However, the load-deflection response of cracked concrete members is not straightforward. After cracking, the intact concrete between cracks can transfer tensile forces normal to the crack plane to the reinforcement through the bond, which contributes to the overall stiffness of the member. This is referred to as the tension-stiffening phenomenon (Gilbert 2008; Ng *et al*. 2010). Researches have confirmed that the deflection behaviour of cracked beams is significantly influenced by the tension-stiffening effect (Kaklauskas 2001; Torres *et al*. 2004; Khalfallah 2008; Lam *et al*. 2010), which should be duly considered in the SLS checking.

Herein, the authors derive a generalised stress-strain tension-stiffening relationship conforming to the provisions in GB 50010-2010. The model will enable deflection checking in the design stage by simple numerical methods, and the deflection checking would deem to satisfy the codified requirements. The inverse technique for deformation analysis developed by Kaklauskas and Ghaboussi (2001) and subsequently modified by Gribniak (2009) and Kaklauskas and Gribniak (2011) is employed for derivation of tension-stiffening relationships from the moment-curvature diagrams calculated based on GB 50010-2010 formulations. To confirm the applicability

of the proposed model, it is adopted in structural analysis of concrete beams with the use of the nonlinear finite element software ATENA. It is envisaged that the proposed model would serve as a design aid for assessing the serviceability performance of concrete beams with variable structural configurations.

RELEVANT PROVISIONS IN GB 50010-2010

In this section, the provisions in GB 50010-2010 (mainly from Clauses 7.2.3 and 7.2.4) in relation to rigidity calculation and curvature analysis for reinforced concrete flexural members are extracted and elaborated. The notations used are basically following the definitions in GB 50010-2010, unless otherwise stated. The short-term curvature κ is related to the applied bending moment and rigidity, as described by the following equation:

$$\kappa = \begin{cases} M_{ext}/B_{s1}, \text{if } M_{ext} < M_{cr} \\ M_{ext}/B_{s2}, \text{if } M_{ext} \geq M_{cr} \end{cases} \quad (1)$$

where M_{ext} and M_{cr} are respectively the external bending moment and the cracking moment, B_{s1} and B_{s2} are respectively the rigidity of uncracked and cracked sections, and are calculated by the following equations:

$$B_{s1} = E_c I_0 \quad (2)$$

$$B_{s2} = \frac{E_s A_s h_0^2}{1.15\psi + 0.2 + 6\alpha_E \rho / \left(1 + 3.5\gamma_f'\right)} \quad (3)$$

in which E_c is the elastic modulus of concrete, I_0 is the moment of inertia of the transformed section, E_s is the elastic modulus of reinforcing steel, A_s is the tension reinforcement area, h_0 is the effective depth of section, ρ is the tension reinforcement ratio ($\rho = A_s/bh_0$, where b denotes the breadth of section), α_E is the modular ratio of reinforcement and concrete ($\alpha_E = E_s/E_c$), γ_f' is the ratio of sectional area of compression flange to effective sectional area of web, and ψ is a coefficient to account for the non-uniformity of strain in tension reinforcement between cracks, and is defined by the following equation:

$$\psi = 1.1 - 0.65\frac{f_{ct}}{\rho_{te}\sigma_s}, \left(0.2 \leq \psi \leq 1.0\right) \quad (4)$$

In Equation (4), f_{ct} is the characteristic tensile strength of concrete, ρ_{te} denotes the quotient of A_s divided by the area of tension zone of concrete section, and σ_s is the stress in tension reinforcement.

The cracking moment M_{cr} in Equation (2) is determined as:

$$M_{cr} = \gamma f_{ct} W_0 \quad (5)$$

where W_0 is the elastic sectional modulus with respect to the extreme tension fibre of the transformed section, γ is the plastic influence coefficient for sectional resisting moment of concrete member and is defined by:

$$\gamma = \left(0.7 + \frac{120}{h}\right)\gamma_m \quad (6)$$

In Equation (6), h is the depth of section in mm and γ_m is the basic value of the plastic influence coefficient and has a value of 1.55 for rectangular sections.

INVERSE TECHNIQUE FOR DEFORMATION ANALYSIS

The inverse technique is used for computing the stress-strain tension-stiffening relationship under the equilibrium conditions of forces and bending moments, from a given moment-curvature or moment-deflection diagram (Kaklauskas and Ghaboussi 2001). It employs an iterative procedure of deformation analysis based on the layer section model (Kaklauskas 2004). The following basic assumptions are involved: (1) smeared crack approach, (2) linearity and continuity of strain distribution within the depth of section - this implies perfect bond between layers; and (3) concrete layers in the tension zone follow an uniform stress-strain tension-stiffening law. These assumptions are rational with respect to the structural behaviour of reinforced concrete beams.

To illustrate the inverse analysis, first consider the solution of structural response of a doubly reinforced concrete member subjected to pure bending by the direct analysis. Figure 1(a) depicts the cross-section of the member, which is divided into horizontal layers corresponding to either concrete or reinforcement (Figure 1(b)). The thickness of reinforcement layer is determined from the condition of equivalent steel area. Denote the external bending moment by M_{ext}, based on the principal of equilibrium and from the material diagrams (which will be further discussed in the below), equilibrium equations can be set up with respect to Figure 1(c). By solving the equilibrium equations, the level of neutral axis and the concrete stress at extreme fibres can be obtained. As the extreme fibre has the maximum strain, by proportionality and from the curvature κ, the strain ε_i at any layer i (refer to Figure 1(d)) can be calculated by means of Equation (7). For the given strain ε_i at any

layer i, by substituting known values into the equilibrium equations, the stress at the layer σ_i is obtained. The stress distribution within the layer section model can be computed and is schematically presented in Figure 1(e).

$$\kappa = \frac{M_{ext}}{IE}; \quad \varepsilon_i = \kappa(y_i - y_c); \quad y_c = \frac{SE}{AE}; \quad AE = \sum_{i=1}^{n} b_i t_i E_{i,\sec}$$
$$SE = \sum_{i=1}^{n} b_i t_i y_i E_{i,\sec}; \quad IE = \sum_{i=1}^{n} \left[\frac{t_i^2}{12} + (y_i - y_c)^2 \right] b_i t_i E_{i,\sec} \tag{7}$$

In the above, AE, SE and IE are the area, the first and the second moments of the area multiplied by secant deformation modulus $E_{i,sec}$, n is the total number of layers, b_i and t_i are respectively the width and thickness of the i-th layer (for a beam with rectangular cross-section, b_i is a constant), y_i is the distance of the i-th layer from the top edge of section, and y_c is the distance of neutral axis from the top edge of section. The notations of other symbols may refer to Figure 1. The materials models assumed in the analysis are illustrated diagrammatically in Figures 1(f), 1(g) and 1(h) for the reinforcement, concrete in compression and concrete in tension, respectively. It should be noted that in this study, the reinforcement is treated as ideally elastic-plastic, and the concrete in compression is modelled by adopting the stress-strain relationship per Appendix C of GB 50010-2010. For the implementation of inverse technique in this research, the material model of concrete in tension is to be determined by back-analysis of moment-curvature diagrams calculated per GB 50010-2010, instead of pre-defined by assumption. For each layer, the secant deformation modulus is determined as $E_{i,sec} = \sigma_i/\varepsilon_i$ ($i = 1 \ldots n$). The analysis is performed iteratively until convergence of secant modulus at each layer is attained. The calculation is terminated when the final loading step is reached.

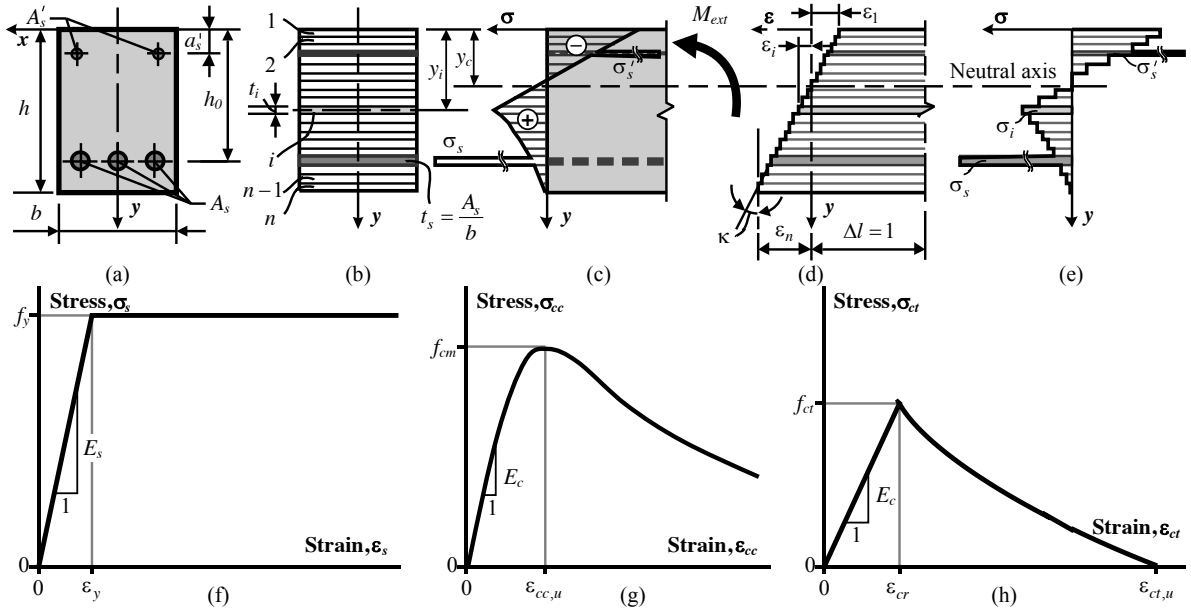

Figure 1 (a)–(e) Layer section model; (f) material diagram for reinforcement steel; (g) material diagram for concrete in compression; (h) material diagram for concrete in tension

To obtain the moment-curvature diagrams based on GB 50010-2010 provisions, the direct technique is utilised. The direct analysis allows prediction of structural response using specified constitutive model and section properties. Whereas to obtain the tension-stiffening relationship from the moment-curvature diagrams, the inverse technique is used. In contrast to direct analysis, the inverse analysis aims at determining parameters of the model based on the response of the structure. Kaklauskas and Ghaboussi (2001) formulated the principles of inverse technique for deriving the average tensile stress-strain relationship of concrete using test data of reinforced concrete beam specimens. From the experimentally-obtained moment-curvature curves, back-analysis was performed with the layer section model via load (bending moment) increments. At each step of load increment, the depth of neutral axis and the concrete stress in the extreme tension fibre were determined by solving the equilibrium equations. Since the extreme fibre has the largest strain, other tension fibres of concrete having smaller strains fall within the portion of the stress-strain diagram which had already been determined (the third assumption in the above). The average stress-strain relationship of concrete in tension was progressively derived along with the bending moment increments.

The present research employs the inverse technique which was modified by Gribniak (2009) and Kaklauskas and Gribniak (2011). The flowchart in Figure 2 illustrates the analysis procedures algorithmically. Computations are performed iteratively via bending moment increments. At each moment increment j, an initial value of secant deformation modulus of the stress-strain relationship is assumed. The curvature $\kappa_{th,j}$ is calculated by the direct analysis. If the relative error $\delta_{j,k}$ between the calculated and the target curvature per codified formulations $\kappa_{code,j}$ does not exceed the tolerance Δ, the basic convergence condition is satisfied (it should be noted that the entire convergence criteria comprise also the changes in internal forces, internal bending moments, and secant moduli of all layers are within specified allowable limits) and the analysis can proceed to the next step of moment increment with an updated secant deformation modulus of each layer. Mathematically, the comparison between relative error and tolerance is represented by the following:

$$\left|\delta_{j,k}\right| = \left|\frac{\kappa_{th,j}}{\kappa_{code,j}} - 1\right| \le \Delta \tag{8}$$

Conversely, if $|(\kappa_{th,j}/\kappa_{code,j}) - 1| > \Delta$, i.e. convergence condition is not met, the analysis is repeated with the secant modulus adjusted by the hybrid Newton-Raphson and bisection procedure (Gribniak 2009; Gribniak *et al*. 2012) until convergence is attained or the iteration number reaches its limit N, which is set at 100 or other values to suit the numerical procedures. Then the analysis proceeds to the next increment step until the final loading step is reached. As of the Newton-Raphson method, it is for root finding of the secant deformation modulus. For brevity, denote the modulus at moment increment j and iteration k by short-hand $E_{j,k}$, and the modulus at moment increment j and iteration (k–1) by short-hand $E_{j,k\text{-}1}$. The updating of modulus is defined by:

$$E_{j,k} = E_{j,k-1} - \frac{\delta\left(E_{j,k-1}\right)}{\delta'\left(E_{j,k-1}\right)} \tag{9}$$

where $\delta'(E_{j,k\text{-}1})$ is the first derivative of the relative error numerically obtained from the central difference equation:

$$\delta'(E) = \frac{-\delta_{II} + 8\delta_{I} - 8\delta_{-I} + \delta_{-II}}{12\eta} \tag{10}$$

$$\delta_{II} = \delta(E+2\eta); \quad \delta_{I} = \delta(E+\eta); \quad \delta_{-I} = \delta(E-\eta); \quad \delta_{-II} = \delta(E-2\eta) \tag{11}$$

with η being the step of difference grid in the Newton-Raphson procedure, and the symbols δ_{II}, δ_{I}, δ_{-I} and δ_{-II} are evaluated per Equation (11). It is noted that in these equations, the indices of the secant deformation modulus are omitted.

During the numerical implementation, if the root found by the Newton-Raphson method does lead to an admissible solution, the updated modulus is used for further analysis. However, if the root is localised and does not lead to an admissible solution, i.e. $\delta(E_{j,k})\cdot\delta(E_{j,k\text{-}1}) < 0$, the analysis would proceed using the bisection method, which reduces the root localisation interval $[E_1, E_2]$ each time until it becomes sufficiently small. The updating of modulus is described by the following:

$$E_{j,k+1} = E_1 + 0.5(E_2 - E_1) \tag{12}$$

$$[E_1, E_2] = \begin{cases} [E_1, E_{j,k}], \text{ if } \delta(E_1)\delta(E_{j,k}) \le 0 \\ [E_{j,k}, E_2], \text{ if } \delta(E_1)\delta(E_{j,k}) > 0 \end{cases} \tag{13}$$

Unlike the Newton-Raphson method, the bisection method requires a single evaluation of $\delta(E)$ per iteration. Through the above numerical process, it yields the average stress-strain tension-stiffening relationship.

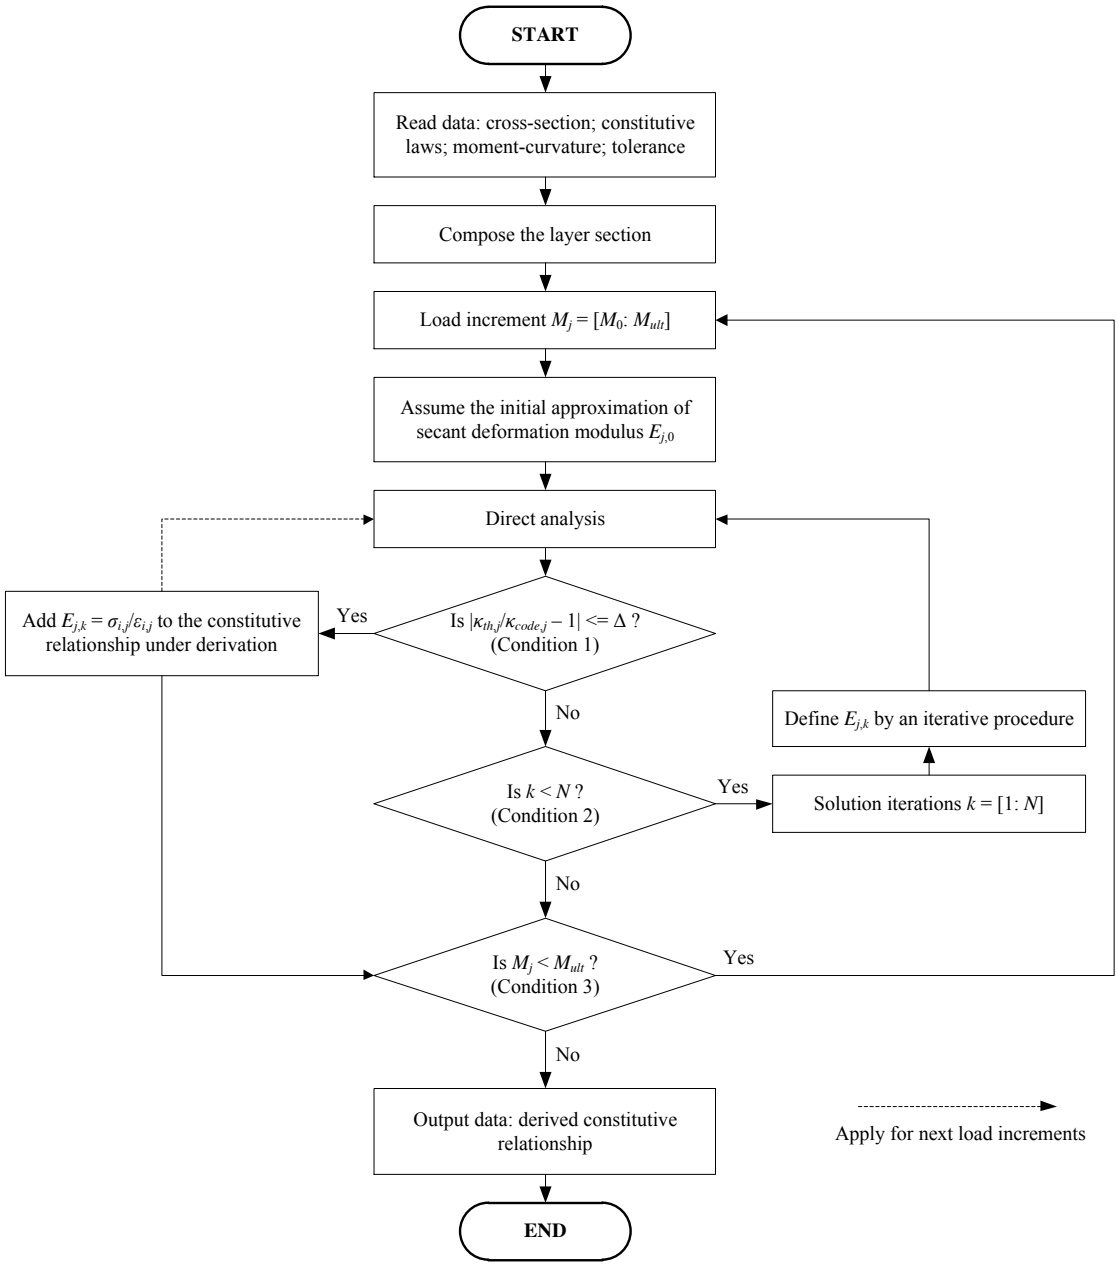

Figure 2 Flowchart of inverse technique

DERIVATION OF TENSION-STIFFENING RELATIONSHIP

The relationship between tension-stiffening behaviour and moment-curvature response is illustrated in Figure 3(a). Consider a simply-supported beam subjected to an increasing loading. When the moment is less than the cracking moment M_{cr}, the beam is uncracked and the response is described by the line segment OA. Upon reaching the cracking moment, the beam is cracked and its stiffness reduces instantly. And the actual moment-curvature response would be along the line segment AB. While assuming the concrete does not carry tension, its moment-curvature response would be along the line segment OC. The difference between OAB and OC represents the stiffening effect by concrete in resisting tension. Further consider the load at service, under which the curvature would be represented by the abscissa of intersection between the level of service bending moment M_{ser} and the moment-curvature curve. It can be seen that the level of M_{ser} insects OAB and OC at different abscissas, indicating that the beam curvature and deflection would be overestimated by neglecting the effect of tension-stiffening.

In deriving the generalised tension-stiffening relationship, the methodology as detailed in the preceding paragraphs is employed. As a numerical experiment, the moment-curvature diagrams of 360 nos. reinforced

concrete beams are calculated per GB 50010-2010. Uniform rectangular cross-section of 200 mm by 400 mm was considered. The concrete grade was varied from C40 to C75. The reinforcement ratio ρ was varied from 0.25% to 2.25%, the modulus of elasticity of reinforcing steel E_s was fixed at 200 GPa per GB 50010-2010 stipulations, the modular ratio α_E was varied from 5.33 to 6.14, and the effective depth to overall section depth ratio h_0/h was varied from 0.725 to 0.925. Figure 3(b) depicts the typical cross-section of the beams.

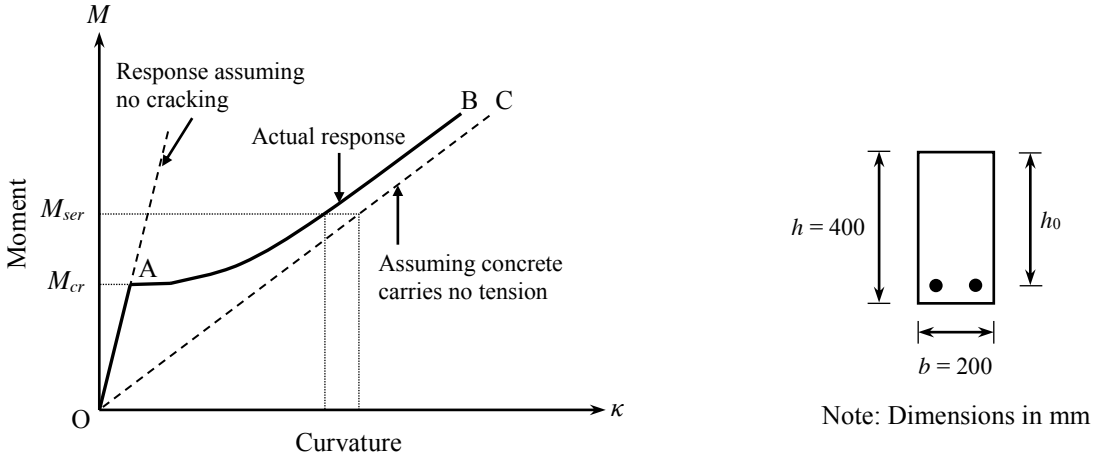

Figure 3 Typical moment-curvature diagram and cross-section of beams

In the layer section model, the cross-section was divided into 200 layers. The centreline of reinforcement layer was coinciding with the centres of reinforcing bars, and the thickness of reinforcement layer t_s was computed as $t_s = A_s/b$. The remaining height portions of the cross-section above and below the reinforcement layer were equally and separately divided into the concrete layers. The number of concrete layers above the reinforcement layer was taken as the nearest integer value of $(n–1)(h_0–t_s/2)/(h–t_s)$, whereas the number of concrete layer below the reinforcement layer was taken as the nearest integer value of $(n–1)(h–h_0–t_s/2)/(h–t_s)$. And the thickness of layers within each height portion was computed with respect to the number of layers and the height of portion.

Through the analysis, the moment-curvature diagram for each beam was obtained by using the procedures outlined in Figure 2. The ultimate bending moment was divided into approximately 90 increment steps. Generally, the step sizes were coarser prior to cracking, and were finer once the cracking moment is reached. Such arrangement is to accord with the basically linear behaviour of tensile stress-strain relation before cracking and its nonlinearity after cracking.

For each moment-curvature diagram, a tension-stiffening relationship was computed by the aforementioned inverse technique. Examples of tension-stiffening relationships are presented in Figure 4 for illustration. From the tension-stiffening diagrams, it can be seen that the stress increases with the strain from the origin up to the maximum value of tensile stress, and drops abruptly to around 40% to 65% of the maximum value, and thereafter gradually decreases with increasing strain. Such abrupt drop in tensile stress was also reported in Damjanic and Owen (1984), Kaklauskas and Ghaboussi (2001), and Kwan *et al*. (2008). As all the tension-stiffening diagrams have similar geometrical characteristics in common, a generalised stress block conforming to GB 50010-2010 can be developed. For ease of implementation, a simple parameterized stress block is proposed herein to simulate the average stress-strain behaviour of tensile concrete. The stress block is depicted in Figure 5. Prior to cracking, the stress block is assumed to be ascending in a linearly elastic manner. The maximum stress γf_{ct} is reached at strain $\gamma\varepsilon_{cr}$, where the stress drops abruptly to αf_{ct}, and linearly and gradually descends to zero at strain $\beta\varepsilon_{cr}$. The abrupt drop of stress is controlled by the parameter α, and the descending branch is controlled by parameters α and β. The following formulation is proposed for the generalised tension-stiffening model:

$$\sigma = \begin{cases} E_c\varepsilon, \text{ if } \varepsilon \le \gamma\varepsilon_{cr} \\ \dfrac{\alpha f_{ct}(\beta\varepsilon_{cr} - \varepsilon)}{\beta\varepsilon_{cr} - \gamma\varepsilon_{cr}}, \text{ if } \gamma\varepsilon_{cr} < \varepsilon \le \beta\varepsilon_{cr} \\ 0, \text{ if } \beta\varepsilon_{cr} < \varepsilon \end{cases} \tag{14}$$

where

$$\alpha = \frac{\sigma}{f_{ct}} \tag{15}$$

$$\beta = \frac{\varepsilon}{\varepsilon_{cr}} \tag{16}$$

In the equations above, γ is as defined in GB 50010-2010, $\varepsilon_{cr} = f_{ct}/E_c$ is the cracking strain. The proposed model is can be easily programmed or input in structural analysis software for automation in design.

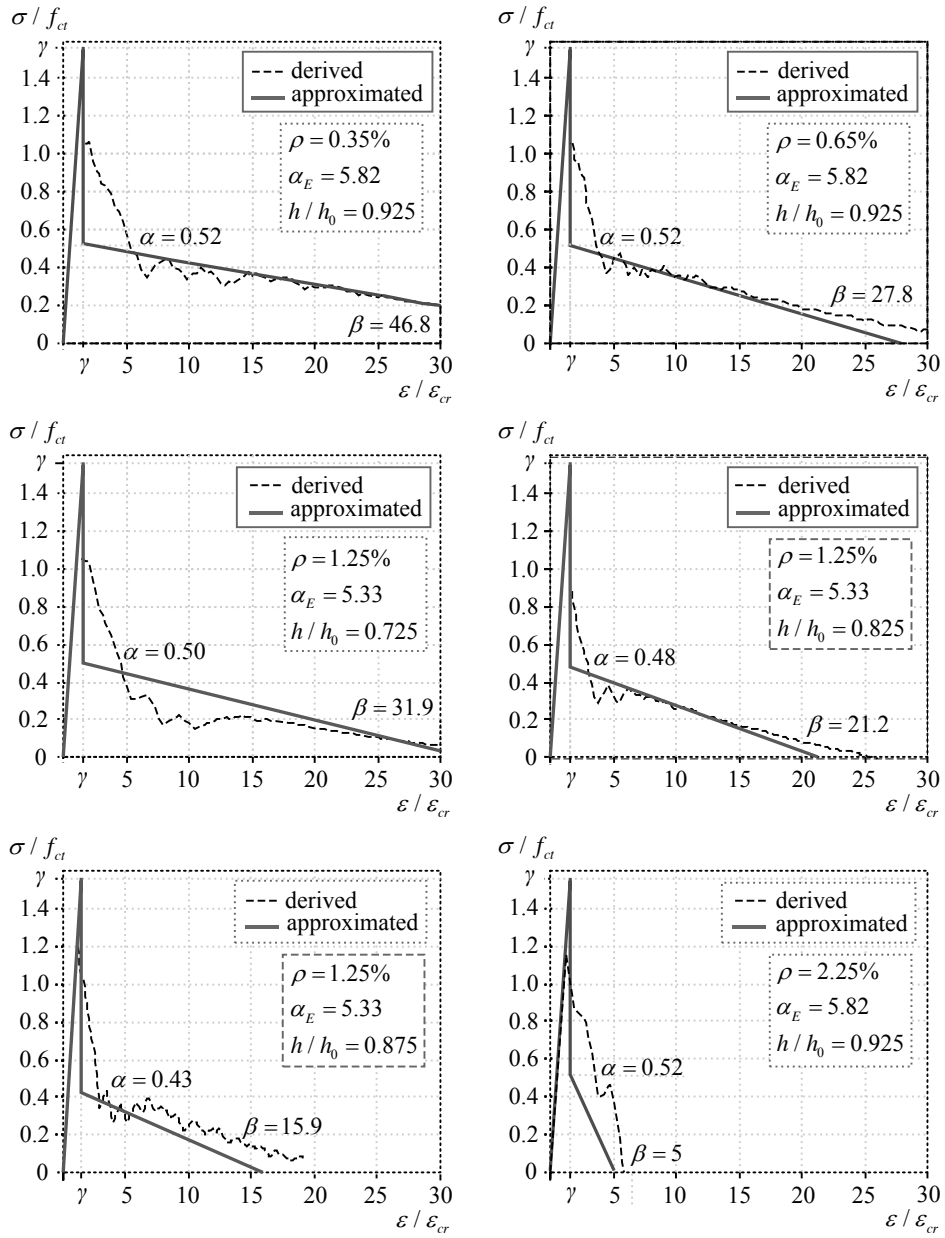

Figure 4 Derived and approximated tension-stiffening relationships

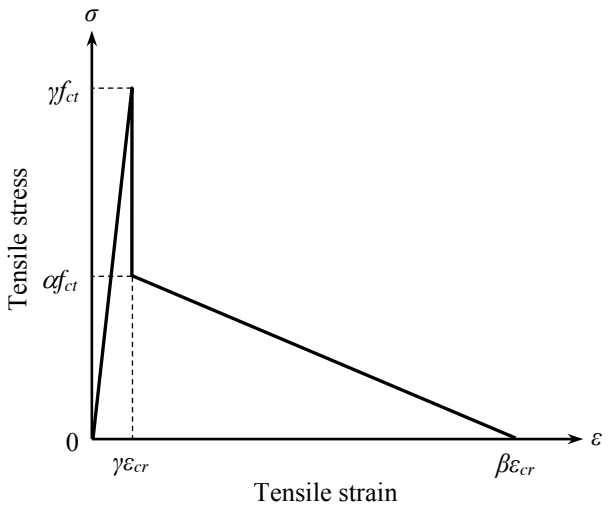

Figure 5 Proposed tension-stiffening model

The proposed tension-stiffening model was established from and validated by numerical experiment consisting of a large number of reinforced concrete beams with varying concrete grades, tension reinforcement ratios, modular ratios of reinforcement to concrete, and effective depth to overall depth ratios. Among these variables, the tension reinforcement ratio was found to have more influence on the shape of stress block, particularly on the value of β. The dependence of the tension-stiffening relationship on the tension reinforcement ratio can be observed from Figure 4. Further numerical studies are ongoing in order to develop accurate and reliable formulas for the parameters α and β applicable for a wide range of concrete beam configurations, as well as to assess the plausible numerical deviations by statistical means. This part of research will be reported in due course.

APPLICATION TO FINITE ELEMENT ANALYSIS

To illustrate the applicability of the proposed tension-stiffening model, it was incorporated into the nonlinear finite element software ATENA for analysis of reinforced concrete beams. The beams have uniform cross-section of 200 mm in width and 400 mm in depth, subjected to two-point loading applied in a symmetrical manner. The distance between loading points is 1.0 m, the shear span at each side is 1.0 m, and the distance between a support point and the beam end is 0.14 m. The total length of beam is 3.28 m. Perfect bond between concrete and steel reinforcement was assumed. To avoid stress concentrations, steel plates of 80 mm in breadth and 30 mm in thickness were mounted to the beam at the loading points and support points. The finite element model is shown in Figure 6. Quadrilateral plane stress finite elements were employed with the use of 50 mm mesh size and 100 mm characteristic length. The ultimate load was divided approximately into 50 increment steps. Standard Newton-Raphson method was used in performing iterations.

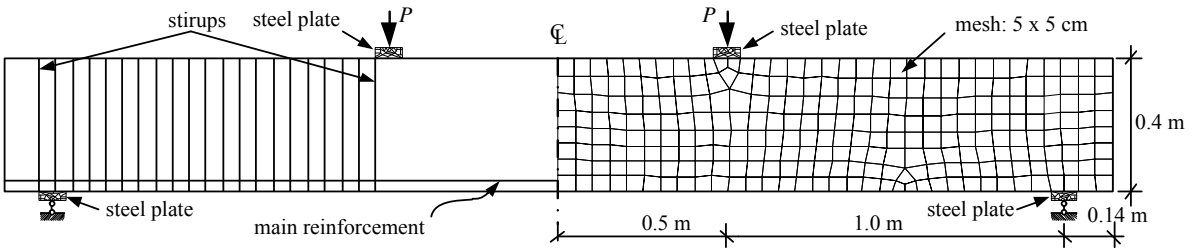

Figure 6 Finite element model in ATENA

The beams are cast from grade C45 concrete. The tension reinforcement ratios, modular ratios, and effective depth to overall depth ratios of beams are shown in Figure 7, which depicts the comparison the moment-curvature diagrams calculated per GB 50010-2010 and the results from ATENA incorporating the proposed model. Good agreement between GB 50010-2010 and ATENA results can be observed. The curvature predictions at the service load level are compared. In practice, the bending moment at service load is usually in the range of 40% to 60% of the ultimate bending moment. Herein, the value of M_{ser} is taken as $0.55M_{ult}$. It is found that the errors of curvature predictions corresponding to the service bending moment were well below 5%.

Though concrete beams with rectangular cross-section are presented herein, beams with variable sections and structural configurations can be analysed by finite element method using the same tension-stiffening model for serviceability checking.

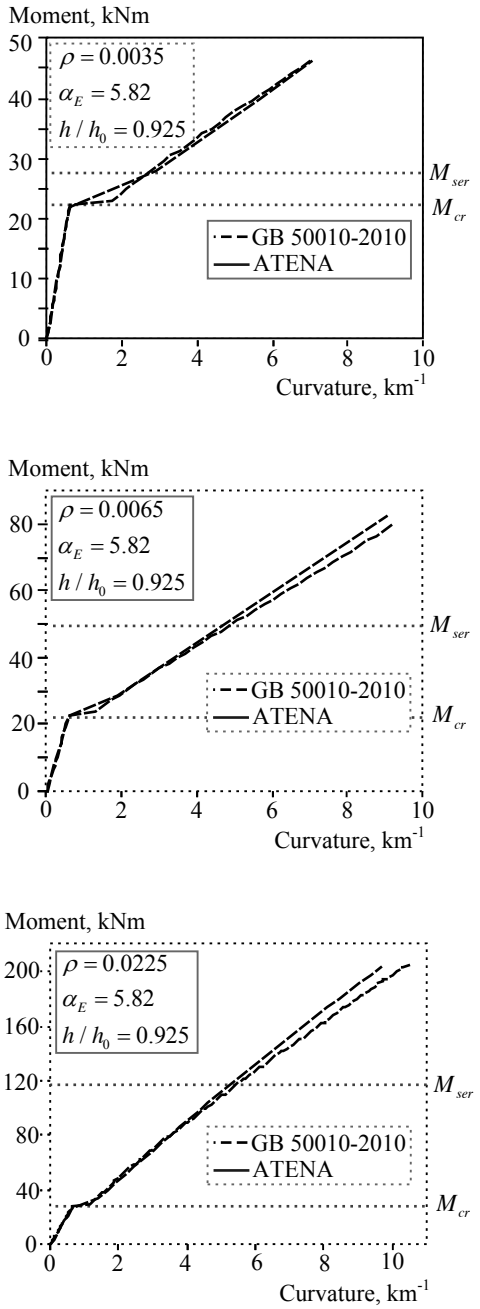

Figure 7 Analytical moment-curvature curves

CONCLUSIONS

In this paper, the authors have proposed a generalised tension-stiffening law conforming to the provisions in the Chinese design code GB 50010-2010 for deformation analysis of reinforced concrete flexural members. By applying the inverse technique developed in precedence, the tension-stiffening relationships have been derived based on the moment-curvature diagrams calculated per GB 50010-2010. A parameterized stress block with simple formulation to account for the tension-stiffening effect has been proposed. The proposed tension-stiffening model has been incorporated in nonlinear finite element analysis of concrete beams to confirm its applicability. From the results of studies, it is concluded that the proposed model can be applied to deformational analysis of reinforced concrete flexural members for serviceability evaluation.

ABSTRACT

The scope of this paper is the shear capacity of in-situ cast joints between precast concrete panels. Current practice with vertical lowering of the wall panels experiences difficulties in the assembly phase, since the traditional U-bar connection requires an overlap in a horizontal plane to allow for the mounting of a vertical locking bar. Where limited space is available bending and subsequent straightening of the U-bars are required to assemble the adjacent panels, a procedure which imposes substantial ductility requirements on the reinforcement as well as some manual workload. This paper introduces a construction-friendly design with U-bars overlapping in the same plane as the panel itself. The design allows for a trouble-free vertical lowering of the panels without pre or post processing of the preinstalled reinforcement loops. Furthermore, an overall more ductile behavior of the joint is obtained. The solution is tested in a push-off experimental setup and the influence of important geometric parameters of the keyed shear joint is investigated. The first peak load carrying capacity is assessed using plasticity models, and the failure modes are identified by the use of digital image correlation. The upper bound models produce satisfactory results capturing the experimental tendencies and predicting the mode of shear failure in the shear keys.

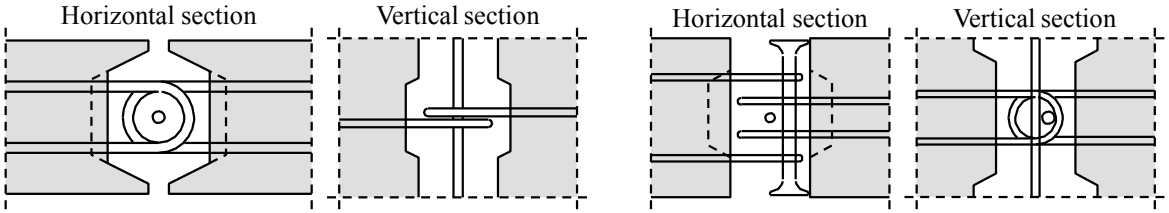
INTRODUCTION

In precast concrete structures, shear walls play an important role in the global stabilizing system for the support of horizontal loads. The connectivity between the shear wall panels is ensured by narrow in-situ cast joints in which mortar with low aggregate sizes is generally preferred as the filling material. Reinforcement loops, laps, or similar, grouted by mortar are thereby the tools at hand to design a strong ductile joint. Not surprisingly the geometry of the connection and the interface properties of the joint play an important role for structural performance. The layout of the interface of the joint has been investigated widely since the introduction of precast concrete structures in the 1950's. The strongest and subsequently most investigated solution is an indented interface, also called a keyed shear joint. However, it turned out that the classical keyed joints constitute a limiting factor in design where ductility and deformation capacity are among the crucial design aspects. In addition the typical/classical solution gives rise to challenges in the construction phase because of the risk of rebars clashing when assembling the precast panels.



(a) *Classical joint layout* (b) *Construction-friendly joint layout*

Figure 1 *Geometrical comparison of layout between classical joint and developed joint*.

The problem of rebars clashing can be seen in Figure 1, which schematically shows the classical solution (left) and the recently developed construction-friendly solution (right). The main difference appears in the orientation and the positioning of the reinforcing loops. As can be seen, the new solution allows for a trouble-free vertical lowering of the precast panels and subsequent installation of transverse lacer bar reinforcement in shape of a double T-headed bar providing increased anchorage in the out of plane direction of the panels. The reinforcement loops are positioned outside the indented area as strut action is active between the keys. In this way the mortar is not utilized for multiple actions. Furthermore, the new design allows for installation of a vertical locking bar similar

to the classical solution. An experimental study of the behavior of the new design has recently been conducted revealing a significant increase in ductility, and furthermore the design allows for the use of larger dimensions of U-bars, applicable for larger panel thicknesses compared to the classical solution. The ultimate behavior of the new design has been analyzed applying rigid-plastic upper bound models. It is found that the shear capacity as well as the critical failure mode can be predicted with satisfactory accuracy.

PREVIOUS INVESTIGATIONS

The classical keyed shear joint has been experimentally investigated intensively since the 1960's. The focus has mainly been on the load carrying capacity and the design aspects of the joint configuration. The report by Hansen et al. (1976) summarizes the work of the CIB commission W23A and the experimental programs that served as basis for the commissions work, including the work of Cholewicki (1971), Pommeret (1972), and Fauchart and Cortini (1972) who used similar test setups as presented in this work. Later on Nimityongskul and Liu (1980), Chakrabarti et al. (1981), Abdul-Wahab (1986), and Serrette et al. (1989) performed tests with different test setups also investigating factors influencing the load carrying capacity. It is generally agreed that the ultimate load carrying capacity is influenced by the number of shear keys and the corresponding cross sectional area of the keys, the strength of the joint mortar, the reinforcement degree and presence of transverse confinement stresses. Deformability and stiffness properties have been investigated by Bhatt (1973) and Bljuger (1976), the former found properties similar to monolithic walls while the latter gave design characteristics of a vertical shear joint depending on the joint type.

The formulas available for prediction of the ultimate load carrying capacity vary widely and are influenced by empirical factors. Most formulas are related to the shear friction hypothesis. However, Chakrabarti et al. (1988) concluded that a theory based on the Mohr-Coulomb failure criterion should be used in preference to the shear friction theory. Abdul-Wahab and Sarsam (1991) confirmed this and concluded that the empirical formulas are limited in application to the method of loading. Jensen (1975) established a formula for the load carrying capacity of a vertical keyed shear joint, based on the theory of plasticity. These findings have been the basis for several formulas introducing empirical factors to fit test results with theory. Christoffersen (1997) expanded the application of plastic theory to include both upper and lower bound solutions in the description of the capacity of a keyed joint.

EXPERIMENTAL PROGRAM

In the present study a total of 23 push off tests were carried out. The program included both a reference investigation of 5 specimens comparing the classical design to the developed design with identical geometrical joint properties (Pedersen and Herløv, 2015). The remaining 18 specimens were subdivided into two investigations related to the geometry of the indentation, see Figure 2, and using the reinforcement configuration seen in Figure 1b. In 8 specimens, the length of the keys, L_k, was varied while the key height was kept constant to half of the panel thickness, t (Svejgaard, 2015). In the remaining 10 specimens the depth of the indentation, d_k, was varied while the key area and the key height were kept constant, with keys protruding into the surface of the panel (Øvrelid, 2015). The tests were carried out in static deformation control and conducted in the lab of DTU.

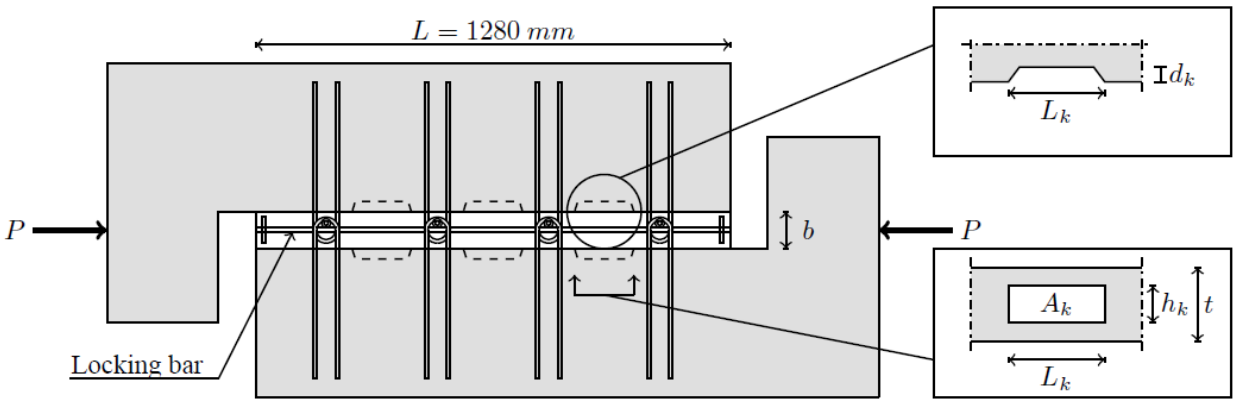


Figure 2 *General geometry of push off specimens, thickness equals 200 mm.*

Specimens and Geometry

The general geometry of the push off test specimens can be seen in Figure 2 and the geometry and material properties are given in Table 1. Specimens R and P refer to *reference* and *pilot* specimens, respectively, where the reference specimens were designed with a reinforcement orientation as given in Figure 1a (noting that the loops were placed outside the indented area) and the pilot specimens were designed with an identical minimum reinforcement area per loop (a 2-on-1 loop design), referred to as A_s in Table 1, and with identical key dimensions. For specimens type I to IX twice the reinforcement area was used in a symmetric design and in order to eliminate the edge effect, anchorage plates were mounted at each end of the locking bar. Each design was tested with 2 replicates and the material properties were found from tensile tests on the steel reinforcement and compression tests on cylinders of the mortar used to fill the joint, with a diameter of 100 mm and a height of 200 mm.

Parameters kept constant for designs I to IX are the U-bar diameter (ϕ = 8 mm), the yield strength of the U-bars (f_y = 487 MPa) the internal bend diameter of the loops (60 mm), the overlapping circular area of the loops, the distance between the outermost loops (30 mm), the lacer reinforcement (16 mm double t-headed bar), the longitudinal locking bar (ϕ_L = 12 mm, f_{yL} = 584 MPa), the thickness of the panels (t = 200 mm), an average precast concrete strength (49.6 MPa), and the width of the joint (b = 100 mm).

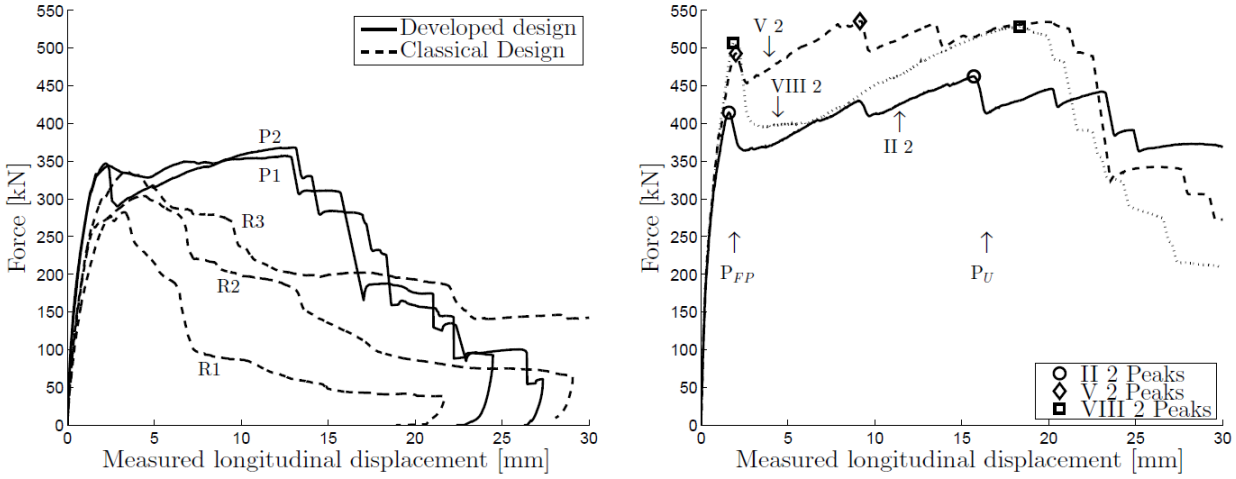
Digital Image Correlation

During the tests, the deformations on the surface of the specimens were monitored using the digital image correlation software, Aramis (GOM, 2009). The method has been use by e.g. Pereira et al. (2011) who studied the cracking behavior of cement, mortar, concrete, and fiber reinforced concrete. Pereira referred that it was possible to monitor relatively small displacements and to see cracks at small crack openings for all materials. For this case the method allows for accurate reporting of the cracking behavior on the surface of the joint. The 2D analysis was performed using photos taken with a 36.3 megapixel digital camera. The high number of pixels allowed for accurate measurement and early detection of crack initiation over the entire length of the joint.

Test Results

Figure 3 contains the comparison of the load-displacement curves for the reference design, Figure 3a, and also some examples of the typical load-displacement curves for the developed joint design, Figure 3b. Figure 3a shows the direct comparison where the results from the classical design comply with previous investigations, e.g. described in details by Hansen et al. (1976). The first (and global) peak is described as the maximum load of the joint followed by a decrease in load with increasing shear displacement. It is highlighted that the response curve of specimen R1 represents a test where the reinforcement loops are shoved away from each other whereas specimen R2 and R3 are shoved towards each other. This demonstrates the effect of reversing the loading direction on the classical design and it may very well be due to this matter that the post peak behavior in literature is reported both as brittle and as ductile.

The comparison reveals the main difference between the two designs. The first peak capacities for the similar configurations are comparable, however the post peak behavior differs significantly as the new design exhibits a far more pronounced ductile behavior. In general the behavior up to first peak is similar. Before cracking, the joint behaves with a stiffness similar to a monolithic wall. At a relatively small load level cracks at the interface between the joint mortar and the precast concrete develop, decreasing the stiffness slightly. At a higher load level diagonal cracks between the corners of each pair of opposite shear keys start to emerge on the surface, as indications of diagonal strut action. After diagonal cracking the stiffness of the joint decreases until the first peak on the load-displacement curve is reached, which corresponds to the value of P_{FP} given in Table 1. For the developed design a drop in the response is observed after the first peak . However, as the displacement increases, the load rapidly increases again until approximately the same level as the first peak. Then, an almost constant load is observed until rupture of the U-bars starts to take place at a displacement in the order of 15-20 mm. The ultimate load of the joint, indicated as P_U in Table 1, is typically found at large displacements, see Figure 3b which presents examples of the main findings of the test series. The load level in Figure 3b is higher than the load level in Figure 3a due to the difference in reinforcement area per loop, however the tendencies are similar.



(a) *Comparison of classical design to developed design.* (b) *Examples of load displacement curves for the developed design.*

Figure 3 Examples of performance of shear keyed joints

The value of P_{FP} depends on the geometric properties of the shear keys and generally a larger key area results in a higher first peak capacity. Specimen II2 has a smaller key area compared to V2 and VIII2. This explains the lower first peak capacity for II2, however the post first peak development shows the same tendencies as specimen VIII2. Furthermore, it is seen that the first peak capacities of V2 and VIII2 are rather similar as the keyed areas are identical, however the post first peak behavior is different as the governing failure mechanisms are different, referring to mechanism B and C introduced in Figure 4. The small key depth of specimen V2 favors shearing/crushing of the key corners whereas the larger key depth of specimen VIII2 results in complete shearing of the key. These partly or complete key shearing failure mechanisms are in agreement with the findings for the classical keyed joint described in Hansen et al. (1976).

It is clear that the test results reveal the ability of the developed design to utilize the joint mortar until rupture of reinforcement at large displacements. The design also proves unaffected by the loading direction, which con-

stitutes a significant difference to the classical design. The improved overall response is favorable concerning structural robustness. The development after first peak, leading to the very ductile behavior, is governed by the reinforcement configuration, the properties of the reinforcement, the properties of the joint mortar and the precast concrete, and finally the geometry of the key, and the frictional properties of the joint mortar.

FAILURE MECHANISM AND UPPER BOUND SOLUTION

In this paper, the load carrying capacity, related to the first peak load, of keyed joints is calculated by use of the theory of plasticity assuming concrete and reinforcement steel to be rigid-perfect plastic materials obeying the associated flow rule. The concrete is considered as a modified Coulomb material with zero tensile strength. For plain strain problems, the energy dissipated per unit area of a failure surface may be determined as follows (Nielsen and Hoang, 2011):

$$W_A = \frac{1}{2}\nu f_c \left(1 - \sin(\alpha)\right) |\mathbf{u}|, \qquad \alpha \geq \varphi \tag{1}$$

Where α is the angle of the displacement vector with the yield line and φ is the internal angle of friction, in this study $\varphi = 30^\circ$ is assumed for the mortar material in the joint. The effectiveness factor ν is introduced to account for concrete not being a perfectly plastic material. The factor is dependent on the problem and in the case of shear in keyed joints no distinctive factor has been developed. Jørgensen (2014) suggests to adopt the effectiveness factor used for beams in shear without shear reinforcement modified to the geometric layout of the keyed shear joint and ignoring the dowel effects of the transverse reinforcement since it is utilized to tensile yielding. The proposed factor is adopte

$$\nu = \frac{0.88}{\sqrt{f_c}}\left(1 + \frac{1}{\sqrt{L_k}}\right), \qquad (f_c \text{ in MPa},\ L_k \text{ in m}) \tag{2}$$

It is noted that the length of the key influences the concrete contribution to the load carrying capacity. It is found that a decrease in key length increases the effectiveness factor, explaining why identical key areas may lead to different load carrying capacities depending on the ratio of the dimensions. In the test series the effectiveness factor ranges from 0.51 to 0.61.

Failure Mechanisms

The load carrying capacity of the joint, P_{cal}, is found by minimizing the energy required to obtain a given failure mechanism. This is obtained from the rate of work performed by the external forces and the rate of internal work dissipated in the yield lines. Figure 4 shows the simplest and also the theoretically most critical failure modes.
For all three failure mechanisms the external work is given by:

$$W_E = P\, u_l \tag{3}$$

The internal work of the three mechanisms may in general be written as:

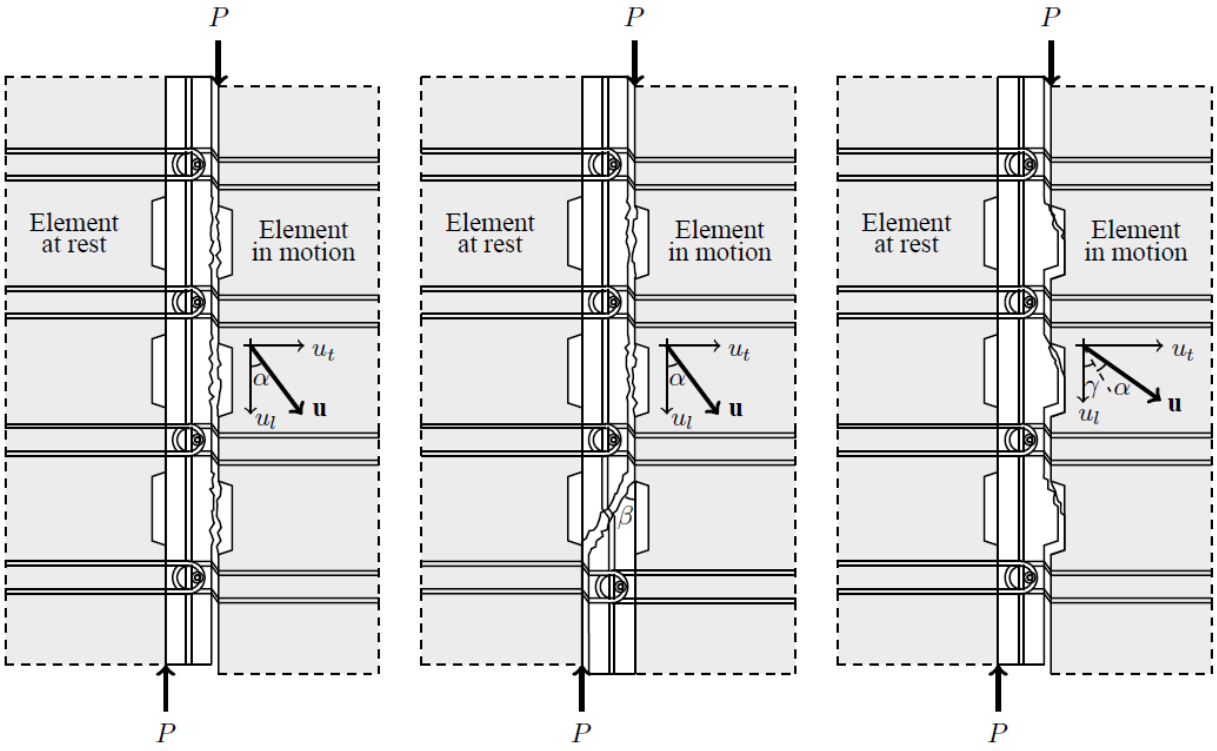
$$W_I = W_{I,j}^c + W_I^s + W_I^{sL} \tag{4}$$
$$W_{I,j}^c = W_A A_j \tag{5}$$
$$W_I^s = A_s f_y u_t \tag{6}$$
$$W_I^{sL} = A_{sL} f_{yL} u_l \tag{7}$$

where $W_{I,j}^c$ is the contribution from a concrete yield line with area A_j, W_I^s is the contribution from the U-bars yielding and W_I^{sL} is the contribution from yielding of the locking bar, if present in the mechanism. The displacement vector for the element in motion and the relations to the relative displacements in the transverse and longitudinal direction for mechanism A and B are given as:

$$\mathbf{u} = \begin{pmatrix} u_t \\ u_l \end{pmatrix} \tag{8}$$
$$u_l = |\mathbf{u}| \cos(\alpha) \tag{9}$$
$$u_t = |\mathbf{u}| \sin(\alpha) \tag{10}$$

For a general description the following parameters are introduced:

$$\Phi = \frac{n+1}{n}\frac{A_s f_y}{A_k f_c}, \quad \Phi_L = \frac{A_{sL} f_{yL}}{n A_k f_c}, \quad \tan\beta = \frac{b}{L_k}, \quad A_k = L_k h_k, \quad A_d = t\sqrt{b^2 + L_k^2}, \quad A_i = h_k \frac{d_k}{\sin\gamma}$$



(a) *Mechanism A - Key cut off* (b) *Mechanism B - One diagonal yield line* (c) *Mechanism C - Inclined key cut off*

Figure 4 *Presentation of the most critical failure mechanisms*.

where A_s refers to the total cross sectional area of reinforcement crossing the joint in a single loop, e.g. $4\frac{\pi}{4}\phi^2$ for the specimen given in Figure 1b. The concrete area A_k refers to the area of a single key, A_d refers to the area of a diagonal yield line and A_i refers to the area of an inclined yield line in a key, see Figure 4. The first peak load carrying capacity in terms of a normalized shear stress is defined as:

$$\frac{\tau}{f_c} = \frac{P_{cal}}{nA_k f_c} \tag{11}$$

In the following, formulas for the failure mechanisms shown in Figure 4 are given for a general design with n shear keys and $(n + 1)$ pairs of U-bar loops crossing the joint. It is noted that the presented loop design ensures yielding of the U-bars and not failure of the joint mortar in the overlapping loop area.

Mechanism A - Key cut off

For failure mechanism A, the rate of internal work is found as a sum of the contribution from n shear keys being sheared off using $A_j = A_k$ and $(n+1)$ reinforcement loops yielding. When solving the work equation, $W_E = W_I$, an upper bound solution is found:

$$\frac{\tau}{f_c} = \frac{1}{2}\nu\frac{1-\sin(\alpha)}{\cos(\alpha)} + \Phi\tan(\alpha) \tag{12}$$

The optimal solution is found by minimizing the expression with respect to the angle of displacement α. The optimal angle is found as:

$$\alpha = \arcsin\left(1 - \frac{2\Phi}{\nu}\right) \geq \varphi \tag{13}$$

From Eq. 13 it is implicitly given that the key area influences the optimal angle of displacement. It is noted that the expression with only slight change of notation is similar to the findings of Jensen (1975) and Christoffersen (1997).

Mechanism B - One diagonal yield line

In failure mechanism B, the rate of internal work is given by $(n-1)$ times $W^c_{I,j}$ with $A_j = A_k$, one times $W^c_{I,j}$ with $A_j = A_d$, and for the reinforcement $(n+1)$ reinforcement loops yielding and one contribution from the

locking bar. The expression for the load carrying capacity is given by:

$$\frac{\tau}{f_c} = \nu\frac{n-1}{2n}\frac{1-\sin(\alpha)}{\cos(\alpha)} + \nu\frac{A_d}{2nA_k}\frac{1-\sin(\beta+\alpha)}{\cos(\alpha)} + \Phi\tan(\alpha) + \Phi_L \tag{14}$$

The optimal angle of displacement is given as:

$$\alpha = \arcsin\left(\frac{n-1+\frac{t}{h_k}-2n\frac{\Phi}{\nu}}{n-1+\frac{A_d}{A_k}}\right) \geq \varphi \tag{15}$$

Mechanism C - Inclined key cut

For mechanism C, the rate of internal work is found as n times $W^e_{I,j}$ with $A_j = A_i$ and $(n+1)$ reinforcement loops yielding. In this mechanism the angle γ is introduced representing the angle between vertical and the inclined yield line. The relative displacements related to the (t,l) coordinate system are given by:

$$u_l = |\mathbf{u}|\cos(\gamma+\alpha) \tag{16}$$

$$u_t = |\mathbf{u}|\sin(\gamma+\alpha) \tag{17}$$

As the relation between the transverse and the longitudinal displacement is dependent on the sum of γ and α, the lower limit of the condition $\alpha \geq \varphi$ is reached at low reinforcement degrees. In the following it is assumed that $\alpha = \varphi$. The optimization of the upper bound solution is then limited to an optimization of γ, which is governed by the key dimensions and the internal angle of friction φ. The load carrying capacity is given by:

$$\frac{\tau}{f_c} = \nu\frac{1}{2}\frac{d_k}{L_k}\frac{1-\sin(\varphi)}{\sin(\gamma)\cos(\gamma+\varphi)} + \Phi\tan(\gamma+\varphi) \tag{18}$$

The optimal angle of the inclined yield line is found as:

$$\gamma = \arctan\left(\frac{\cos(\varphi)}{\sin(\varphi)+\sqrt{1+\frac{2\Phi}{\nu}\frac{L_k}{d_k}\frac{\cos(\varphi)}{1-\sin(\varphi)}}}\right) \tag{19}$$

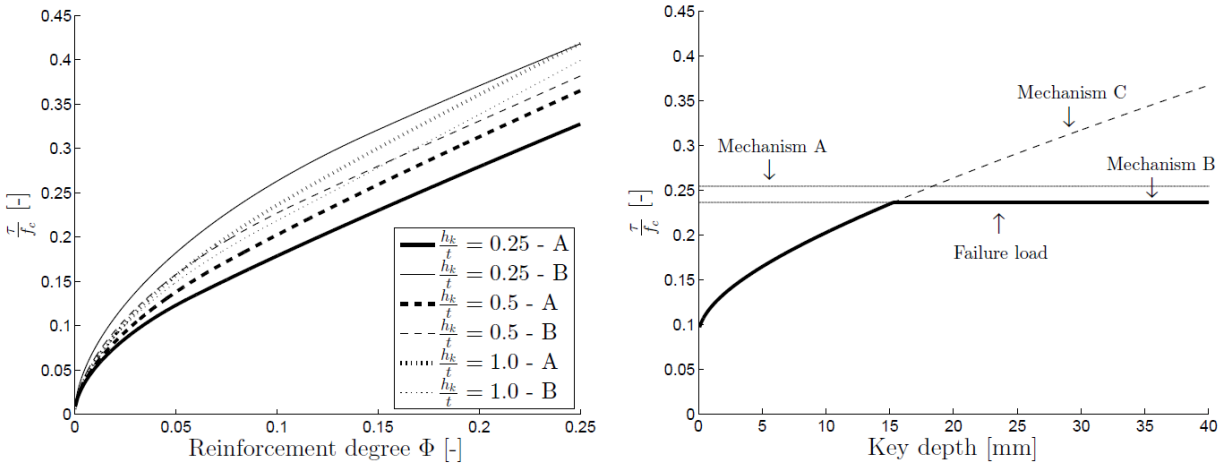
It appears that the internal angle of friction of the joint mortar influences the failure mode significantly and to a large extent dictates, in combination with the key depth, which of the failure mechanisms that constitutes the critical mechanism.

INFLUENCE OF GEOMETRY ON FAILURE MODE

From the load carrying capacities given in Eqs. 12, 14 and 18 and the corresponding optimal displacement angles, it is evident that the geometry of the joint and in particular the geometry of the keys play an important role in deciding, which failure mechanism is governing. Figure 5 contains the results of the theoretical comparison of the three presented failure mechanisms with reinforcement arrangements similar to the experimental program only varying the geometric parameters of the keys. Figure 5a demonstrates the influence of the key height as a function of reinforcement degree, revealing that a higher relative key height favors failure mechanism B compared to a small relative height which favors failure mechanism A. Figure 5b demonstrates the influence of the key depth on the failure mechanism of a joint configuration similar to specimens V to IX, corresponding to a relative key height of 1. Not surprisingly the smaller key depths favor failure mechanism C. In this context the transition point between the failure mechanisms is of particular interest as the deformation characteristics of the joint change with changing failure mechanism.

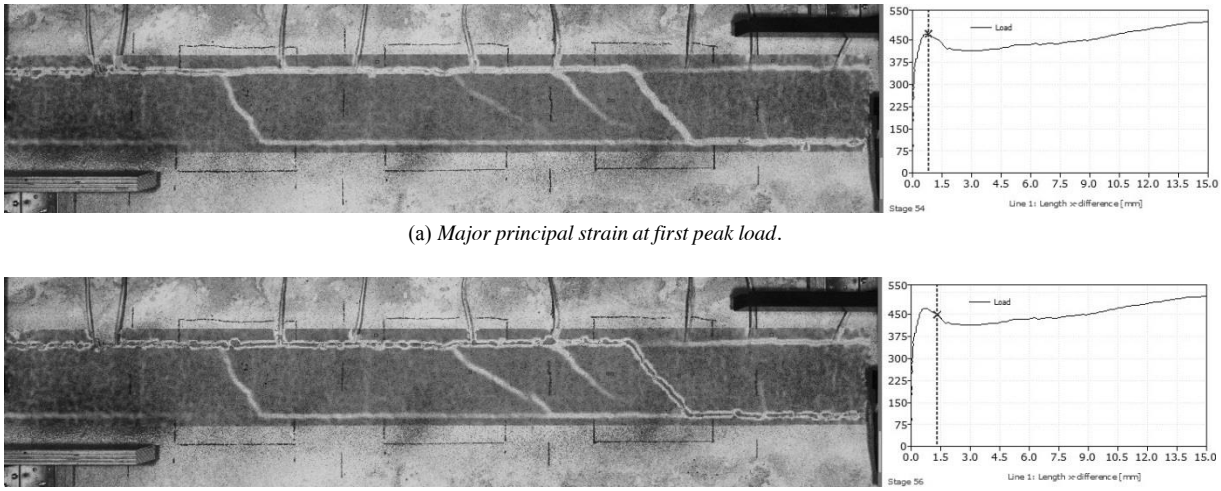
FAILURE MECHANISMS BASED ON EXPERIMENTAL OBSERVATIONS

Based on the experimental observations, the theoretical failure mechanisms are evaluated. It appears that a failure mechanism similar to mechanism B with a relatively large crack opening in one diagonal crack prior to the first peak load is governing independent of the height of the key. Figure 6 shows Aramis recordings of the failure process of specimen III2 which according to calculations should reach the first peak load carrying capacity corresponding to mechanism A. It appears that diagonal cracks develop before first peak, as described earlier, and the relative displacements during the failure is taking place in the already existing cracks. The crack opening of the governing



(a) *Varying relative height of key, $f_c = 33\,MPa$.* (b) *Varying depth of key, $\varphi = 30^\circ$, $f_c = 31\,MPa$, $\nu = 0.58$.*

Figure 5 *Theoretical prediction of failure mode and corresponding load carrying capacity.*



(a) *Major principal strain at first peak load.*

(b) *Major principal strain just after first peak.*

Figure 6 *Aramis record of strain localization and cracking behavior of joint around first peak, specimen III2.*

Diagonal crack prior to first peak is approximately 0.5 mm, measured in Aramis, which leads to the conclusion that the dissipation in the diagonal yield line must be significantly reduced and thereby favoring mechanism B.

In the following, two additional failure mechanisms are introduced, namely mechanism D similar to mechanism B but omitting the mortar contribution from the diagonal yield line, and mechanism E based on mechanism C, however, introducing a diagonal yield line and omitting the mortar contribution from the diagonal. For both cases the contribution from the longitudinal locking bar is still considered. The relevance of these failure mechanisms is reduced with increasing length of the joint and thereby an increased number of keys, however, for the limited geometry tested, the influence of the boundary effect included in these mechanisms is relevant. The load carrying capacity of mechanism D is found as:

$$\frac{\tau}{f_c} = \nu \frac{n-1}{2n} \frac{1-\sin(\alpha)}{\cos(\alpha)} + \Phi \tan(\alpha) + \Phi_L \tag{20}$$

The optimal angle of displacement is given as:

$$\alpha = \arcsin\left(1 - \frac{2n\Phi}{(n-1)\,\nu}\right) \geq \varphi \tag{21}$$

For the mechanism E, partly consisting of inclined key cut off and partly a diagonal yield line, the load carrying capacity, assuming $\alpha = \varphi$, is found as:

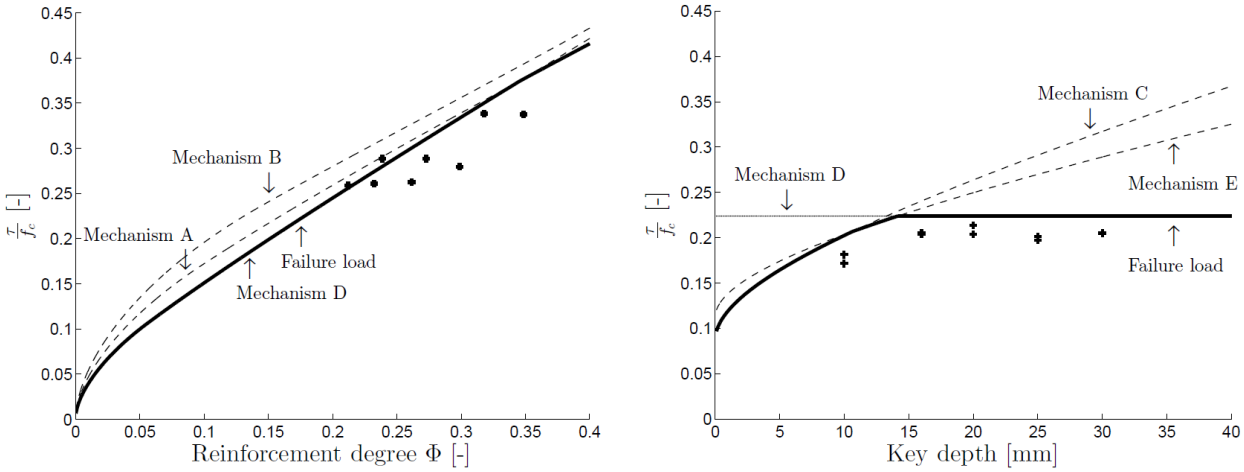
$$\frac{\tau}{f_c} = \nu \frac{n-1}{2n} \frac{d_k}{L_k} \frac{1-\sin(\varphi)}{\sin(\gamma)\cos(\gamma+\varphi)} + \Phi \tan(\gamma+\varphi) + \Phi_L \tag{22}$$

The optimal angle γ of the inclined yield line in the keys is found as:

$$\gamma = \arctan\left(\frac{\cos(\varphi)}{\sin(\varphi) + \sqrt{1 + \frac{2n\Phi}{(n-1)\nu} \frac{L_k}{d_k} \frac{\cos(\varphi)}{1-\sin(\varphi)}}} \right) \tag{23}$$

COMPARISON OF TESTS WITH THEORY

Figure 7 contains a comparison of the presented upper bound models with the test results of the first peak load carrying capacity. It is seen that the refined mechanism D captures the behavior and predicts the load carrying capacity of the specimens with varying key area. It is also seen that mechanism E explains the cracking behavior of the specimens with small key depths before mechanism D becomes the governing mechanism for larger key depths. An overall acceptable correlation is obtained using the proposed effectiveness factor. Better correlation can be found by reducing this factor, e.g. as suggested by Jørgensen (2014) for the shear capacity of shear joint cast with mortar and reinforced with wire ropes.



(a) *Comparison for specimens I-IV, f_c=33 MPa.* (b) *Comparison for specimens V-IX, f_c=31 MPa.*

Figure 7 *Comparison of theory with results, using $\varphi = 30^\circ$ for the joint mortar.*

CONCLUSION

A construction-friendly design of loop connection for joints between precast concrete panels has been developed and presented. It has been shown that the overall performance in terms of ductility of the joint is superior compared to the commonly used classical design. The load carrying capacity related to the first peak on the response curve has been predicted by use of an upper bound plasticity model. The theoretical failure mechanisms have been refined based on observations from the experiments and an overall good agreement has been obtained. The influence of the key area has been addressed and the theoretical influence of the key height on the failure mode has been outlined. The refined mechanisms D and E, based on the experimental tendencies, predict the load carrying capacity well and allow for prediction of the transition between failure modes of complete key cut off or inclined key cut off, see Figure 5b.

ACKNOWLEDGEMENT

The experimental research presented in this paper has been financially supported by the Danish Association for Precast Concrete Elements and the Cowi Foundation. The test elements have been produced at the concrete element factory Expan and the experimental work has been conducted with support from B.Eng. Rune Pedersen, B.Eng. Mads Herløv, M.Sc. J. Svejgaard and M.Sc. L. Øvrelid. The authors gratefully acknowledge these valuable contributions.

ABSTRACT

Water seepage in buildings has been posing serious social dispute to the people worldwide and, in particular, Hong Kong. It causes disturbance to the public and consequential litigation cost. On 31 December 2004, the HKSAR Government set up the Joint Office to deal with the complaints of water seepage in buildings and to carry out investigations. With over 25,000 complaints each year, it is necessary to review and develop technologies to address the problem of water seepage in buildings. Common methods of investigation are dye test, protimeter measurement, infrared thermography and microwave moisture measurement. With the purposes of issuing a notice, an order, a charge, or to satisfy the burden of proof in civil proceedings, the standard of investigating water seepage has to one with high degree of certainty. Such standard is generally unachievable due to, inter alia, (a) inability to identify the source(s)/cause(s) of water seepage and (b) non-corporation of owners/occupiers of premises alleged of causing water seepage. In respect of (a), it depends on the condition of the affected areas; how the tests are performed; and correct interpretation of the test results. To improve the methods of investigating water seepage, an alternative approach is developing to identify the source(s) of water seepage from moisture readings obtained from the alleged water seepage sites and vibration readings obtained from exposed waste pipes without entering the alleged source sites. It is necessary to dedicate tools to match the accuracy/reliability of methods of investigation with the goals of the parties and the goals of the investigation and to provide the parties with opportunities to decide how they would like to proceed. By applying a performance-based approach, the method of investigation is shifted from an informative approach to a consultative approach with interaction by the party/parties. By not carrying out unnecessary and/or unreliable tests, overall cost and time can be reduced. This may ultimately assist the public to resolve the problem of water seepage in buildings.

KEYWORDS

Water seepage, buildings, investigation, performance-based approach.

INTRODUCTION

For more than 20 years, water seepage in buildings has been posing serious social dispute to the people in Hong Kong. It causes disturbance to the public and consequential litigation cost. In 1990, Buildings Department of the HKSAR Government implemented and still implements measures on design and planning to alleviate possible water seepage in new buildings (APP-105). It facilitates, inter alia, ease of locating water seepage from water-borne pipes and ease of repair and replacement of such piping. As to the existing buildings, the Joint Office (operated since 31 December 2004) was set up by Food and Environmental Hygiene Department of the HKSAR Government and Buildings Department to deal with the complaints of water seepage in buildings and to carry out investigations (FHB 2005). As shown in Table 1, over 25,000 complaints are received each year (DEVB 2013) and majority of the complaints are yet to be resolved. With up to 20,000 requests from tenants in public housing for seepage repair in 2014, the Hong Kong Housing Authority (looking after public housing in Hong Kong) also expressed difficulties in tackling water seepage. LCPH (2014) refers.

Table 1 Complaints as reported by the Joint Office

Year	2010	2011	2012	2013[3]
Seepage reports received	25,717	23,660	27,353	22,802
Cases handled[1]	22,971	23,210	24,553	18,390

Cases screened out[2]	11,051	12,219	13,727	9,618
Cases with seepage source identified	4,737	4,199	4,053	3,495
Cases with seepage ceased during investigation	4,861	4,703	4,810	3,444
Cases with warrants for entry granted by the Court	136	90	101	47
Cases with Nuisance Notices issued	3,379	3,064	3,639	3,151

[1]The cases handled in a year do not necessarily correspond to the seepage reports received in the same year.
[2]While some of the seepage reports received do not involve health nuisance, and hence do not fall within the scope of follow-up action under the statutory authority of the Joint Office, the Joint Office will also screen out some other cases as non-actionable by reason of unjustified cases, seepage ceased or reports withdrawn by the informants, etc., and investigation into the sources of water seepage will not be conducted for such cases.
[3]From 1 January to 30 September.

The problem of water seepage in buildings is getting more and more serious over the years. Even though the claim and the repair cost are only a fraction of the legal cost, it is not uncommon for the parties of a water seepage complaint to end up in litigation proceedings. In DCCJ 5323 of 2007, the Court allowed HK$43,300 (US$5,600) as loss and damage with no legal cost. As quoted from DCCJ 5903 of 2008, "*water leakage claims are both expensive and difficult litigations*".

Pursuant to the reported cases on matters related to water seepage in buildings, main difficulties in resolving water seepage disputes are due to (a) inability to identify the source(s)/cause(s) of water seepage and (b) non-corporation of owners/occupiers of premises alleged of causing water seepage ("the alleged source sites"). It is necessary to improve and/or develop methods and the approach to investigate the cause(s) of water seepage in buildings.

In this paper, the results of a preliminary study are presented, showing the problems with common methods of investigation, taking into consideration the anticipated accuracy of investigation and the difficulties in performing the tests. Two solutions are proposed including to develop an alternative method of investigation and to implement a performance-based approach.

ANTICIPATED ACCURACY OF INVESTIGATION

Two common sources of water seepage in buildings are from the external, e.g. rainfall, and from above or the alleged source sites, e.g. domestic use of water (Lam 2007). The former is obvious and can readily be identified with certainty. The main difficulty is to identify the source/cause of water seepage coming from above (e.g. from the bathroom immediate above an alleged water seepage site). If the parties are cooperative, there is a good chance that the problem of water seepage can be alleviated by investigating/identifying the sources and carrying out proper repair. In majority of the cases, repeated repair will have to be carried out. If the matter cannot be resolved amicably, the parties will end up in a deadlock and may complain to the Joint Office or other government offices for follow up action.

As far as the HKSAR Government is considered, the main purpose of investigating water seepage in buildings is perhaps to enable the enforcement of relevant provisions of the ordinances. The following are some of the examples.

- Public Health and Municipal Services Ordinance at Section 127(3): Where the source of seepage is identified, the Joint Office may issue a Nuisance Notice to the person concerned requiring the abatement of nuisance within a specified period of time, failing which the person will be subject to prosecution. Upon conviction, the person concerned is liable to a maximum fine of HK$10,000 (US$1,300) and a daily fine of HK$200 (US$26).

- Public Health and Municipal Services Ordinance at Section 127(4): The Joint Office may apply to the Court for a Nuisance Order requiring the person concerned to abate the nuisance. Failure to comply with the order will result in prosecution. Upon conviction, the penalty will be a maximum fine of HK$25,000 (US$3,200) and a daily fine of HK$450 (US$58).

- Buildings Ordinance at Section 28(3): When the drains or sewers of a building are inadequate or in a defective or insanitary condition, Buildings Department may by an order require the owners of the building

to carry out necessary drainage works. Failure to comply with the order will result in prosecution. Upon conviction, the penalty will be a maximum fine at level 5 (HK$5,000 or US$640) and to imprisonment for 1 year; and a further daily fine of HK$5,000 (US$640).

- Workworks Ordinance Section 28: When there is a leakage from water pipes, the person who wastes or misuses, or causes or permits to be wasted or misused, a supply of water from the waterworks shall be guilty of an offence and will be liable on summary conviction to a fine at level 4 (HK$2,500 or US$320).

When issuing a notice, an order or a charge, it is crucial to provide sufficient evidence to justify the action. In the premises, the standard of proof is beyond reasonable doubt and the government is required to support the action based on conclusive evidence. Although the standard of proof in a civil action is based on the balance of probability, the plaintiff/applicant is also required to provide good evidence with reasonable degree of certainty. The plaintiff/applicant is anticipated to reply to the defence on alternative sources of water seepage and/or alternative causes of water seepage. Therefore, the plaintiff/applicant is required to prove the cause(s) of water seepage and to rebut alternative sources of water seepage. All in all, the standard of investigating water seepage in buildings is to be one with high degree of certainty and the investigation so conducted is able to distinguish all possible causes of water seepage.

COMMON METHODS OF INVESTIGATION

Different techniques for investigating the causes and/or sources of water seepage are referred to Wai (2015), HKIS BDS (2014), Watt (2007), Bungey et al. (1986) and Dill (2000). As far as water seepage in buildings is concerned, we are dealing with private dwellings. In Hong Kong, over 90% of our buildings are reinforced concrete structures. Thus, method of investigation involves measurement of moisture content in concrete. These can be categorized into Methodology 1 and Methodology 2.

Methodology 1: The alleged source site is first subjected to dyed water to simulate the water source(s). Afterwards, measurement of moisture is carried out in the alleged water seepage site. Typical examples include flooding test, water spray test and dye test. It is generally considered as the most direct means to identify/differentiate different water source(s). However, it is not applicable in majority of the cases due to non-corporation of owners/occupiers of the alleged source site thereby disallowing any flooding test, water spray test or dye test to be carried out from the alleged water seepage site.

Methodology 2: Without simulating the water source(s), measurement of moisture is carried out in the alleged water seepage site. Source(s) and cause(s) of water seepage are interpreted from the measurement and this requires high level of professional knowledge and expertise.

Table 2 lists the commonly used techniques for investigating the causes and/or sources of water seepage.

Table 2 Common methods of investigating water seepage

Description	Methodology	Degree of penetration
Dye test	1	Through thickness penetration
Protimeter measurement	2	Limit to surface
Infrared thermography	2	From surface to nominal depth
Microwave moisture meter	2	Up to 110 mm or more

Methodology 1

- **Dye test** is the most commonly used technique, inexpensive and requiring minimal technical skills. It is used by the Joint Office as the routine method for systematic investigation and is recommended as a DIY investigation tool (FEHD and BD). Dye test is carried out by ponding the alleged source site (e.g. flooding the bathroom) with dyed water ("the ponding area"). The result is positive if dye is visible from below. Recently, fluorescent dyes are used thereby signs of water seepage are observed from below by an ultraviolet light in dark condition. Quite often dye is not detected from below in the damp area ("negative results") even though water originates from the ponding area. In the early 2000s, the Court (DCCJ 20154 of

2001) commented that "*the dye test could not be conclusive evidence to rule out that there was no leakage*". In 2005, effectiveness of dye test was already criticized by Advisory Council on Food and Environmental Hygienic (ACFEH 2005). In 2014, the Appeal Court (CACV 186 of 2013) affirmed that "*the negative test results (are) of no assistance to the case*".

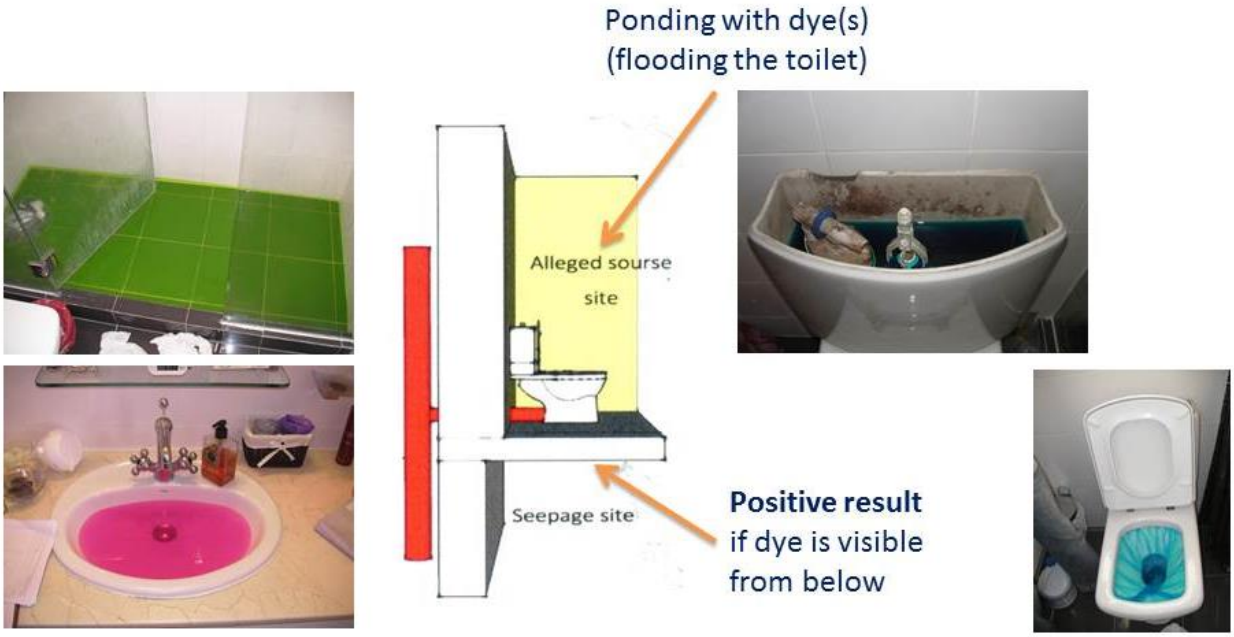

Figure 1 Dye test

Methodology 2

- **Protimeter** is a device commonly used to assess the surface moisture content of a material (Figure 2(a)). Surface moisture content is measured through pushing two needles/electrodes into the material. It enables rapid assessment of surface moisture content. Due to the heterogeneous properties of concrete and unknown properties of finishes on the surface of concrete, readings obtained from a protimeter cannot be taken directly as surface moisture content, unless the readings reflect very high moisture content. As pre-calibration of surface moisture content of concrete is virtually not possible, readings are taken from both affected areas and non-affected areas (or control points) and the values are compared to estimate the surface moisture content of affected areas.

- **Infrared thermography** is based on the principle that wet and dry building components have different rates of heat gain and retention. This technique is normally applied using a hand-held infrared camera with recording device (Figure 2(b)). Wet zone is identified based on physical characteristics of wet material with slower heat gain and heat loss. It may be able to display water paths, hidden water pipes, etc. that are close to the surface. As temperature differential can be very small (between 0.1C to 0.5C) for identifying a wet area, an uneven surface, e.g. spalling/delamination of finishes, may distort the temperature gradient making the thermographic images unreliable. As shown in Figure 2, this is usually the case in an affected area.

- **Microwave moisture meter** has gained popularity in measuring the moisture content of a material. It is based on the propagation of electromagnetic waves in the material. Moisture content is estimated from the energy loss due to absorption of water. The device includes a generator and a receiver (Figure 2(c)). It has the disadvantage of requiring a good contact surface for both generator and receiver which may not be possible to achieve in majority of the cases (Figure 3). It is also sensitive to heterogeneous nature of concrete that may cause error in the readings obtained from the measurement. As each measurement is presented as averaged moisture up to a certain depth, accuracy is also adversely affected by the presence of cavities, pipes or reinforcement embedded inside concrete.

(a) Protimeter (b) Infrared thermography (c) Microwave moisture meter

Figure 2 Common techniques to detect moisture inside concrete

Figure 3 Affected areas with delamination of finishes and/or spalling of concrete cover

Apart from dye test with the advantage of identifying water path(s) or source(s) of water seepage directly, the above are all interpretive testing methods. In some cases, microwave moisture measurement may also provide good indication of the water path(s) or source(s) of water seepage but this largely depends on the quality of the test data.

Protimeter and infrared thermography can only identify the presence of moisture near the surface. As moisture measurements are indirectly assessed via electrical resistance and heat, respectively, foreign materials inside concrete may cause similar changes on the measurement to that of water. For instance, presence of salt may affect the reading and thus the accuracy of the measurement. Therefore, the data is used to compare the moisture condition between two different areas of the same material, namely control points not affected by water seepage and the affected areas.

Data obtained from the field works has suggested that there exists no universal method that can provide reliable results to identify the cause(s) of water seepage. Method of investigation has to be determined case by case based on the condition of concrete at the surface and in the interior. It is common for the parties to perform a combination of tests as listed in Table 1. Unfortunately, inconsistent and/or conflicting results are often obtained between the tests. In majority of the cases, the parties end up in civil actions. In DCCJ 1428 of 2012, inconsistent results were reported when different dyes were used. The Court commented that "*such inconsistency may well suggest that the seepage ... was not so serious in terms of permeability or extensiveness as to allow the dyes to be readily observable*". Further,

dye was observed at two spots in the alleged water seepage site but negative results were reflected by infrared thermography. It is necessary to develop alternative method of investigation and one is suggested below.

As indicated in the above, accuracy depends on the condition of the affected areas and how the tests are performed. Correct interpretation of the test results further relies on an understanding of the underlining principle; limitations; and the pros and cons of applying different methods of investigations. We are of the view that there is in lack of an expertise or a unify approach to select the proper tests; to perform the tests and/or to interpret the results. Obviously, it is very difficult if not impossible task for the parties, who are laymen to the tests, to select the tests; to perform the tests and/or to interpret the results, save and except dye test. A performance-based approach is proposed to handle water seepage in buildings.

ALTERNATIVE METHOD OF INVESTIGATION

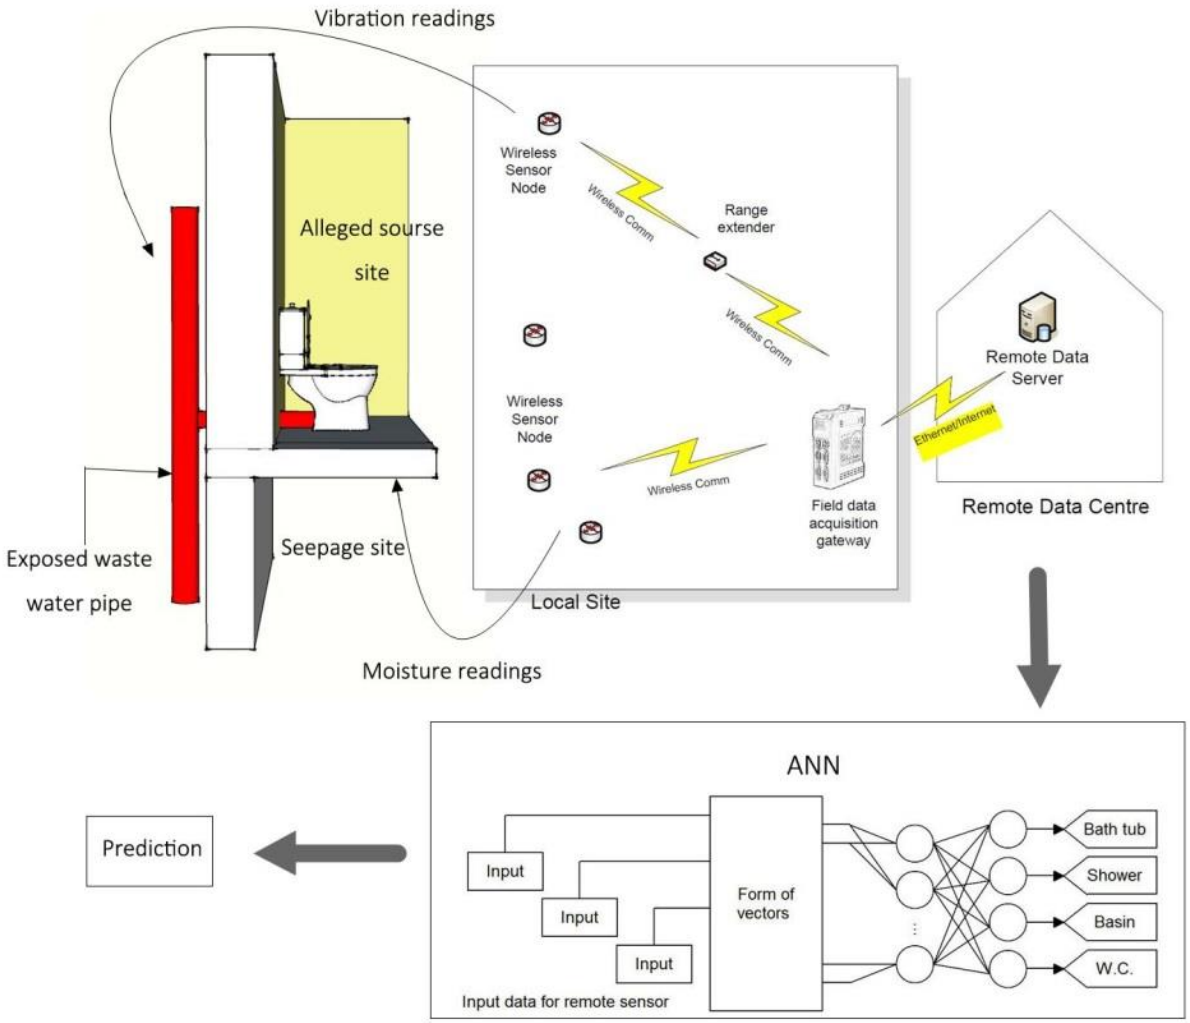

Figure 4 Wireless sensor nodes, remote data center and detection methodology

In or about 2010, Innovation and Technology Commission of the HKSAR Government invited Hong Kong Applied Science and Technology Research Institute to look into ways to measure and trace water seepage. Subsequently, Seed Project titled "Advanced Detection of Water Seepage" was carried out to explore a method of identifying source(s) of water seepage from moisture readings obtained from the alleged water seepage site and vibration readings obtained from exposed waste pipes without entering the alleged source site ("the test system"). Aimed at the architecture of the test system, it has been demonstrated that the test system provides feasible means to identify

the source of water seepage in an ideal environment (Lau et al. 2012). In Stage 2 of Seed Project, the test system will be further developed (i) to advance the hardware, (ii) to develop the detection methodology and (iii) to carry out full-scale field tests. Figure 4 shows the architecture of the test system after redevelopment.

The main challenge at Stage 2 is to develop methodology on detection and prediction. Vibration readings obtained from exposed waste pipes will be analyzed to identify the discharge time-history of each and every pipe in the alleged source sites through pattern recognition. The discharge time-histories will be mapped against the moisture readings obtained from the alleged water seepage site. Based on the mapping, source(s) of water seepage will be identified mathematically with high degree of certainty.

A PERFORMANCE-BASED APPROACH

Firstly, selection of appropriate method(s) plays an important, if not the deciding, role to the investigation. Accuracy and reliability of the test results may depend on, inter alia, the condition of the alleged water seepage site. To provide a systematic scheme of selection, it is necessary to develop tools to evaluate and recommend appropriate method(s) of investigation to cater for the specific condition of the alleged water seepage site that can reasonably anticipated in our building stock. This requires input from the party/parties in order to have a fair understanding of the root of the problem.

Secondly, there is in lack of opportunities for the parties, who are the laymen, to understand the issues/difficulties and to exit from the dispute at the first instance before ending up in a deadlock. We are of the opinion that the parties have to be given every opportunity to decide as to the cause of action. Ironically, they are affected by the decision. By shifting from an informative approach to a consultative approach with interaction between the parties, they are provided with as much information as possible to enable them to look into the matters amicably at each and every intermediate stage of investigation.

So far, a board consensus on the above is still lacking. It is necessary to dedicate tools to match the accuracy/reliability of methods of investigation with the goals of the parties (like cost and time) and the goals of the investigation (like accuracy; reliability; efficiency; difficulties; expectation; etc.), and to provide the parties with opportunities to decide how they would like to proceed. Figure 5 outlines a holistic view of the various goals based on a performance-based approach. With the appropriate tools, reliable testing methods can be identified and a common ground to investigate can be obtained. The following are the main components.

Baseline assessment is to be completed by the party/parties to specify basic features of the premises; history of water seepage incident(s); condition of affected areas; seriousness and duration of water seepage; and an indication as to whether all the parties will be in full cooperation or not.

First screening and **Second screening** screen out cases that are outside the scope of the Joint Office with recommendations to the party/parties on the best way forward.

Progressive monitoring requires the party/parties to continuously monitor and report condition of the premises, e.g. condition of the affected area; seriousness of water seepage. The data is then automatically matched the weather condition published by Hong Kong Observatory to provide a summary of the likelihood of each possible cause of water seepage.

Performance based assessment looks into the characteristics of the cases especially the correlation of water seepage with duration to provide an assessment on cost (in terms of cost of repair and cost of testing); accuracy; reliability; efficiency (in terms of available testing methodologies); and difficulties (in terms of constraints). Based on the assessment, the party/parties is/are provided with a broad picture of the reasonably anticipated outcome if the tests are so carried out.

Goals are the expectation of the party/parties and are to be input by the party/parties. These include tangible goals like cost; time; etc. and intangible goals like difficulties; etc.

Recommendations and **estimation** are reported to provide the party/parties an updated assessment of the outcome if the tests are so carried out.

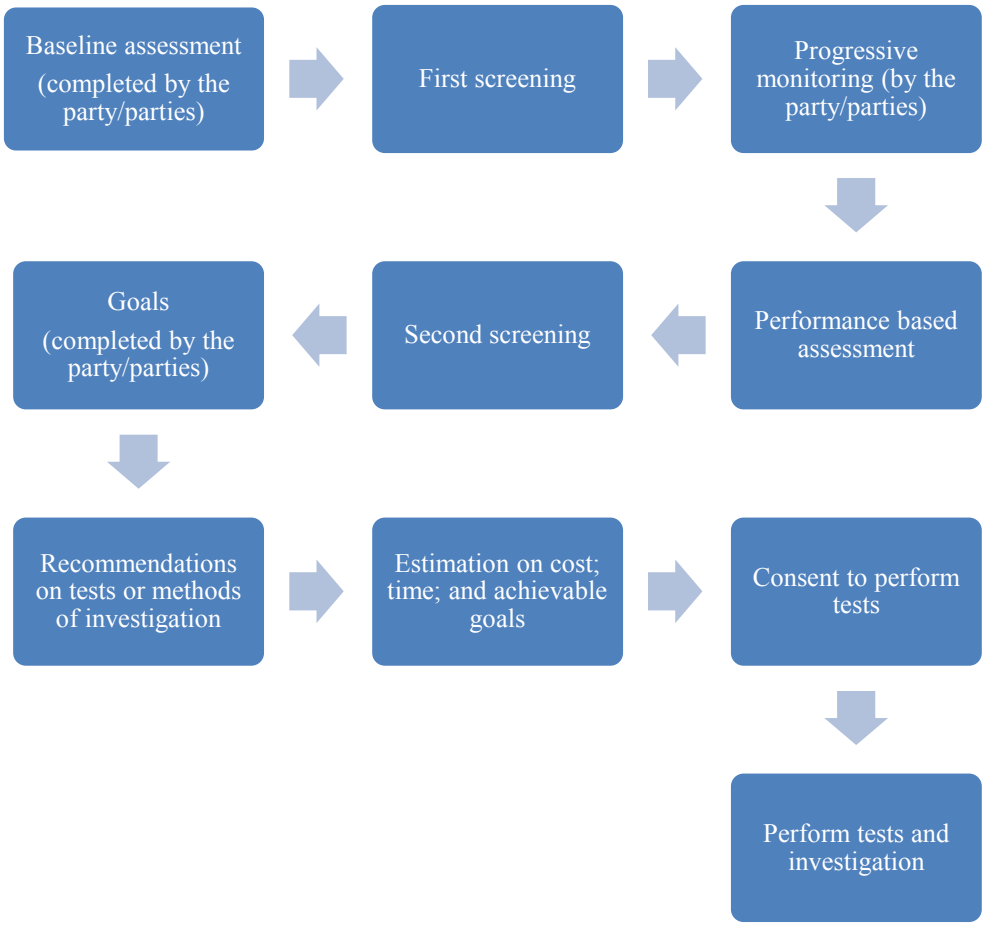

Figure 5 An outline of a performance-based approach

By following a performance-based approach, it is possible to reduce the overall cost and time by not carrying out unnecessary and/or unreliable tests. This may ultimately assist the public to resolve the problem of water seepage in buildings.

CONCLUSIONS

Pursuant to reported cases and relevant provisions in the ordinances, the standard of investigation is to be one with high degree of certainty and the investigation so conducted is able to distinguish all possible causes of water seepage. Common difficulties in resolving water seepage disputes are due to (a) inability to identify the source(s)/cause(s) of water seepage and (b) non-corporation of owners/occupiers of premises alleged of causing water seepage. In respect of (a), it depends on the condition of the affected areas; how the tests are performed; and correct interpretation of the test results. It is necessary to improve and/or develop methods of investigating water seepage. As an alternative approach, it is suggested to identify the source(s) of water seepage from moisture readings obtained from alleged water seepage sites and vibration readings obtained from exposed waste pipes without entering the alleged source sites. Further, it is desirable to shift the method of investigation from an informative approach to a consultative approach with interaction by the party/parties. We need to dedicate tools to match the accuracy/reliability of methods of investigation with the goals of the parties and the goals of the investigation and to provide the parties with opportunities to decide how they would like to proceed. By following a performance-based approach, it is possible to reduce the overall cost and time by not carrying out unnecessary and/or unreliable tests. This may ultimately assist the public to resolve the problem of water seepage in buildings.

DESIGN METHOD FOR RC BEAM RETROFITTING USING GLOBAL ENERGY BALANCE

G.X. Guan[1,*]
[1] G&K Consultancy Ltd. and Conhubform Construction Technology Co. Ltd., Hong Kong, China
[*] E-mail: Garfieldkwan@gmail.com, Xgg@conhubform.com.hk

ABSTRACT

Flexural retrofitting of RC beams using FRP plate is a common way to increase the flexural capacity. Retrofitted beams commonly fail by debonding of the FRP plate, which occurs well before the target flexural capacity. Debonding prevention has been accounted-for empirically in most design approaches so far. The Global Energy Balance Approach (GEBA) using fracture mechanics has been proposed to determine the debonding load of an FRP-RC beam that is affected by the plate curtailment location. The GEBA results for various FRP-RC beams can be summarised using debonding contours on plots of moment capacity against the safe plate curtailment locations, and the debonding contours constructed in this way for the beams with the same ratio of depth to fracture energy are virtually the same. This paper shows how GEBA can be incorporated into the design process to prevent premature debonding of the FRP plate. The method makes use of the debonding contours and derives from these simplified design charts that could be made available to designers. The retrofitting design consideration and the theoretical background of this unified design method are first explained, followed by the derivation of the conceptual design charts. Numerically correct design charts are then constructed for a wide range of design cases. Finally, a worked example is used to explain the way to apply the unified design method using design charts.

INTRODUCTION

FRP plate retrofitting considerations

FRP plates can be used to enhance the capacity of under-reinforced RC beams to make the beams stronger but has the effect of reducing the ductility. It is relatively easy to decide how much FRP is needed to achieve a certain strength, but it is harder to ensure that the beam retains ductility. Retrofitted beams are known to suffer from premature debonding at loads below their design strength. This paper shows how to design beams for strength, ductility and debonding prevention. Figure 1 shows typical moment curvature relationships for three beams. Curve (A) applies to an unstrengthened under-reinforced beam; it has a relatively long plateau at virtually constant load as the steel yields before the concrete crushes. Curve (B) shows the effect of adding a moderate amount of strengthening; the beam yields at a higher load because of the presence of the CFRP, and continues to resist more load after the steel yields because the CFRP remains elastic. However, final crushing of the concrete occurs at a lower deflection because the neutral axis is deeper. The limiting case is shown in Curve (C) for a balanced section, where the concrete crushes at the same time as the steel yields.

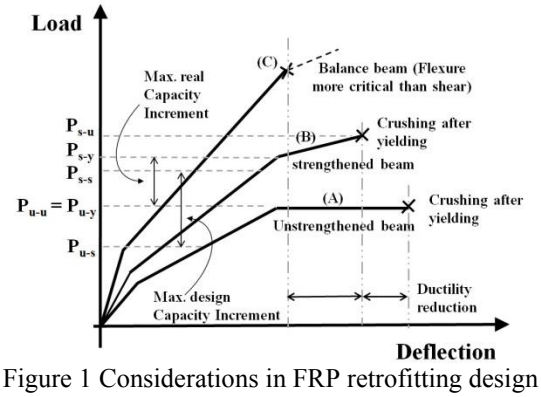

Figure 1 Considerations in FRP retrofitting design

The original service load is shown as $P_{u\text{-}s}$ while the original ultimate load capacity is $P_{u\text{-}u}$. There are several limits on the amount of flexural strengthening that is possible.

1. Most beams are under-reinforced to prevent brittle failure. The beam should not be strengthened to such an extent that it now becomes over-reinforced, so one limit on the amount of FRP gives the corresponding balanced section design (Curve C).
2. It is undesirable for the beam to undergo plastic deformation under normal service loads to avoid incremental plasticity, so the retrofitted service load limit ($P_{s\text{-}y}$) is calculated from the moment that causes first yield of the original steel reinforcement, typically at mid-span where the moment is highest. Hence the retrofitted service load ($P_{s\text{-}s}$) should always be less than the strengthened yielding capacity. The real increase in load capacity is then given by $P_{s\text{-}s} - P_{u\text{-}s}$. The increase of strengthened ultimate capacity ($P_{s\text{-}u} - P_{u\text{-}u}$) is greater than the increase in yielding capacity ($P_{s\text{-}y} - P_{u\text{-}y}$) because of the gain in stress in the CFRP after the steel has yielded.
3. The theoretical ultimate strength $P_{s\text{-}u}$ cannot be used at the working load but it may be needed to provide adequate reserve of strength if the beam is overloaded. The FRP plate rupture strain is typically much greater than the steel yield strain, so the beam would fail by concrete crushing. This is the beam's ultimate state.
4. The increase in flexural capacity should not alter the ultimate failure state from flexure to shear.

Plate end debonding prevention from fracture consideration

Tests have shown that plate end (PE) debonding, which initiates from a horizontal crack at the plate end in the concrete cover, is a common mechanism of failure for retrofitted beams. It is essential that PE debonding does not occur, not only when the steel is elastic, but also when the steel is yielding. PE debonding can normally be prevented by extending the FRP plate towards the support, but it is important to know how long the plate should be. The designer needs to choose the curtailment location L_{cur} in such a way that premature PE debonding is prevented.

In order to prevent premature PE debonding, different innovative techniques have been proposed, for example: (i) to extend the FRP plate towards the supports (Ross et al. 1999, Rahimi & Hutchinson 2001), (ii) to wrap FRP sheets around the beam or the web to reduce the beam cracks (Arduini et al. 1997, Teng et al. 2002), (iii) to anchor the FRP plate end into the beam by additional FRP straps (Hoult & Lees 2009), and (iv) to incorporate various anchorage systems such as bolting (Hsu et al. 2003, Jones et al. 1988). These inventions are far from mature and some are not practical: at the same time they aim to prevent debonding rather than to understand it. On one hand they are helpful in promoting FRP retrofitting for engineering use at an early stage in its development, but on the other hand they tend to dilute the real understanding of the debonding mechanism and bury risk in the future. Although FRP retrofitting has developed quickly, the understanding of debonding is far from mature.

Unlike intermediate-crack-induced (IC) debonding, which is commonly prevented by limiting the section strains, e.g. in ACI-440 design guide, PE debonding normally initiates well away from the load, at a place where the flexural strains are small. Strain criteria are thus not relevant. A study based on fracture analysis of concrete, which relates the change in the strain energy in the beam and the potential energy of the load to the energy that is released in the concrete when the fracture propagates, has been used to predict when debonding would occur. This is known as the Global Energy Balance Approach (GEBA), and has been used by different researchers, e.g. Achintha & Burgoyne (2008), Gunes et al. (2009), Carpinteri et al. (2009) and Guan & Burgoyne (2012). The key comparison is between the Energy Release Rate G_R and the Fracture Energy of Concrete G_f. The particular value of G_f is normally well within the range from 0.05 to 0.3 N/mm from Shah & Carpinteri (1991) and Bazant & Becq-Giraudon (2002).

A parametric study of GEBA has been presented by the authors in Guan et al. (2012) , where debonding contour (DBC) plots have been used as the PE debonding criterion: G_R varies as a function of the loading state at which debonding occurs, and as a function of where the fracture takes place. G_R is determined from M-κ models, so the DBC can be plotted on a graph of normalised moment capacity ($M/f_c'bd^2$) and curtailment location (L_{cur}/L_{shear}), which allows the strength design and the debonding design to be combined, as shown in Figure 2.

The DBC is where the G_R surface intercepts the horizontal plane that is defined by G_f. The DBC varies for beams with different depths, reinforcing steel, FRP material etc. A detailed discussion of the DBC is found in Guan et al. (2012), where it was shown that a normalized debonding criterion using a ratio of beam depth and fracture energy (h/G_f) could be used for design. A step-by-step illustration of the design approach is given below.

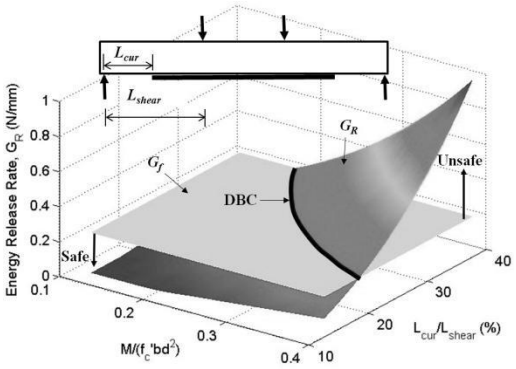

Figure 2 Determination of DBC

UNIFIED RETROFITTING DESIGN APPROACH

It is straightforward to design the amount of FRP required using simple beam theory by assuming that the FRP plate acts as a second layer of fully-bonded reinforcement. It has been recognised that debonding prevention is much more complicated, as explained in Carpinteri et al (2009) and Buyukozturk et al. (2004). Here, it is achieved using the DBC obtained from GEBA.

Design method and schematic charts

In a typical contour plot (Figure 3), the state of an FRP-RC beam with a given FRP plate curtailment length (L_{cur}/L_{shear}) under a particular design load ($M/f_c'bd^2$) at midspan is represented by a data point called the beam state point (BSP). It is necessary to establish the safe region for the BSP. The strength limit is obtained from flexural design, by checking when first yielding of the steel occurs at midspan, which gives a limiting value for the applied moment: it is represented by the vertical yielding line (YL). The debonding criterion limits L_{cur}/L_{shear} by means of the DBC. The regions where flexural or debonding failure might occur are shown. The BSP must lie within the shaded region to keep the beam safe.

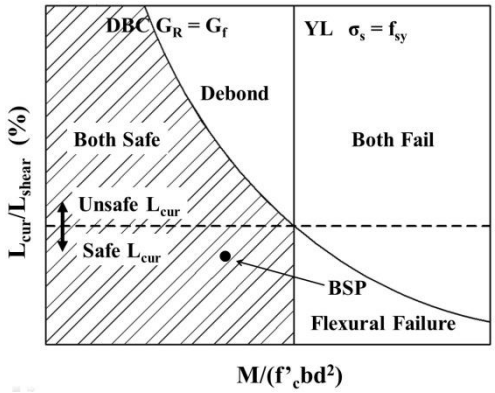

Figure 3 The four regions for BSP defined from CBD and YL

For reasons of economy, it is desirable that the strengthening should bring the section as close as possible to the YL line. Therefore, the value of L_{cur}/L_{shear} should be lower than the value given by the dashed line that passes through the intersection of the DBC and YL. This defines a limiting maximum curtailment length. If a beam is designed such that the BSP lies above this dashed line, premature debonding occurs before the beam's flexural capacity is reached. Because the unstrengthened beam was under-reinforced, debonding prevention is mainly a function of the tension steel ratio (ρ_s) and the FRP ratio (ρ_f). To strengthen a particular RC beam, ρ_s is fixed but the designer can change ρ_f, whereas when considering different RC beams ρ_s also varies. The effect of these two changes are shown separately in Figs 4 (a) and (b); adding either type of reinforcement always moves YL to the right (YL1 to YL2), but it has different effects on the DBC. Increasing ρ_f means that debonding occurs more easily so the debonding line moves. In contrast, with a larger ρ_s, debonding is less likely. The maximum curtailment ($L_{cur\text{-}max}$) changes correspondingly.

In order to make the above design charts cover a wide range of design cases, say for ρ_s from 0.4 to 2.0% and ρ_f from 0.1 to 1.5%, a very large number of DBCs and YLs would be needed and the charts would be very complicated. However, it is noted that the critical point is the intersection point of the DBC and YL. Any designed BSP below and to the left of this point is safe, which leads to the simpler design charts described below.

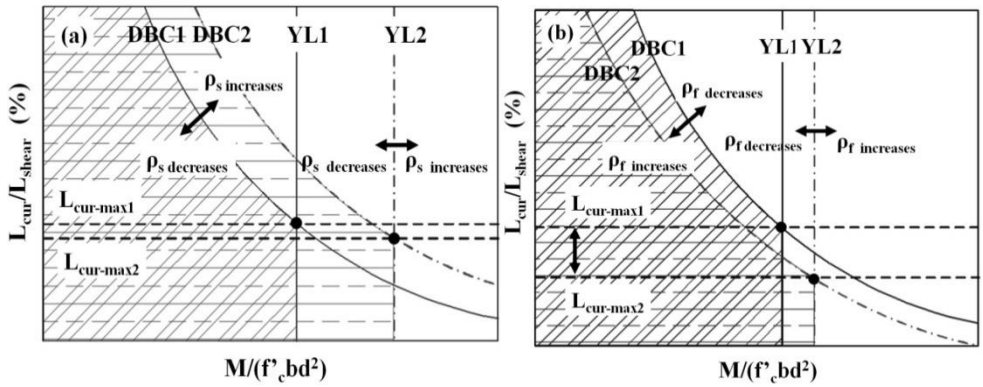

Figure 4 (a) Change of the 'Both safe' region with increasing ρ_s; (b) Change of the 'Both safe' region with increasing ρ_f

Simplified design method and schematic charts

Simplified design for pre-yielding stage

The intercepts of the DBCs and the YLs are used to construct simplified design charts as illustrated in Figure 5(a): Firstly, keep ρ_f constant and vary ρ_s continuously. The locus of intercepts of the DBC's and the YL's form a curve. This track of intercepts is named the steel-ratio track of intercepts (STI). A family of STI can be constructed by repeating the above step for different ρ_f values. With a set of STI's, the variation of ρ_s is represented by the movement of a point along one STI, and the change of ρ_f is the change between different STIs. It is noted that if the moment is reduced, the STI line gets higher, which implies that L_{cur} could be higher, but the DBC also gets higher, but more steeply (Figure 5(b)). So if the user chooses to use the STI line for design the FRP will not debond before yielding. However, the STI cuts into the unsafe region in post-yielding stage so it should not be used for post-yielding design.

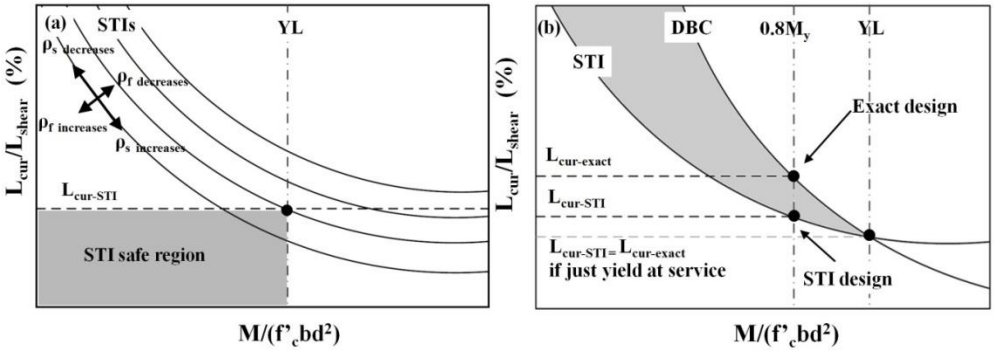

Figure 5 (a) Conceptual design chart with ST; (b) Comparison between STI design and the exact design

Simplified design for post-yielding stage

Although the service load must occur while the steel is still elastic, it has already been mentioned that the beams may have to carry loads above yield in order to provide sufficient reserve of strength. It is essential that the FRP does not debond before the ultimate strength of the beam is reached. This can be accomplished by means of a different set of curves, which are constructed in the same way as the STI curves, by varying ρ_f only, giving the FRP-ratio track of intercepts (FTI) (Figure 6(a)). The increase of ρ_s makes debonding less likely while an increase of ρ_f makes it more likely. Graphically, FTI and STI curves have a similar trend but different inclinations and for a particular combination of (ρ_s, ρ_f) they cross each other at the yielding state. In the pre-yielding stage, the STI line lays below the DBC, so for design purposes it gives conservative results. Beyond yield, the FTI lines are below the DBC, and thus are conservative (Figure 6(b)). If the reserve of strength that is

required beyond yield is high, it is possible that a negative curtailment is predicted as shown in Figure 6(b) (no positive intercept for the FTI at $1.5M_y$). This indicates that an anchorage is required in addition to the bond.

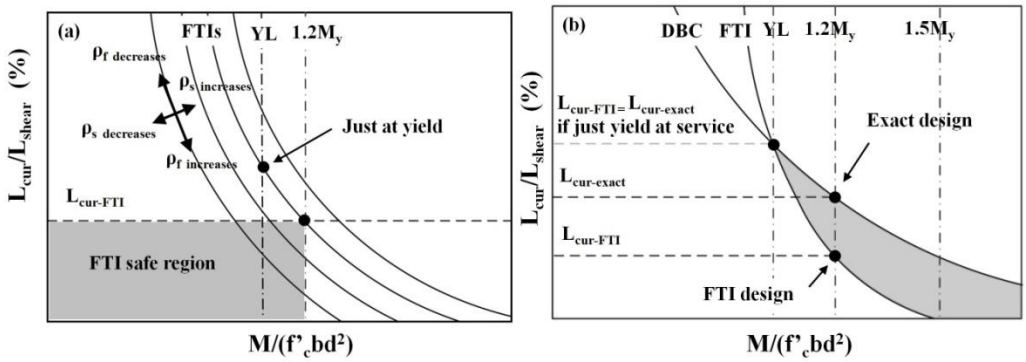

Figure 6 (a) Conceptual design chart with FTI; (b) Comparison between FTI design and the exact design

Unified design procedures

1. The area of steel is known, so ρ_s is fixed
2. Simple beam theory is applied to determine the amount of FRP needed to satisfy the requirements for both the service load (when the steel must not yield), and the ultimate load (when it probably will). The higher value of A_f and hence ρ_f are chosen.
3. The designer uses the STI curves to determine L_{cur} at the service load, and the FTI curves to determine L_{cur} at the ultimate load.

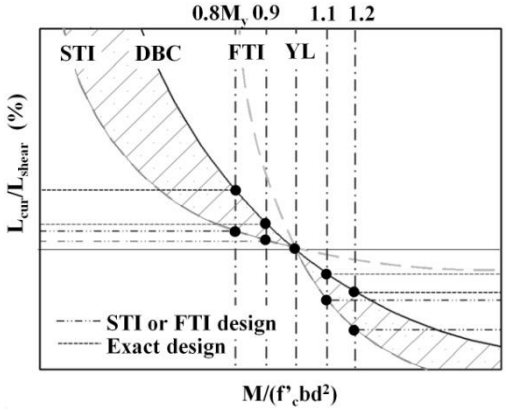

Figure 7 Comparison of the exact design, and design based on STI and FTI

Figure 7 illustrates these principles by combining the STI and FTI curves, together with the DBC. If the designer wished to do an exact design, the maximum allowable curtailment is given by the intersection of the applied moment and the DBC, shown by the dotted line in Figure 7. To obtain a DBC requires complicated computation, and each DBC corresponds to only one design scenario so there are too many DBCs to be provided for design charts. Meanwhile, STI and FTI are compacted charts that can be provided as design charts to cover a wide range of design scenarios. The chain-dotted lines in Figure 7 show how the curtailment locations would be chosen using the simplified method. Notably, the values of L_{cur}/L_{shear} obtained from the simplified method are always below the exact values, and are thus conservative. The hatched areas are the marginally safe areas that may be used to design the FRP-RC beam to a more economical or more extreme capacity state. A detailed worked example is provided below to show how an FRP retrofitting design is made using this method.

DETAILED DESIGN CHART CONSTRUCTION

The charts given below are constructed for beams with cylindrical concrete strength f_c' = 37 MPa, with steel yield strength f_y = 530 MPa and Young's modulus E_s = 200 GPa, and with FRP elastic modulus E_f = 165 GPa. The STI and FTI are the locus of intersections of YLs and DBCs. Here the YLs are constructed assuming the tension steel yields at the strain f_y/E_s, the FRP plate behaves elastically, and the concrete in compression follows an unfactored parabolic stress-strain relationship in Hognestad et al. (1955). When considering DBC, the most important parameter is the ratio h/G_f (MPa^{-1}). It was shown in Guan et al. (2012) that DBCs for beams with the

same h/G_f value are virtually identical. Thus the DBCs and the resulting STI and FTI charts below apply to all the beams having the same h/G_f.

Construction of detailed STI design charts

The STI curves can give a conservative design curtailment in the pre-yielding stage, so that they are used to consider debonding prevention for the service state. Figure 8(a) shows a typical STI design chart that relates to a 400 mm deep beam, with G_f taken as 0.15 N/mm, so $h/G_f = 2.67\times10^3$ MPa^{-1}. It has been produced by keeping ρ_f constant (at 0.5%) and varying ρ_s continuously. The family of thin curved lines are the DBCs for different values of ρ_s, while the different vertical dashed lines are the corresponding YL lines. The darker curved line is the STI which goes through the intersections of the corresponding pairs of DBCs and YLs. The darker solid (vertical) line relates to $\rho_s = 1.0\%$. One STI curve covers the retrofitted design of a beam with a certain depth and ρ_f value, but various ρ_s values.

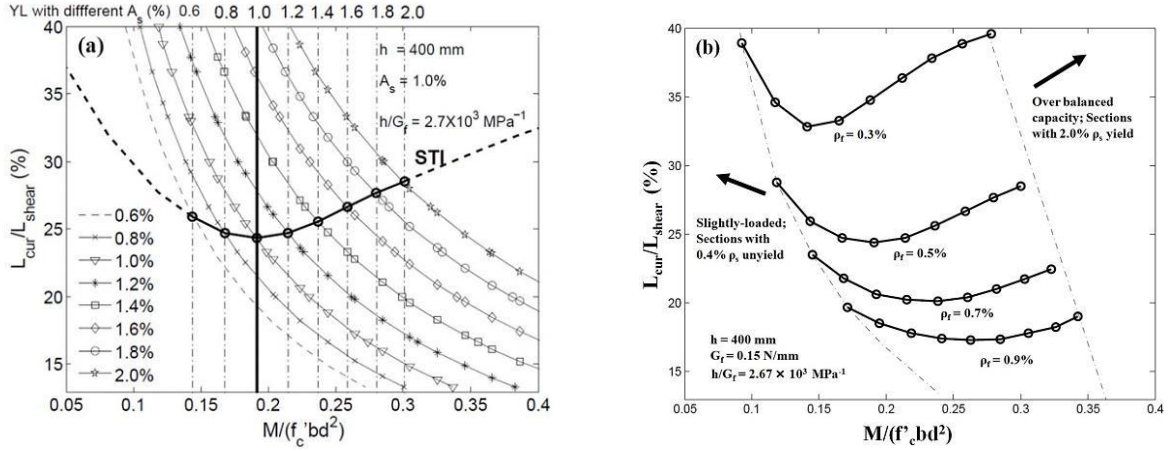

Figure 8 (a) Construction of STI for beam having h = 400 mm and G_f = 0.15N/mm; (b) Numerically correct STI for 400 mm deep beam ($h/G_f = 2.7\times10^3$ MPa^{-1})

Design charts can be produced by repeating the process used to find Figure 8(a) for different ρ_f values, to give a family of STIs for beams with a fixed value of h/G_f. Figure 8(b) shows such a plot for $h/G_f = 2.67\times10^3$ MPa^{-1} and h = 400 mm. The darker curves are the exact STIs, covering the range of ρ_s from 0.4% to 2.0%. It is evident from the figures that if a lot of FRP is present, (for example ρ_f = 0.9%), PE debonding is likely and the plate must be extended close to the support (L_{cur}/L_{shear} is small). If less FRP is needed, PE debonding is less likely and the plate can be curtailed further away from the support (L_{cur}/L_{shear} is larger).

Construction of detailed FTI design charts

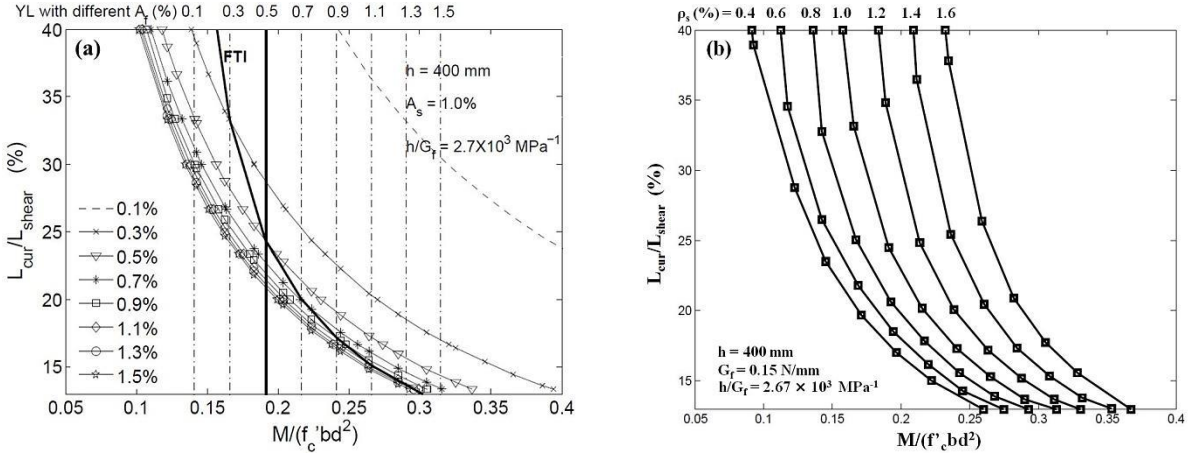

Figure 9 (a) Construction of FTI for beam having h = 400 mm and G_f = 0.15N/mm; (b) Numerically correct FTI for 400 mm deep beam ($h/G_f = 2.67\times10^3$ MPa^{-1})

The FTI curves can give a conservative design curtailment in the post-yielding stage and thus they are adopted to consider debonding that ensures the ultimate capacity. They are constructed in a similar manner to the STI

charts, but this time keeping ρ_s constant and varying ρ_f continuously. Figure 9(a) relates to a beam of 400 mm deep, with G_f taken as 0.15 N/mm. By repeating the process for different ρ_s, a family of FTI is given to cover all the design cases for 400 mm deep beams with h/G_f value as 2.67×10^3 MPa^{-1}, as in Figure 9(b).

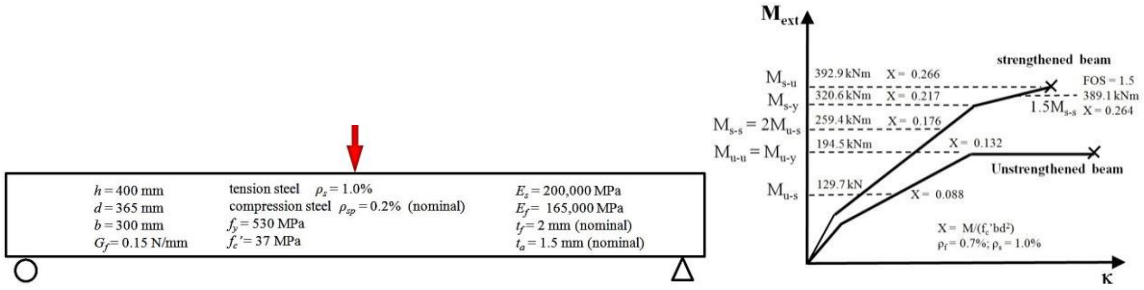
Significance of the simplified design

A pair of STI and FTI Band charts is required for one design to consider both service state and ultimate state. Since h/G_f typically has a value in the range $0.5 – 20\times10^3$ MPa^{-1} for beams ranging from 200 to 1000 mm deep, and having a G_f ranging from 0.05 to 0.30 N/mm, in total, about ten pairs of STI and FTI Band charts are able to cover most design scenarios. Thus, the simplified design with STI and FTI Band charts provides a convenient way for practical engineering.

The effects of varying FRP elastic modulus is equivalent to varying the amount of FRP with a certain elastic modulus, since FRP is always elastic. On top of these STI and FTI Band charts, the change of material properties such as the concrete strength (f_c') and the steel yielding strength (f_y) will lead to variations.

WORKED EXAMPLE

A typical problem faced in a design office is to retrofit an existing beam. The design details of a one-span simply-supported beam that requires retrofitting is shown in Fig 10.



(a) (b)

Figure 10 (a) Parameters for beam design; (b) Summary of the flexural retrofitting design results

The calculations in the Appendix show that the original ultimate moment capacity ($M_{u\text{-}y}$) is assessed to be 194.5 kNm, which with a factor of safety of 1.5 gives an unstrengthened working load capacity ($M_{u\text{-}s}$) of 129.7 kNm. Suppose it is now required to take twice its original service load, which implies that the strengthened service load ($M_{s\text{-}s}$) should be 259.4 kNm. If it is to retain a factor of safety of 1.5 at ultimate this implies that $M_{s\text{-}u}$ should exceed 389.1 kNm. The results of the retrofitting design to raise the flexural capacity are summarised in Figure 10 (b): the upper and lower curves represent the behaviours of the strengthened and unstrengthened beams respectively. By adding 0.7% FRP ($\rho_f = 0.7\%$) to the original beam, the beam is able to take over twice the original service load before the tension steel yields ($M_{s\text{-}y} > M_{s\text{-}s}$), and has a FOS over 1.5 at the ultimate state ($M_{s\text{-}u} > 1.5M_{s\text{-}s}$).

It is now necessary to use the principles outlined in this paper to determine where the FRP can be curtailed. When debonding is considered, the unified design method is applied. The design charts provided will be the STI and FTI charts (Figs 8 and 9). The critical number that determines which sets of design charts to use is h/G_f , which is 400/0.15 = 2.67 MPa^{-1} in this case. Figure 11(a) is a reproduction of Figure 8(b), but with the relevant lines highlighted. For the service state, a vertical line is first drawn at $M/(f_c'bd^2) = 0.176$ which represents the moment capacity required at service after retrofitting. Then the maximum curtailment in the problem is found to be 21.5% L_{shear}

When considering the ultimate state, the FTI band charts are used for debonding prevention; Figure 11(b) is a reproduction of Figure 9(b), again with the relevant lines highlighted. Following the same procedures, the maximum curtailment for the beam is estimated as L_{cur}/L_{shear} = 16.0%. Consequently, the ultimate state governs the debonding prevention, and the FRP plate should be curtailed less than 16.0% of the shear span away from the supports.

The exact maximum curtailment obtained from the DBC charts (exact design) is also provided here (Figure 11(c)). The maximum values of L_{cur}/L_{shear} given by the exact design at service and ultimate states are 24.8% (intercepting $M_{s\text{-}s}$) and 16.8% (intercepting $1.5M_{s\text{-}s}$) respectively, which are greater than those predicted

by simplified design above. Furthermore, if the FRP plate is curtailed to 17.8% of the shear span, it debonds when the tension steel yields. If the FPR plate is curtailed to 16.8%, debonding and crushing of compressive concrete almost occur simultaneously as the ultimate failure mechanism, since in this case $M_{u\text{-}s}$ (= 0.266) is close to $M_{s\text{-}s}$ (= 0.264). These values all exceed the value of 16.0% given by the simplified design charts. It should be noted that the DBC curves would not generally be available to designers, whereas it is suggested that simplified STI and FTI band charts could be provided.

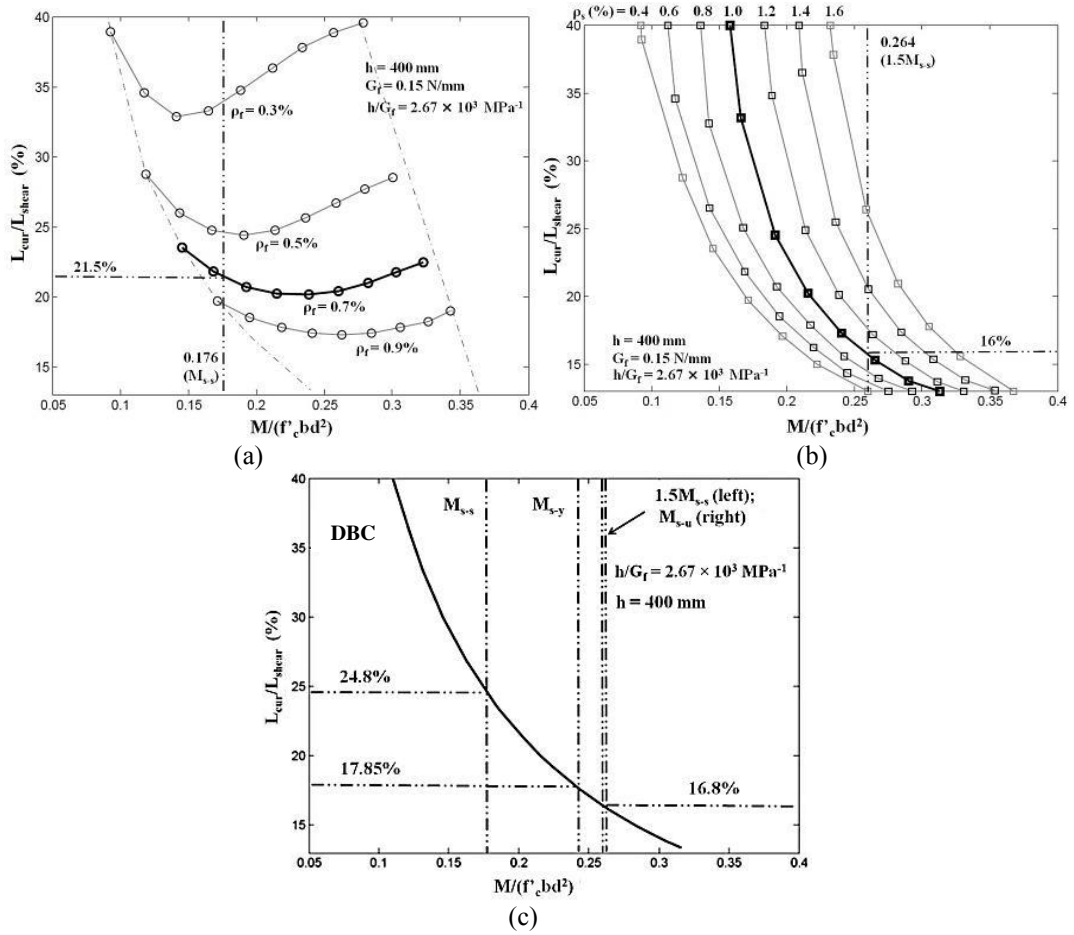


Figure 11 Determination of the curtailment from (a) STI; (b) FTI; and (c) DBC design charts

If the FRP ratio initially guessed cannot provide enough flexural capacity at service or ultimate state, it should be increased. However, an increase in FRP ratio reduces the critical curtailment length, which means the plate has to be placed closer to the supports. If the space for the extension of the FRP plate is the primary constraint, debonding prevention consideration will govern the retrofitting design, and the FRP ratio should be kept as small as possible. Otherwise, additional mechanical anchorage is needed to prevent premature debonding.

CONCLUSIONS

This paper proposes a unified design method for FRP retrofitting design considering flexural capacity and plate end debonding prevention simultaneously. In this design method, the flexural consideration is based on conventional beam theory to select the proper amount of FRP, represented by the normalized section capacity ($M/f_c'bd^2$) in terms of yielding line (YL) in charts. Assessment of PE debonding is based on concrete fracture analysis, applying the debonding contour (DBC). A retrofitting designer then has to select the proper amount of FRP material and the curtailment to make a beam fall into the safe region given by the combination of YL and DBC. A more concise simplified design chart is proposed to cover a large range of design cases for beams with different depths, different reinforcement ratios, various amount of FRP material, and in both service and ultimate states. This new approach provides a way of incorporating a fracture mechanics approach to debonding in a conventional beam design.

APPENDIX Flexural capacity design for the beam in the worked example

STEP 1 Assessment of original capacity

The original design flexural capacity corresponds to the first yield of the section, as shown in Figure A-1.

The concrete compression is calculated using an equivalent rectangular stress distribution according to ACI318-08, where α_1 and β_1 are taken as 0.85 and 0.77 respectively, and the results are in Figure A-1(b). From force equilibrium:

$$0.85 \times 0.77 \times f_c' bx + \rho_{sp} bdE_s \varepsilon_{sp} = \rho_s bdf_y \quad \text{(A1)}$$

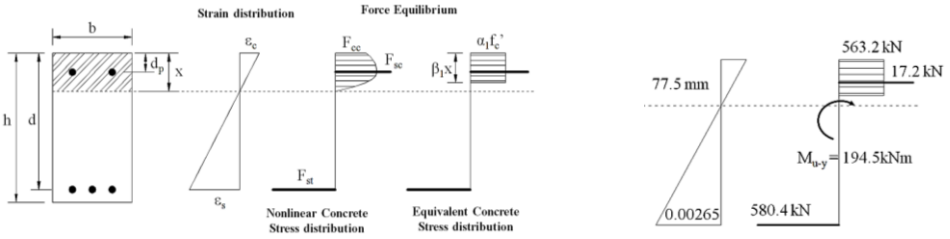
where $\varepsilon_s = f_y / E_s = 0.00265$ and $\varepsilon_{sp} = \dfrac{x - d_p}{d - x}\varepsilon_s$

Substituting values and solving gives:

x = 77.5 mm; F_{cc} = 563.2 kN; F_{sc} = 17.2 kN; F_{st} = 580.4 kN.

Since the beam is under-reinforced, the contribution of the nominal compression steel is negligible. The moment capacity of this unstrengthened section (at yield) is thus:

$$M_{u-u} = M_{u-y} = F_{st}(d - 0.5 \times 0.77x) = 580.4 \times (365 - 0.5 \times 0.77 \times 77.5) = 194.5kNm \quad \text{(A2)}$$



(a) (b)

Figure A-1 (a) Section analysis according to ACI; (b) Original RC beam at just yield (ultimate state)

STEP 2 Design of amount of strengthening

The beam is now to be strengthened so that $M_{s\text{-}s}$ = 259.4 kNm, and $M_{s\text{-}u}$ > 1.5 $M_{s\text{-}s}$ so is 389.1 kNm. After some trial and error it is found that FRP plate having a cross-sectional area equal to 0.7% of the beam section (ρ_f = 0.7%) is will provide the necessary strengthening. This amount of FRP is OK, by checking the new service and ultimate conditions, as shown in Figure A-2.

At service load, the tension steel in the strengthened beam (FRP-RC) just yields; this should occur at a moment greater than $M_{s\text{-}s}$. Using the method above, the section gives:

x = 127.1 mm; F_{cc} = 923.4 kN; F_{sc} = 44.9 kN; F_{st} = 580.4 kN; F_p = 388.0 kN.

$M_{s\text{-}y}$ = 320.6 kNm > $M_{s\text{-}s}$ = 259.4 kNm, OK. At service, $M_{s\text{-}y}/(f_c'bd^2)$ = 0.217

At ultimate load, the top concrete crushes. Using an ultimate compressive strain of 0.003, section analysis yields:

x = 152.0 mm; F_{cc} = 1104.4 kN; F_{sc} = 101.1 kN; F_{st} = 580.4 kN; F_p = 625.2 kN.

$M_{s\text{-}u}$ = 392.9 kNm > 389.1 kNm, OK; At ultimate state, $M_{s\text{-}u}/(f_c'bd^2)$ = 0.266

Notations

A_s , A_{sp} , A_f -- Cross-sectional areas of tension steel, compression steel and FRP plate

b -- Width of the RC beam

c -- Concrete cover thickness

d -- Effective depth of the RC beam

E_c -- Young's modulus of concrete

f_y -- Yield stress of tension steel

f_c' -- Concrete cylinder compressive strength

F_{cc} , F_{ct} , F_{sc} , F_{st} , F_p -- Resultant force of concrete in compression, concrete in tension, compression steel, tension steel, and FRP retrofitting plate respectively

h -- Depth of the RC beam section
L_{cur} -- Curtailment length (the distance from the FRP plate end to the support)
L_{shear} -- Shear span of the FRP-RC beam
$M_{s\text{-}s}$, $M_{s\text{-}y}$, $M_{s\text{-}u}$ -- strengthened service/yield/ultimate moment capacity
$M_{u\text{-}s}$, $M_{u\text{-}y}$, $M_{u\text{-}u}$ -- unstrengthened service/yield/ultimate moment capacity
$P_{s\text{-}s}$, $P_{s\text{-}y}$, $P_{s\text{-}u}$ -- strengthened service/yield/ultimate load capacity
$P_{u\text{-}s}$, $P_{u\text{-}y}$, $P_{u\text{-}u}$ -- unstrengthened service/yield/ultimate load capacity
t_f -- Thickness of the FRP strengthening plate
t_a -- Thickness of the adhesive layer
ε_s -- Strain at tension steel
ε_{sp} -- Strain at compression steel
ε_f -- Strain at the centre of FRP strengthening plate
ε_c -- Strain at top concrete fibre
ρ_s -- Tension steel ratio (A_s/(bd))
ρ_{sp} -- Compression steel ratio (A_{sp}/(bd))
ρ_f -- FRP strengthening material ratio (A_f/(bd))
κ -- Curvature

ABSTRACT

Crack widths are important considerations in both serviceability and durability design of concrete structures and should be evaluated to ensure compliance with design limits. However, existing empirical formulas for maximum crack width prediction are discrepant with each other, and they cannot reveal key information such as crack number and crack spacing. To obtain such information, finite element analysis has to be adopted. However, conventional finite element analysis has its limits in carrying out crack analysis. Particularly, the common smeared crack models, which do not realistically reflect bond-slip of reinforcing bars, would not give correct crack widths. In contrast, the discrete crack models are difficult to apply because of the need to adaptively generate discrete crack elements according to the cracks formed during the loading process. In this paper, a pseudo-discrete crack model is developed for finite element implementation. The conventional smeared crack model is transformed and reformulated, and a novel crack queuing algorithm is introduced for crack analysis. The method has been applied to analyse concrete beams in the literature. It is demonstrated that the computational results of crack number, spacing and widths agree closely with the measured results.

KEYWORDS

Crack width, crack queuing algorithm, pseudo-discrete crack model, finite element analysis.

INTRODUCTION

In the design of reinforced concrete structures, crack width is a major factor to be considered, and has to be limited to a certain maximum allowable value to ensure the serviceability and durability performance. However, only empirical formulas for crack width prediction are given in design codes, such as British Standard BS 8110, American Concrete Institute ACI 224R-01, and Eurocode 2, and these formulas do not agree with each other. One probable reason is that the phenomena of crack initiation, propagation and widening are fairly complicated and difficult to analyse. Specialised numerical techniques are required to deal with the stress concentrations at crack tips, stress redistribution during crack formation, and bond-slip of steel reinforcing bars when cracks widen. Hence, conventional finite element methods have limited capability in analysing the crack number, spacing and widths in concrete.

Finite element methods for concrete cracking simulation may be categorized into discrete crack model and smeared crack model. The discrete crack model was first proposed by Ngo and Scordelis (1967) where the crack location was predetermined, also by Nilson (1968) where crack propagation was restricted to follow the boundaries of finite elements. Adaptive insertion of discrete crack elements according to the analytical stress field could lead to more realistic crack patterns (Hillerborg et al. 1976; Ingraffea and Saouma 1985; Bittencourt et al. 1996), but this requires re-meshing in each iteration step (Yang and Chen 2005). Such would incur high demand of computational resources and rendering the adaptive discrete crack model difficult to apply.

Rashid (1968) was among the earliest researchers who developed the smeared crack model, in which the formation of a crack is simulated by altering constitutive properties of the concrete element containing the crack, i.e. the crack is in effect smeared within the volume of concrete element. The smeared crack model may be further categorized into the non-rotating crack model (Rashid 1968; Suidan and Schnobrich 1973; Cervenka 1985) and rotating crack model (De Borst and Nauta 1985; Willam et al. 1987). In the non-rotating crack model, the crack directions are assumed to be fixed once the cracks are formed but in the rotating crack model, the cracks are allowed to rotate with the principal strain directions. However, in most smeared crack models, the steel reinforcing bars are also smeared within the concrete element (Cope et al. 1980; Gupta and Akbar 1984). As a result, the bond-slip of the steel reinforcing bars, which has great influence on the crack width, is ignored.

To predict the crack number, spacing and widths, accounting for the bond-slip of reinforcing bars is not a sufficient condition. Since there would be stress concentration at crack tips, the fracture toughness of concrete needs to be considered. Moreover, during crack formation and propagation, there would be immediate stress redistribution in the vicinity of cracks, which would relieve the tensile stresses normal to the cracks to elude the formation of other cracks close to the newly formed cracks. In conventional finite element methods, stress relief is not taken into account and consequently, many false cracks which should not exist in reality are often generated. Herein, a pseudo-discrete crack model taking into account the stress concentration and fracture toughness in the cracking criteria is developed, and stress relief upon crack formation is simulated using a novel crack queuing algorithm, which allows only one crack to form at a time and evaluating the stress redistribution so caused by re-analysing the concrete stresses before allowing another crack to form. Through transforming and reformulating the smeared crack model, the pseudo-discrete crack model successfully circumvents the difficulty in applying the discrete crack model.

MODELLING STRATEGIES BY FINITE ELEMENT METHOD

The proposed discrete crack model was implemented in a nonlinear finite element programme developed by the authors. In this section, the basic assumptions and methodologies of modelling are stated. The sign convention adopted is tension positive and compressive negative. At each load increment step, direct iteration based on secant stiffness is performed.

Concrete Elements

The concrete is modelled by 3-noded triangular elements, which is allowed to have tensile cracks formed inside the element. To cater for the nonlinear behaviour, the biaxial stress-strain relations in the local coordinates are transformed into two uniaxial stress-strain relations such that each of the two axial stresses is taken as a function of the equivalent uniaxial strain in that direction (Wang et al. 1999; Kwan et al. 1999; Ng 2007). The equivalent uniaxial strains, denoted by ε_1^e and ε_2^e, are defined by Equations (1) and (2), in which ε_1 and ε_2 are the axial strains in the local coordinates, and ν_1 and ν_2 are the Poisson's ratios.

$$\varepsilon_1^e = \frac{1}{1-\nu_1\nu_2}\left(\varepsilon_1 + \nu_2\varepsilon_2\right) \tag{1}$$

$$\varepsilon_2^e = \frac{1}{1-\nu_1\nu_2}\left(\varepsilon_2 + \nu_1\varepsilon_1\right) \tag{2}$$

When the equivalent uniaxial strain is compressive, the stress-strain curve developed by Desayi and Krishnan (1964) is used. Under tension, the concrete is assumed to be linearly elastic before cracking and have no tensile capacity after cracking as adopted in the elasto-plastic analyses by Kwan et al. (1998). To account for the biaxial behaviour, the biaxial strength envelope developed by Kupfer and Gerstle (1973) is adopted.

Regarding the cracking criteria, if there is no crack tip nearby a concrete element, it is assumed that the concrete would crack when the tensile stress exceeds the tensile strength. On the other hand, if there is a crack tip nearby, both the tensile strength and fracture toughness are considered, as will be elucidated in the subsequent section. Once cracks are formed, the crack directions are fixed. In other words, the non-rotating crack model is adopted.

Rebar Elements

The reinforcing bars are separately modelled by discrete rebar elements. It is because the crack width is largely dependent on the bond-slip between reinforcing bar and concrete. Each rebar element has 2 nodes having the same coordinates as the nodes of the concrete elements to which the rebar element is connected, but the nodes on the steel bar element can have different displacements from those of the concrete elements so as to allow for bond-slip. For the constitutive modelling, the steel reinforcing bars are assumed to be linearly elastic and plastic with strain hardening (Mander 1983).

Rebar-Concrete Interface Elements

To allow for bond-slip between reinforcing steel and concrete, interface elements with 2 connection points and 4 nodes are inserted between the rebar elements and the concrete elements (Goodman et al. 1968; Ng et al. 2011; Kwan and Ng 2013). At each connection point there are paired nodes and a shear spring to simulate the bond stress-slip relation, which refers to CEB-FIP Model Code 1990. The bond-slip at a connection point is calculated as the difference in longitudinal displacements of the 2 nodes there, and the stiffness of shear spring

at the connection point is evaluated as the bond stiffness times the perimeter of the steel reinforcing bars times half of the length of interface element. It is noteworthy to point out that as the bond-slip will change direction across a crack (this will be explicated in detail later), the interface elements should be formulated using discrete shear springs as proposed by the authors, rather than using continuous shear springs (Keuser and Mehlhorn 1987; Jendele and Cervenka 2006).

IMPLEMENTATION OF PSEUDO-DISCRETE CRACK MODEL

A number of specialised numerical techniques have been devised for the implementation of pseudo-discrete crack model, as detailed in the following sections.

Crack Queuing Algorithm

Upon the formation of a crack, there would be stress redistribution and the tensile stress perpendicular to the crack would be relieved thereby eluding the formation of other cracks in the vicinity. The stress redistribution has to be accounted for by re-analysing the concrete stresses before allowing any other cracks to be formed. Otherwise, false cracks caused by numerical instability would appear upon the exertion of a load increment, and erroneous computed crack pattern, crack spacing and crack widths would result. This necessitates the crack queuing algorithm (Kwan et al. 1999), which is first introduced herein to the pseudo-discrete crack model.

At each loading step, the concrete element with the highest tensile stress to tensile strength ratio is searched. If the ratio is less than 1.0, no new crack is formed and the analysis can proceed to the next load increment step. Otherwise, if the ratio is equal to or higher than 1.0, only this concrete element is allowed to crack, and its stiffness matrix is altered to reflect the crack formation. Then, the whole concrete structure is re-analysed with the same loading level so as to cater for the stress redistribution. This process is repeated until no more new crack is formed after re-analysis, the analysis proceeds to the next loading step. Using this crack queuing algorithm, the crack pattern so obtained would contain genuine cracks with realistic crack widths.

Fracture Toughness

Near crack tips, there is occurrence of stress concentration (Griffith 1920) and if very fine element mesh is used, the tensile stresses obtained in the concrete elements in front of and close to crack tips can be much higher than the tensile strength of concrete. If the tensile strength is solely adopted as the cracking criterion, the crack pattern obtained would be mesh size dependent and the crack propagation would be very rapid and unstable. In order to avoid the mesh size dependence and stabilise the crack propagation, the fracture toughness K_{IC} is incorporated as a cracking criterion.

According to Erdogan and Sih (1963), crack propagation initiates when $\sigma_\theta(2\pi r)^{0.5} \geq K_{IC}$, in which σ_θ is the circumferential stress (the stress perpendicular to the line joining the point being considered to the crack tip) and r is the distance from the point being considered to the crack tip. In graphical representation, the stress field near a crack tip in polar coordinates is illustrated in Figure 1, where r and θ are the polar coordinates with the crack tip as the origin. Mathematically, the criterion may be written as:

$$\sigma_\theta \geq \frac{K_{IC}}{\sqrt{2\pi r}} \tag{3}$$

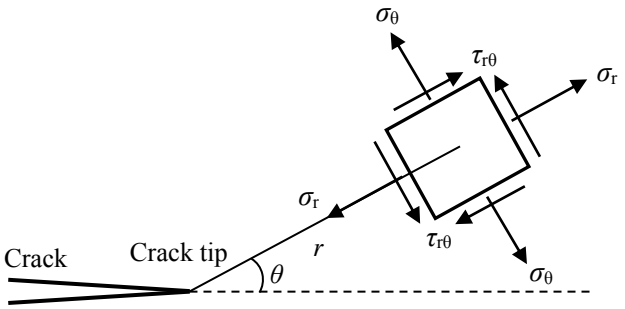

Figure 1 Stress field near crack tip in polar coordinates

In actual application, for each concrete element being considered, a search is conducted to find out if there is any crack tip in the adjoining concrete elements, i.e. concrete elements having one or more common nodes with the concrete element being considered. If there is any crack tip in any of the adjoining concrete elements, the distance r is determined as the distance from the centroid of the concrete element being considered to the centroid of the concrete element containing the crack tip. Having determined the distance r, the cracking criterion for the concrete element being considered is modified as maximum tensile stress exceeding the equivalent tensile strength f_t^e, which is taken as the maximum of $K_{IC}/(2\pi r)^{0.5}$ and tensile strength of concrete f_t. With this modified cracking criterion, the crack propagation would remain stable even when a very fine mesh is used in the finite element analysis.

Crack Width Calculation

For a concrete element which is cracked, the crack is assumed to be formed at the centroid of element and non-rotating. After re-analysis to allow for stress redistribution due to formation of the crack, the tensile stress in the direction perpendicular to the crack would drop to a negligibly small value, which may be assumed as zero. Based on this assumption, the crack width can be calculated from the nodal displacements of the cracked concrete element.

As shown in Figure 2, the crack through the centroid would separate the concrete element into two portions, each at one side of the crack. Denote the 3 nodes of concrete element by I, J and K, in such a manner that node I is the node closest to the crack and nodes J and K are at opposite sides of the crack (node J and K are always belonging to different portions of the concrete element), and further denote the crack angle (the angle between the normal direction of the crack and the x-axis) by α. The displacement of node J from the crack d_J and the displacement of node K from the crack d_K may be computed as:

$$d_J = -u_J \cos\alpha - v_J \sin\alpha \tag{4}$$

$$d_K = u_K \cos\alpha + v_K \sin\alpha \tag{5}$$

in which u_J and v_J are the nodal displacements of node J in the x- and y-directions, and u_K and v_K are the nodal displacements of node K in the x- and y-directions. From these displacements, the crack width w can be calculated from Equation (6). It should be noted that the absolute value is taken because the nodes J and K may swap in position leading to negative value of their relative displacement from the crack.

$$w = | d_J + d_K | \tag{6}$$

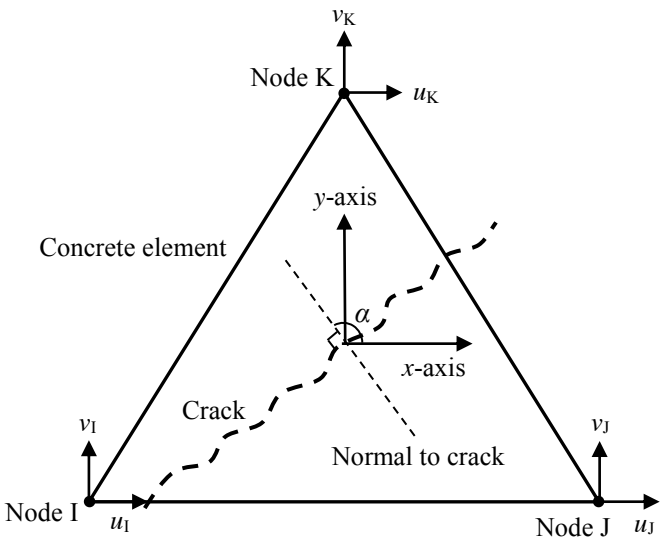

Figure 2 Calculation of crack width

APPLICATIONS TO CONCRETE BEAM ANALYSIS

Beam Specimens Analysed

To evaluate the applicability and accuracy of the finite element analyses incorporating the pseudo-discrete crack model, 19 nos. reinforced concrete beam specimens tested by Clark (1956) are analysed and compared with the experimental results. All these beams have a total length of 3353 mm and a span length of 2743 mm. They have an uniform cross-section of 381 mm depth by 152 mm width. The longitudinal reinforcement ratio varied from 1.01% to 2.58%. No stirrups were provided. All the beams were subjected to two-point loading and the loading points were spaced 1372 mm apart symmetrically, as shown in Figure 3. The beams are designated by beam number in the form of A-B-C-D, where A is the depth of section (in inches), B is the width of section (in inches), C is the bar size number and D is a serial number, as listed in Table 1.

Table 1 Details of beam specimens tested by Clark (1956)

Beam number	Rebar diameter (mm)	No. of rebars	Effective depth (mm)	Reinforce-ment ratio (%)	Concrete strength (MPa)
15-6-8-1	25.4	1	330.2	1.01	26.8
15-6-8-2	25.4	1	330.2	1.01	25.9
15-6-6-1	19.1	2	339.9	1.10	30.1
15-6-6-2	19.1	2	339.9	1.10	29.2
15-6-6-3	19.1	2	333.5	1.12	27.2
15-6-7-1	22.2	2	357.1	1.42	26.8
15-6-7-2	22.2	2	331.7	1.53	22.4
15-6-7-3	22.2	2	331.7	1.53	29.5
15-6-7-4	22.2	2	331.7	1.53	29.0
15-6-7-5	22.2	2	331.7	1.53	27.9
15-6-10-1	32.3	1	326.6	1.65	24.6
15-6-10-2	32.3	1	326.6	1.65	28.7
15-6-8-3	25.4	2	330.2	2.03	26.6
15-6-8-4	25.4	2	330.2	2.03	26.7
15-6-9-1	28.7	2	344.4	2.46	28.1
15-6-9-2	28.7	2	328.7	2.58	28.6
15-6-9-3	28.7	2	328.7	2.58	27.2
15-6-9-4	28.7	2	328.7	2.58	28.6
15-6-9-5	28.7	2	328.7	2.58	24.4

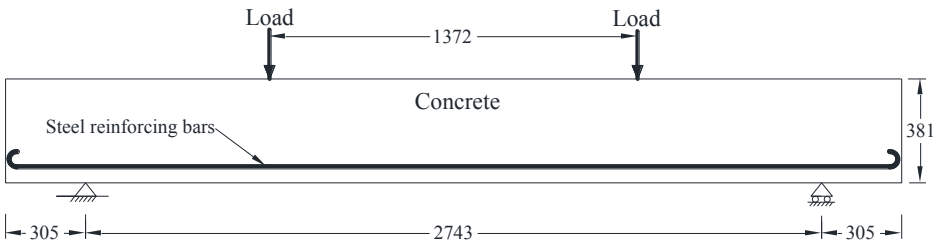

Figure 3 Details of concrete beam (dimensions in mm)

The material properties of the beams are summarised in Table 2. For concrete, the compressive strengths reported by Clark (1956) are used in the analysis. The corresponding range of concrete compressive strengths is stated in Table 2. Since the tensile strengths and initial elastic moduli of concrete were not given by Clark, values calculated based on the reported compressive strengths using the formulas given in American Concrete Institute ACI 318R-02 are used in analysis and stated in Table 2. The Poisson's ratio is assumed to be 0.2 for all concrete. The fracture toughness of concrete was also not presented by Clark, thus the value obtained by Chen et al. (2011) for similar concrete is used.

Table 2 Materials properties of beam specimens

Concrete	
Uniaxial compressive strength (MPa)	22.4-30.1
Uniaxial tensile strength (MPa)	2.6-3.1
Initial elastic modulus (GPa)	22.4-26.0
Poisson's ratio	0.20
Fracture toughness ($MNm^{-2/3}$)	1.26
Steel reinforcement	
Yield strength (MPa)	275.7
Ultimate tensile strength (MPa)	482.6
Initial elastic modulus (GPa)	200.0
Tensile strain at start of strain hardening (%)	1.0
Ultimate tensile strain (%)	10.0
Rebar-concrete bond	
Peak bond stress (MPa)	9.5-11.1
Slip at start of peak bond stress (mm)	0.6
Slip at end of peak bond stress (mm)	0.6
Slip at start of residual bond stress (mm)	2.5
Residual bond stress (MPa)	1.43-1.67

For the steel reinforcing bars, the yield strength and ultimate tensile strength reported by Clark (1956) are used in the analysis. The initial elastic modulus, tensile strain at start of strain hardening and ultimate tensile strain were not reported and are assumed to be 200 GPa, 1% and 10%, respectively. For bond between rebar and concrete, the parameters for bond stress-slip relation are taken from CEB-FIP Model Code 1990. Since no stirrups were provided, the parameters corresponding to unconfined concrete are used in the analysis.

Each reinforced concrete beam is discretized into 13×112 concrete elements, 112 rebar elements along the same line, and 112 interface element also along the same line. The loading is applied in the form of prescribed displacements at the two loading points. In other words, the loading is applied under displacement control.

Results and Discussions

From the finite element analysis results, the crack locations and the variations of steel stress and bond-slip of the reinforcing bars of a typical beam 15-6-8-1 after the formation of the first three cracks are plotted in Figure 4. It is found that the first three cracks were formed at almost the same time. Moreover, the analytical spacing and pattern of the first three cracks agree very well with the spacing and pattern obtained experimentally by Clark (1956). The crack spacing and pattern have been obtained for the other beams, and are found to be in close agreement with the experimental results presented by Clark in all case. Hence, the proposed pseudo-discrete crack model is capable of reproducing the crack patterns of concrete beams.

From the variation of steel stresses plotted in Figure 4(a), it can be seen that the steel stress varies along the rebar with a certain peak value at every crack location. This is because right at a crack, the tension induced by flexure is taken solely by the reinforcing bars but between cracks, the tension induced by flexure is shared amongst the reinforcing bars and the uncracked concrete bonded thereto. Furthermore, from the variation of bond-slip along the reinforcement plotted in Figure 4(b), it is evident that the bond-slip changes direction at every crack. Basically, at the left side of a crack, the reinforcing bars slip towards the right (or the concrete slips towards to left), and vice versa. In other words, the reinforcing bars are always pulling the concretes at the two sides of the crack together so as to limit the crack width while the concretes at the two sides of the crack tend to slip away from the crack (Ng et al. 2010; Lam et al. 2010). In view of the abrupt change in direction of bond-slip at a crack, therefore, discrete shear springs were adopted to formulate the interface elements.

The photograph of experimentally obtained crack pattern reported by Clark (1956) and the analytical crack pattern at yielding of tension reinforcement of beam 15-6-8-1 are presented in Figures 5(a) and 5(b) respectively. It can be seen that the experimental and analytical crack patterns agree well with each other, albeit the presence of random factors in cracking behaviour to a certain extent. Minor non-symmetry in crack trajectories is noted for the analytical crack pattern. This might be due to numerical problems. As an amelioration measure, refinement of load increment steps during the execution of crack queuing algorithm is recommended for further research.

Figure 5 Crack pattern of beam 15-6-8-1 at yielding of tension reinforcement

For the reason that the maximum crack width governs the serviceability design, the maximum crack widths but not individual crack widths were reported by Clark (1956). Hereunder, the maximum crack widths obtained from finite element analyses are compared to the experimental results. The 19nos. beam specimens are divided into 4 groups generally according to their reinforcement ratios. The maximum crack width of each beam in these 4 groups is plotted against the steel stress at the widest crack in Figures 6 to 9.

Figure 6 plots the crack widths of beams with reinforcement ratio of 1.0 to 1.1%. In general, when the steel stress is lower than 150 MPa, the analysis overestimated the crack widths. While at higher steel stress level, the analytical crack widths resembled more closely the measured crack widths. Figure 7 plots the crack widths of beams with reinforcement ratio of 1.4 to 1.5%. At steel stress lower than 150 MPa, the analytical crack widths were generally slightly larger than the measured values but at higher steel stress levels, the analytical crack widths became in general slightly smaller than the measured values. Figure 8 plots the crack widths of beams with reinforcement ratio of 1.7 to 2.0%. The analytical crack widths generally agreed very well with the measured results. For beam 15-6-8-3, there was an abrupt increase of measured crack width when the steel stress increased beyond 240 MPa, such might be due to experimental errors. Finally, Figure 9 plots the crack widths of beams with reinforcement ratio of 2.5 to 2.6%. The analytical crack widths were initially slightly larger than the measured values, as the steel stress increased, the analytical crack widths became slightly smaller than the measured values.

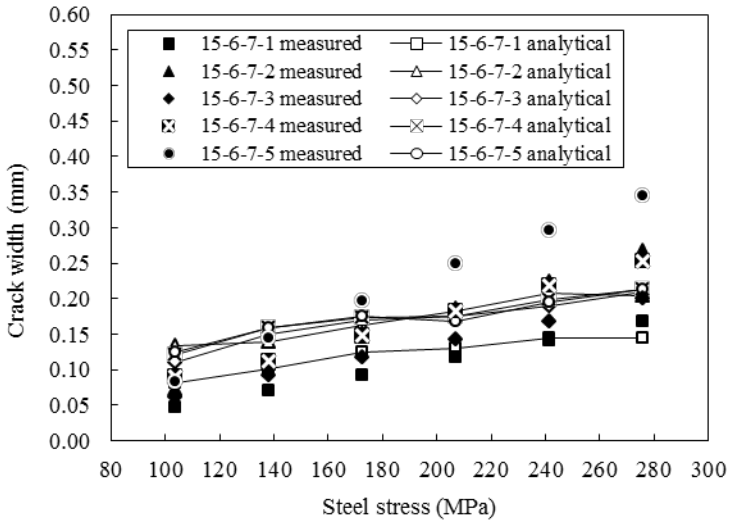

Figure 7 Analytical and measured crack width of beams 15-6-7-1, 15-6-7-2, 15-6-7-3, 15-6-7-4 and 15-6-7-5

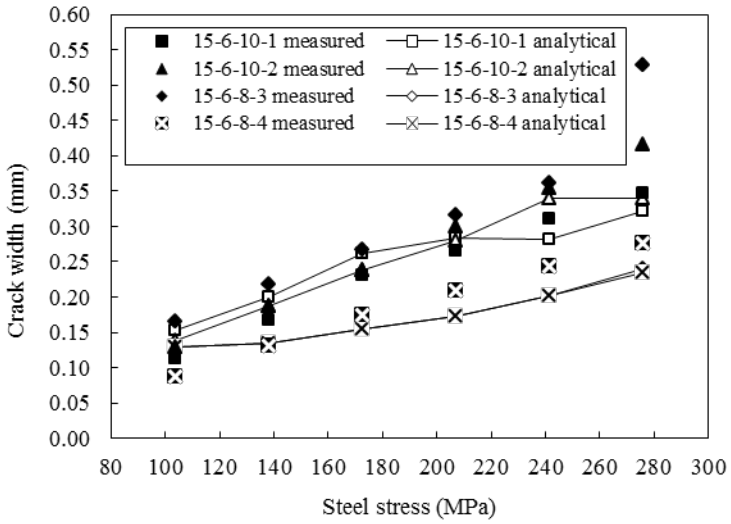

Figure 8 Analytical and measured crack width of beams 15-6-10-1, 15-6-10-2, 15-6-8-3 and 15-6-8-4

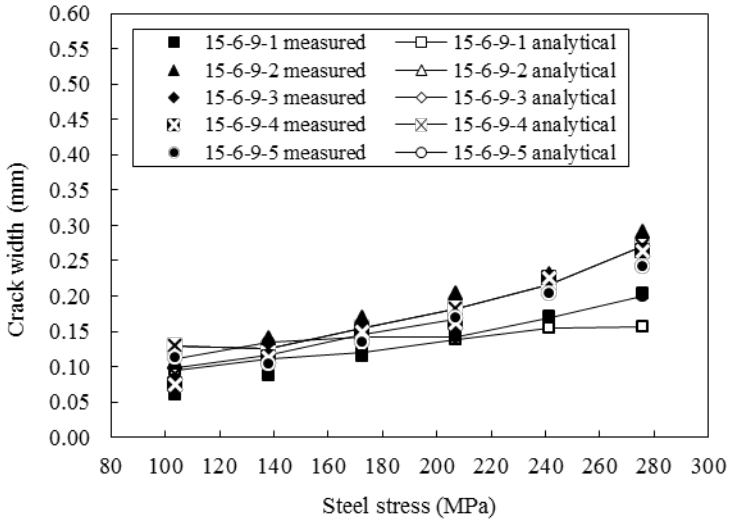

Figure 9 Analytical and measured crack width of beams 15-6-9-1, 15-6-9-2, 15-6-9-3, 15-6-9-4 and 15-6-9-5

The increase in maximum crack width and crack numbers with the steel stress level was studied. From the analytical results, it is observed that for a beam with relatively small number of bars or low reinforcement ratio, the crack number would increase more slowly but the crack width would increase more rapidly with the steel stress. Whereas for a beam with relatively large number of bars or high reinforcement ratio, the crack number would increase more rapidly but the crack width would increase more slowly with the steel stress. The pseudo-discrete crack model presented herein provides a useful tool for investigating the effects of various structural parameters on the cracking behaviour.

CONCLUSIONS

A new pseudo-discrete crack modelling technique for crack analysis of reinforced concrete members by the finite element method has been developed. Discrete rebar elements have been employed to model the reinforcing bars and interface elements incorporating discrete shear springs have been employed to model the bond between rebars and concrete. Specialised numerical techniques have been devised to overcome the difficulties in generating the discrete crack pattern and calculating the crack width: (1) a crack queuing algorithm of allowing only one crack to form at each iteration step so as to cater for the stress redistribution due to formation of new crack before allowing another crack to form; (2) a concrete cracking criterion incorporating both the tensile strength and fracture toughness of concrete in order to avoid mesh size dependence and unstable crack growth due to the stress concentration at crack tips; and (3) a simple method of calculating the crack width from the nodal displacements of the concrete element containing the crack. To verify the applicability and accuracy of the pseudo-discrete crack model, reinforced concrete beams tested in the literature have been analysed for cross-comparison. It has been demonstrated that the analytical crack pattern, numbers and spacing all agree closely with the experimental results.

ABSTRACT

The heat generation from chemical reactions of hardening concrete causes temperature rise and thermal expansion. When the concrete temperature eventually cools down to the ambient, thermal contraction would result. If the tendency of volume change and associated thermal movement are restrained, thermal stresses would be induced and this would lead to early thermal cracking. The issue of thermal cracking should be duly considered in mass concrete construction. Regarding concrete bridge construction, the piles, pile caps, bridge piers, crosshead girders, and bridge diaphragms are typical examples of mass concrete elements. A bridge project in real-life is selected for study in this paper, with focus on the segment-on-pier accommodating the diaphragm of prestressed concrete girder deck. The segment was instrumented to measure its actual early age temperature rise on site. Finite element simulation and analysis was conducted to evaluate the time variations of temperature distributions and thermal stresses induced in the bridge segment. The risk of thermal cracking can be indicated by the measurement and analysis results. The techniques employed in this study are useful for planning of temperature control measures in similar projects.

KEYWORDS

Bridge segment, finite element method, heat generation, temperature rise, thermal stress.

INTRODUCTION

When concrete is under curing and hardening, the exothermic chemical reactions of cementitious materials liberate heat and cause the temperature of concrete to rise at its early age. Due to variable distances within the concrete members to the boundary and variable boundary conditions, the temperature rise is in general non-uniform. Near to the surfaces, the temperature is closer to the ambient temperature, while within the interior of the concrete member, the temperature is higher. The non-uniformity of temperature distribution within mass concrete structures is particularly apparent (ACI Committee 207 2005). Subsequently, when the temperature of the concrete eventually drops to the ambient, the concrete tends to contract. If the tendency of volume change and the associated thermal movement are restrained, tensile stresses are induced in the concrete, and early age thermal cracking would result if the restrained tensile strain exceeds the tensile strain capacity of concrete.

The occurrence of thermal cracking would impair the structural integrity, serviceability, durability and appearance of concrete structures. Hence, it is imperative to prevent or mitigate the thermal cracking problem. Such necessitates the control of both the maximum temperature and temperature differential of concrete structures (Bamforth 2007). Depending on the characteristics of the project and the movement constraints, different measures such as pre-cooling of ingredients before concrete batching/placing, installing internal cooling pipes, mist spraying, optimizing concrete mix design, insulating/cooling the formwork and optimizing formwork striking time may be applied (Kwan et al. 2004; Bamforth 2007). Theoretically speaking, the choice of measures or combinations of measures should be based on proper modelling and analysis of the thermal regime of structures and its time-variation (Springenschmid 1995). These are usually performed by means of finite element method (De Schutter 2002; Du et al. 2011).

The mitigation of thermal cracking and design of temperature control measures for massive concrete structures should be duly considered. In the construction of concrete bridges, the piles, pile caps, bridge piers, crosshead girders and diaphragms are examples of massive concrete members to which special attention on thermal cracking control should be paid. Based on a prestressed concrete box girder bridge project in real life, this paper reports the on-site monitoring of early age temperature rise and finite element analysis of temperature distributions and thermal stresses induced in a segment-on-pier accommodating the diaphragm of prestressed concrete girder deck. Details of the bridge and the segment-on-pier under investigation will be presented in the following sections.

BACKGROUND INFORMATION OF BRIDGE AND SEGMENT-ON-PIER

Structural Form of Bridge

The bridge chosen for study is Jinghe Bridge in Mainland China. Jinghe Bridge is located in Qingyang, Gansu Province. It forms part of the Zhangfeng Expressway in northwest China. The total length of bridge is 1,726 m and the main spans are arranged in lengths of (87 + 162×5 + 87) m, as shown in Figure 1. The bridge deck is haunched over each span for improved structural efficiency and aesthetics. Construction started in 2009. The bridge piers and the segment-on-pier for the main spans were cast in-situ components, upon which continuous prestressed concrete box girder decks with variable depth were constructed by balanced cantilever method (Du et al. 2011).

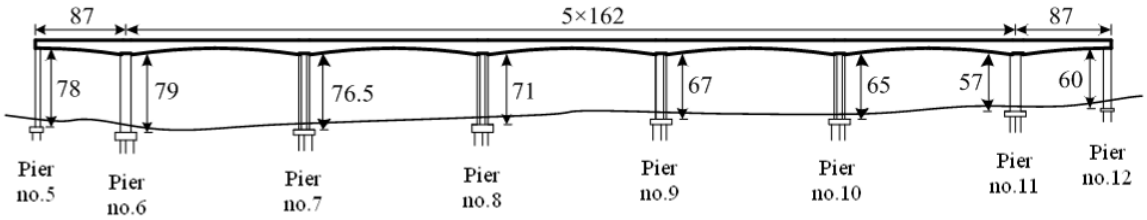

Figure 1 Main spans of Jinghe Bridge (dimensions in m)

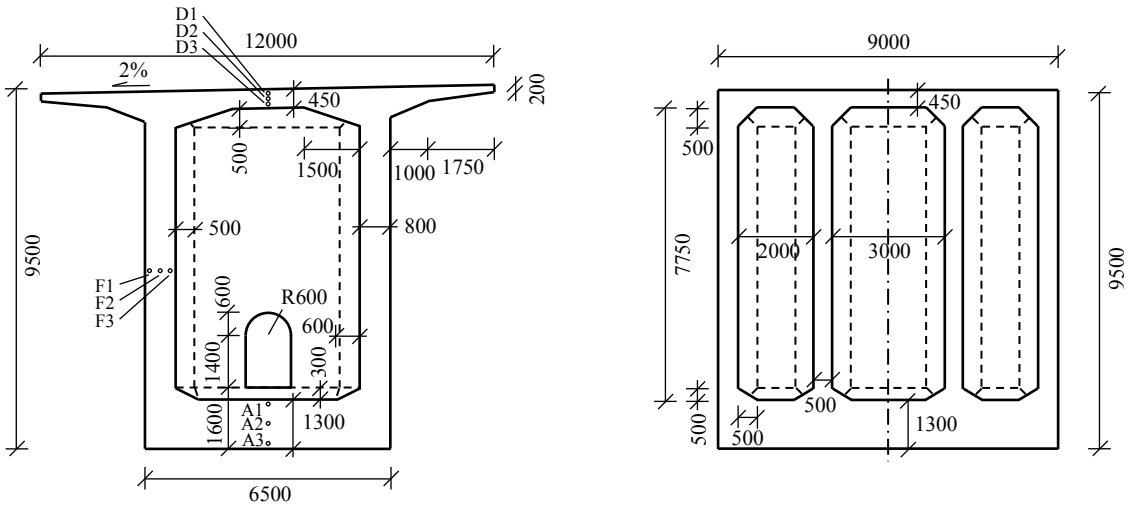
Structure and Materials of Segment-on-Pier

The segments-on-pier over bridge piers nos. 7 to 10 are selected for study. The 4 nos. segments-on-pier have common geometry as depicted in the typical cross section and elevation in Figure 2. Each segment has a transverse width of 6.5 m at the pier head and 12.0 m at the top flange. The structural height of segment is 9.5 m and the length in longitudinal direction is 9.0 m, along which the segment is provided with three cellular voids. The voids are separated by 0.5 m thick solid diaphragms each with a horseshoe shaped opening of 1.2 m in width and 2.0 m in height at the centre. The cellular voids are of 4.9 m width in transverse direction and 7.75 m in height. The middle cellular void directly above the axis of bridge pier has length of 3.0 m in the longitudinal direction and the cellular voids at its two sides both have length of 2.0 m.

The bottom flange of the segment-on-pier has thickness of 1.3 m. The webs are vertical and have thickness of 0.8 m. The top flange is tapered with gradual reduction in thickness away from the root of webs. Its thickness at the centreline of the girder section is 0.45 m. The surface level of top flange follows a transverse gradient of 2%. To reduce stress concentrations, chamfers and splays are provided at corners and at changes in sections.



(a) Typical cross section (b) Typical elevation

Figure 2 Geometry of segment-on-pier (dimensions in mm)

The segment-on-pier was cast of C55 concrete. Three mix proportions as tabulated in Table 1 had been proposed and they are hereunder designated as Mix 1, Mix 2 and Mix 3. Mix 1 is a cement concrete mix, Mixes 2 and 3 contain pulverized fuel ash (PFA) in the binder at a replacement rate of approximately 17% by mass, with the aim to reduce the cement content and hence the heat of hydration (Ng et al., 2011; Ng and Kwan 2012). The water to binder (W/B) ratio by mass of Mixes 1, 2 and 3 are 0.33, 0.25 and 0.26 respectively, and the paste volume of all three mixes is about 27%. Plywood of 20 mm thickness was adopted for external formwork for concrete casting, while 3 mm thick prefabricated steel formwork was used internally. The convection heat transfer coefficients of the wooden and steel formwork were evaluated to be 3.98 and 17.26 $W/m^2/^oC$ respectively.

Table 1 Concrete mix proportions

	Mix 1	Mix 2	Mix 3
Water content (kg/m^3)	163	135	133
Cement content (kg/m^3)	494	451	423
PFA content (kg/m^3)	0	92	86
Fine aggregate (kg/m^3)	681	663	711
Coarse aggregate (kg/m^3)	1112	1118	1100
Admixture (kg/m^3)	5.93	5.97	5.60

MEASUREMENT OF HYDRATION TEMPERATURE RISE

To measure the temperature rise of the segment-on-pier after casting, temperature sensors were embedded at the segment cross-section intersecting the centre of pier. A total of 9 sensors were employed, with 3 sensors at middle of top flange, mid-height of one web, and middle of bottom flange, respectively. The sensors were Type RT resistance temperature detectors designed for embedment in concrete structures. The measurement range, resolution and accuracy of the sensors were -40ºC to 150ºC, ±0.1ºC and ±0.3ºC, respectively. The numbering of sensors is shown in Figure 2(a). At the top flange, 3 sensors, designated as D1, D2 and D3 were embedded along the centreline of section near the upper surface, middle of thickness, and near the lower surface, respectively. At the web, 3 sensors, designated as F1, F2 and F3 were embedded at the mid-height of segment near the external surface, middle of thickness, and near the internal surface, respectively. At the bottom flange, 3 sensors, designated as A1, A2 and A3 were embedded along the centreline of section near the upper surface, middle of thickness, and near the lower surface, respectively. The measurement of temperature enabled comparison with established acceptable limits of peak temperature and thermal gradient, which are usually taken as 70ºC (MTRC 2009) and 20ºC/m (MTRC 2009; Architectural Services Department 2011), respectively.

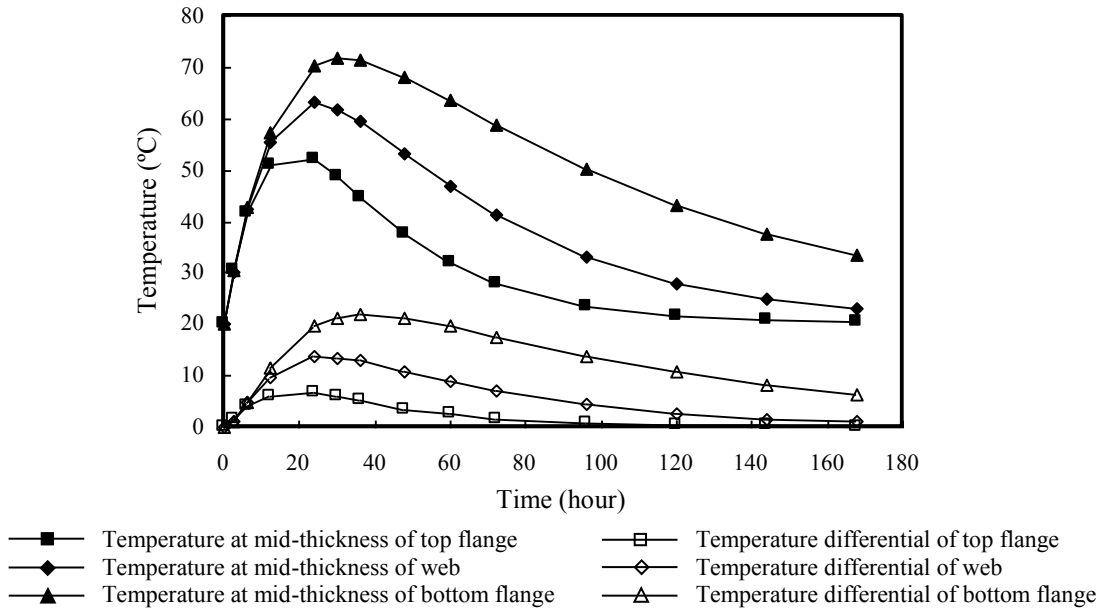


Figure 3 Variation of measured temperature with time

The temperature rise of the bridge pier was monitored continuously over the first 7 days after casting. The ambient temperature was also measured. Throughout the casting and curing of segment, the ambient temperature varied between 15ºC and 25ºC with a mean temperature of 20ºC. Figure 3 displays the variation of measured temperature with time. It can be seen that the peak temperature of concrete was reached generally at 24 to 30 hours after casting. The maximum temperatures of the top flange, web, and bottom flange were 52.3ºC (attained at 24 hours after casting), 63.3ºC (attained at 25 hours after casting), and 71.7 ºC (attained at 30 hours after casting), respectively. Though the first two values were smaller than the 70ºC limit, the last value was larger than the 70ºC limit and might be incurring excessive thermal movement (Bamforth 2007). The maximum temperature differentials across the mid-thickness and near-surface sensors at the top flange, web, and bottom flange were respectively 6.6ºC (attained at 25 hours after casting), 13.7ºC (attained at 26 hours after casting), and 21.9ºC (attained at 36 hours after casting). It is noted that the time to attain the maximum temperature differentials is generally longer than the time to attain the peak temperature. Dividing the temperature differentials by half the concrete thicknesses, the corresponding thermal gradients are 29.3ºC/m, 34.3ºC/m and 33.7ºC/m, which are all larger than the 20ºC/m limit and might cause excessive differential thermal stresses (Bamforth 2007). Therefore, the vulnerability of the segments-on-pier to thermal cracking should be studied in detail and duly mitigated.

FINITE ELEMENT ANALYSIS OF TEMPERATURE EFFECTS

Numerical analysis was conducted by finite element method to compute the temperature and stress distributions using the commercial software Midas-FEA. By virtue of symmetry, one quarter of the segment-on-pier was modelled by 6,572 four-node tetrahedron finite elements. In the following discussions, *x*-direction is the longitudinal direction along the span of bridge deck, *y*-direction is the transverse direction and *z*-direction is the vertical direction. Figure 4 depicts the finite element model. The tension-positive sign convention is adopted. The properties of concrete elements used in analysis are presented in Table 2.

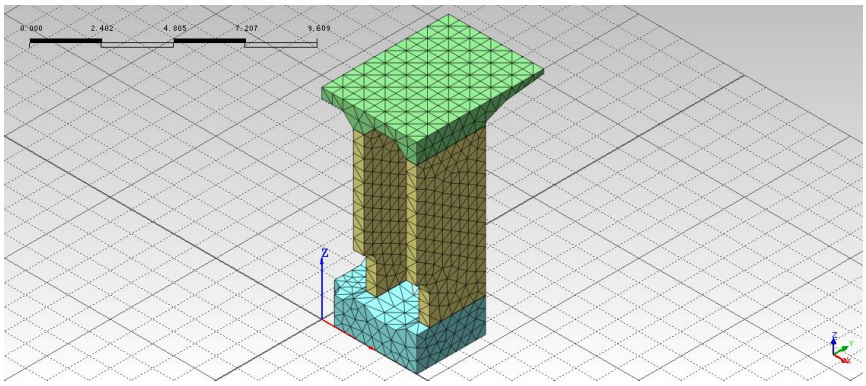

Figure 4 Finite element model of segment-on-pier

Table 2 Properties of concrete elements

Elastic modulus at age of 28 days (GPa)	35.5
Poisson's ratio	0.2
Tensile strength at age of 28 days (MPa)	2.74
Coefficient of thermal expansion (με/ºC)	10
Specific heat capacity (J/kg/ºC)	954
Thermal conductivity (W/m/ºC)	2.92
Convection heat transfer coefficient ($W/m^2/ºC$)	18.72
Density (kg/m^3)	2460

Computation of Temperature Distribution

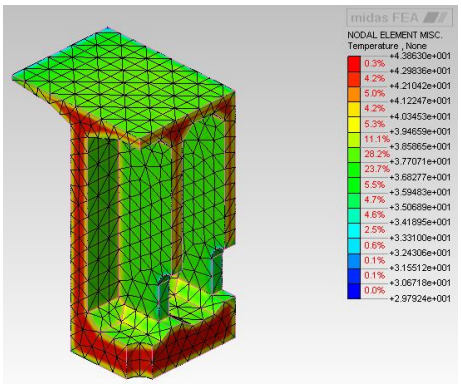
The analysis took into account the actual construction sequence. The ambient temperature was assumed to be constant at 20ºC. Since the segment-on-pier is situated on the bridge pier, the presence of the bridge pier was simulated in the boundary conditions. To model the temperature rise during concrete hardening, step-by-step integration in the time domain was performed with the heat generation of concrete described by the time-varying function $H(t)$, which is given in the following equation proposed by Zhu (1998):

$$H(t) = H_o \cdot \left[1 - \exp\left(-at^b\right)\right] \quad (1)$$

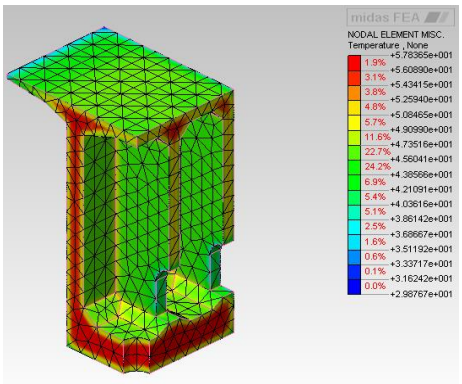
where H_o is the ultimate heat generation of concrete evaluated as 145.4 MJ/m^3, a and b are coefficients dependent on the concrete properties and are taken respectively as 0.69 and 0.56, and t is the age expressed in days. The term inside the square bracket on the right hand side of Equation (1) is the maturity function of concrete. The adiabatic temperature rise of concrete at age t, $T_A(t)$, is estimated by Zhu (1998):

$$T_A(t) = \frac{H(t) \cdot (C + k_e P)}{\psi \rho} \quad (2)$$

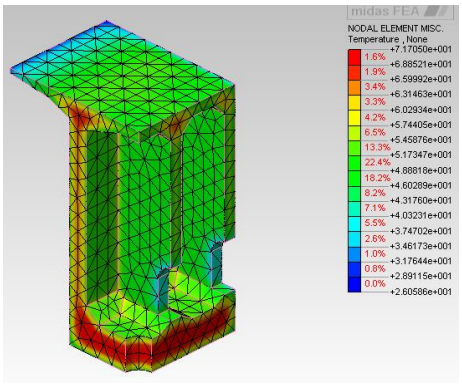
where C (kg/m^3) is the cement content, P (kg/m^3) is the PFA content, k_e is the cement equivalence factor of PFA, ψ (J/kg/ºC) is the specific heat capacity of concrete, and ρ (kg/m^3) is the density of concrete. When the heat generation of concrete is at its ultimate, the adiabatic temperature rise was computed as 65.9ºC.



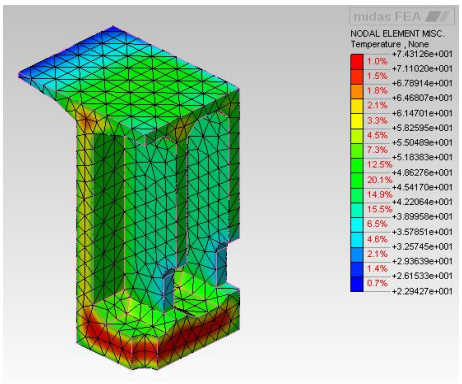
(a) 6 hours after concrete casting



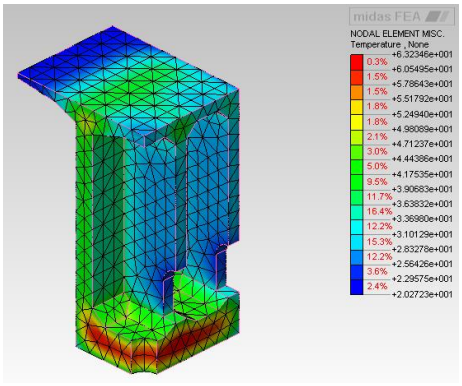
(b) 12 hours after concrete casting



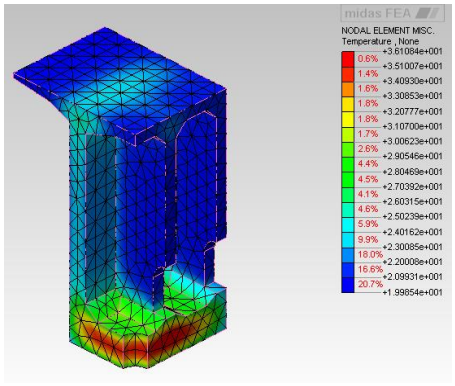
(c) 24 hours after concrete casting



(d) 36 hours after concrete casting



(e) 72 hours after concrete casting



(f) 168 hours after concrete casting

Figure 5 Computed temperature distributions

The temperature distributions within the segment-on-pier at different time after concrete casting were determined from finite element analysis and are depicted in Figure 5. It is observed that the difference between the measured and computed temperature values is generally less than 2ºC, demonstrating the reliability of the finite element analysis. Nonetheless, measures such as increasing the fineness of the finite element mesh are advisable to further improve the accuracy of analysis.

Evaluation of Thermal Stresses and Cracking

During hardening, the elastic modulus of concrete increases, as described by Equation (3) in accordance with CEB-FIP Model Code 1990 (Comite Euro-International du Beton 1993):

$$E_c(t) = E_{co} \cdot \exp\left[0.5s\left(1 - \sqrt{28/t}\right)\right] \quad (3)$$

where E_{co} is the elastic modulus of concrete at age of 28 days, s is a coefficient depending on the type of cement (taken as 0.25 for ordinary Portland cement), and t is expressed in days.

The stresses in all elements at each time step were computed. Figure 6 plots the element stresses in x-, y- and z-directions at the instrumented locations. It is evident that during concrete curing, generally higher tensile stresses would develop near the external and internal concrete surfaces, whereas concrete around mid-thickness would remain compressive or subject to a small tensile stress. The thermal stresses induced in the bottom flange are having larger magnitudes than those in the top flange and web. This indicates that the magnitude of thermal stresses increases with the thickness of concrete. The analysis results revealed that the peak tensile stresses occurred approximately at the same time when the temperature differential across the concrete thickness was the largest. The computed maximum tensile stress was 1.71 MPa, occurring at the upper surface of the bottom flange at 36 hours after casting. When the concrete was cooling down in subsequence, stresses of the opposite signs would gradually develop.

To assess the vulnerability of the segment-on-pier to thermal cracking, the computed tensile stresses are checked against the tensile strength of concrete. The concrete tensile strength at different time is evaluated per Equation (4) in accordance with Model Code 1990 (Comite Euro-International du Beton 1993):

$$f_t(t) = f_{to} \cdot \exp\left[s\left(1 - \sqrt{28/t}\right)\right] \quad (4)$$

where f_{to} is the tensile strength of concrete at age of 28 days. The development of tensile strength of concrete with time is juxtaposed in Figure 6. It is seen that the computed tensile stresses in both x- and y-directions are higher than the tensile strength over certain time intervals, especially during the first 2 days after concrete casting. Therefore, the tensile strain capacity of concrete would possibly be exceeded and the segment-on-pier might exhibit cracking if additional temperature control measures are not provided.

EFFECTIVENESS OF THERMAL CRACKING CONTROL MEASURES

Use of PFA Concrete Mixes

To examine the effect on using PFA concrete mixes, finite element analyses were conducted for the scenarios of adopting Mixes 1, 2 and 3 for casting the segment-on-pier for comparison. Based on Equation (2), it is estimated that the adiabatic temperature rise of these 3 mixes are respectively 65.9ºC, 61.6ºC and 58.5ºC. The computed peak temperature, maximum temperature differential, and maximum tensile stress with respect to each of the 3 concrete mixes are tabulated in Table 3.

From Table 3, it is evident that by incorporation of PFA in the concrete mix to reduce the cement content, all the peak temperature, maximum temperature differential, and maximum tensile stress are reduced. Amongst the 3 concrete mixes, Mix 3 which has the lowest cement content is the most effective. The associated reductions in the peak temperature, maximum temperature differential, and maximum tensile stress are greatest at the bottom flange and are respectively 6.13ºC, 3.41ºC, and 0.18 MPa. It should be noted that though the maximum temperature is reduced to less than 70ºC, the thermal gradient is still as high as 28.4ºC/m and the tensile stress is still exceeding the tensile strength of concrete at the corresponding early age. Therefore, further optimisation of the concrete mix to lower the heat generation such as by incorporation of ground granulated blastfurnace slag and limestone fines and/or combining with other thermal cracking control measures are recommended.

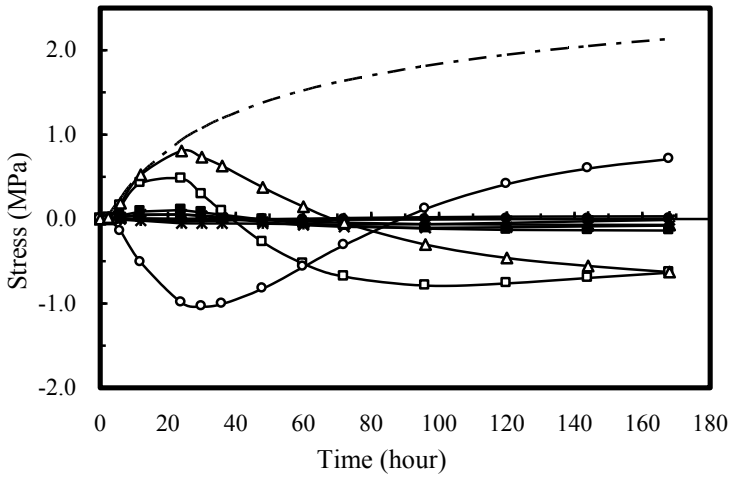
(b) Variations of stresses in *y*-direction



(c) Variations of stresses in *z*-direction

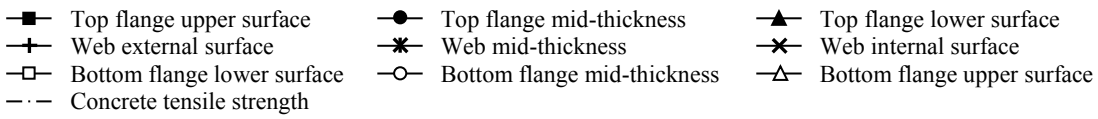


Figure 6 Variations of stresses with time

Table 3 Effects of different concrete mixes

	Mix 1			Mix 2			Mix 3		
Location	Top flange	Web	Bottom flange	Top flange	Web	Bottom flange	Top flange	Web	Bottom flange
Peak temperature (ºC)	52.27	63.25	71.67	50.17	61.86	68.83	48.52	58.75	65.54
Max. temperature differential (ºC)	6.58	13.72	21.90	5.72	12.03	19.32	4.81	11.12	18.49
Max. tensile stress (MPa)	1.07	1.00	1.71	0.99	0.97	1.59	0.98	0.94	1.53

Concrete Casting in Lifts

In view of the congested arrangement of prestressed tendon ducts and reinforcing bars inside the segment (this also precludes the embedment of internal cooling pipes), as well as the large quantity of concrete placement and difficulties in concreting, casting of the segment-on-pier in separate lifts was considered from constructability and from quality control viewpoints. Alternative casting schedules were simulated by finite element analyses before putting into practice. The segment with total height of 9.5 m is divided into 2 lifts, the first lift being 4.5 m in height and the second lift being 5.0 m in height. The time interval between the first and second concrete casting is 6 days.

By adopting casting in lifts, the computed time variations of temperature at mid-thickness of top flange, web and bottom flange are plotted in Figure 7. In the same figure, the computed temperature differentials at the top flange, web and bottom flange are plotted. Temperature distributions within the cast segment portion at different time were obtained from step-by-step time integration of the finite element analysis. The temperature distribution within the partially completed segment-on-pier at 24 hours after casting the first lift and the temperature distribution within the completed segment-on-pier at 24 hours after casting the second lift as determined from the analysis are depicted in Figure 8.

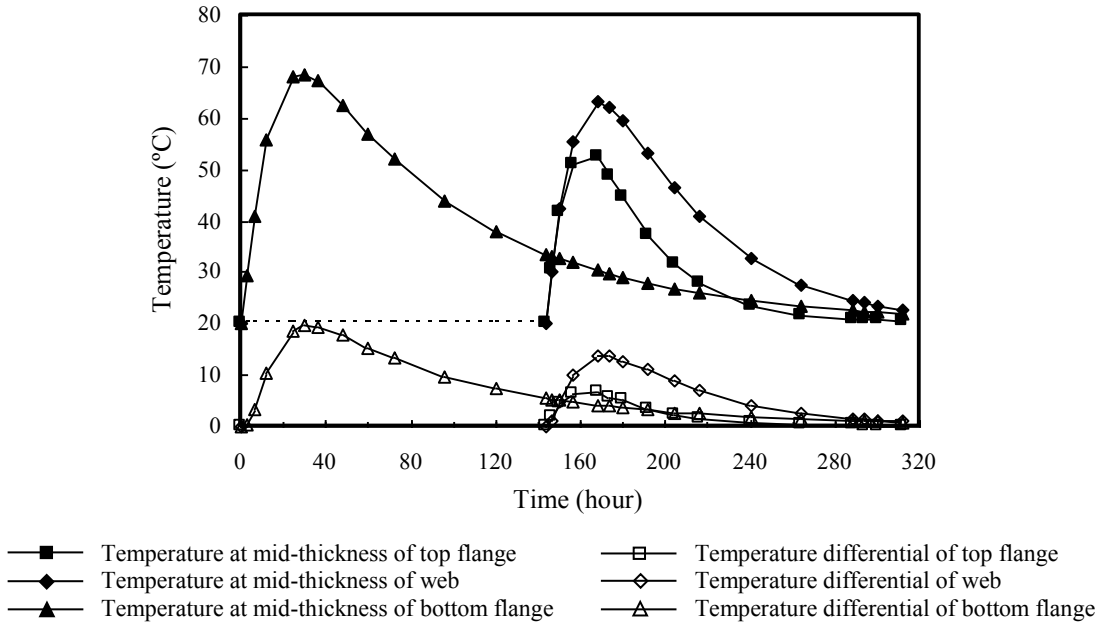

Figure 7 Time variation of temperature with casting in lifts

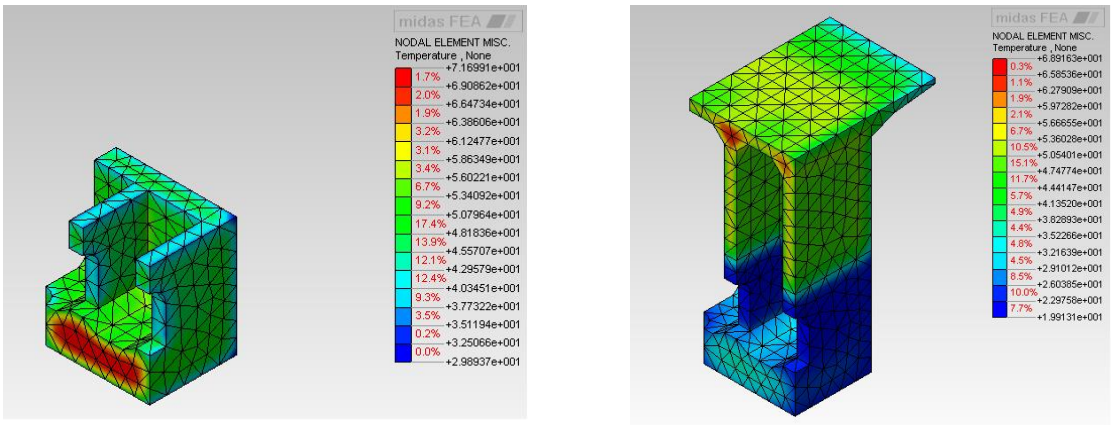
From the analysis results, the peak temperatures at the mid-thickness of top flange, web and bottom flange are respectively 52.3ºC, 63.3ºC and 68.6ºC, and the maximum temperature differentials at top flange, web and bottom flange are respectively 6.6ºC, 13.7ºC and 19.6ºC. The computed peak temperature, maximum temperature differential, and maximum tensile stress with respect to each casting schedule are tabulated in Table 4. It can be seen that casting in 2 lifts does not have significant effect in mitigating the temperature rises and

thermal stresses at the top flange and web. Nevertheless, the mitigation effect is more significant at the bottom flange. The peak temperature at mid-thickness of bottom flange is decreased by 3.03ºC, and the maximum temperature differential at bottom flange is decreased by 2.31ºC. This is mainly due to the increased exposed surface area of the bottom flange (in the absence of upper portion of the segment-on-pier) for more effective heat dissipation. On the other hand, the boundary conditions of the upper portion of segment after being cast are not significantly altered. With the reduction in maximum temperature differential at the bottom flange, the maximum tensile stress thereat is also reduced. It should be noted that by adopting a 2-lift casting schedule, though the maximum temperature is reduced to lower than 70ºC, the thermal gradient is as high as 30.2ºC/m and the tensile stress is exceeding the tensile strength of concrete at the same age. It is envisaged that further increasing the number of lifts would not bring about major improvements, but would be highly undesirable from practical viewpoint. Therefore, the use of other thermal cracking control measures with or without combining the 2-lift casting schedule is more advisable.



(a) 24 hours after first concrete casting (b) 24 hours after second concrete casting

Figure 8 Computed temperature distributions with casting in lifts

CONCLUDING REMARKS

The issues of hydration temperature rise and early thermal cracking should be duly considered in mass concrete construction, including mass concrete elements in bridges such as piles, pile caps, bridge piers, crosshead girders, and bridge diaphragms. The early age temperature rise and thermal stresses induced in the typical segment-on-pier accommodating the diaphragm of prestressed concrete box girder deck of Jinghe Bridge in Gansu Province, Mainland China have been investigated, with the aim to control and mitigate the risk of early thermal cracking. The segment-on-pier has been instrumented with embedded sensors for on-site monitoring of temperature rise. Besides, numerical analysis by finite element method has been conducted to evaluate the temperature distributions and thermal stresses induced in the segment-on-pier at different time. It has been found that the peak temperature at the bottom flange and the maximum thermal gradients caused by temperature differentials of the segment would be excessive, and the computed maximum tensile stresses at the bottom flange would exceed the tensile strength of concrete, indicating the vulnerability of the segment to thermal cracking problem. Temperature control measures should be applied during construction to mitigate the risk of thermal cracking. The effectiveness of adopting concrete mixes containing pulverized fuel ash to replace part of the cement as well as casting of concrete in lifts have been evaluated. With reference to the computation results

revealed from the current study, it is recommended to combine different thermal cracking control measures and optimise the mitigation measures with the aid of finite element analysis as demonstrated in this paper.

ABSTRACT

Concrete-filled-steel-tube (CFST) columns are becoming increasingly popular owing to the superior behaviour contributed by the composite action. Previous experimental and theoretical studies have proved this composite action can be further improved by providing external confinement in the form of steel rings, tie bars, spirals or jackets. A theoretical model developed by the authors previously based on (1) an accurate hoop strain equation; (2) an actively confined concrete model; (3) a three-dimensional steel model; (4) Interaction of core concrete, steel tube and external confinement was adopted in this study to conduct a parametric study, which was aimed at investigating the effects of material strengths, geometric properties and external confinement (steel jackets) on the uni-axial behaviour of CFST columns. From the results in parametric study, it is shown that the maximum strength of CFST columns increases as the material strengths increase, or the diameter-to-thickness ratio of steel tube decreases. Moreover, it is also concluded that adding external confinement is more effective in improving the uni-axial behaviour of CFST columns than solely increasing the wall thickness of steel tube.

KEYWORDS

Concrete-filled-steel-tube, external confinement, parametric study, theoretical model.

INTRODUCTION

Concrete-filled-steel-tube (CFST) column, which consists of a hollow-steel-tube column in-filled with concrete, is widely adopted in many structures nowadays attributed to the superior behaviour by the composite action. In CFST columns, due to the supporting effect provided by the core concrete, the inward buckling of steel tube can be prevented, resulting in higher buckling resistance. Moreover, the steel tube can act as both longitudinal and transverse reinforcement, which provides both axial resistance and confining stress. The uniform confining stress can improve the strength and ductility of core concrete much more effectively than stirrups in traditional reinforced concrete columns. Besides, it saves construction materials and shortens construction cycle time because the steel tube can serve as permanent formwork. Despite the above advantages, during the initial elastic stage under compression, the confining stress may become negative (i.e. hoop compressive stress) due to the different dilation of steel tube and concrete [1]. This will reduce the strength, elastic stiffness and ductility of CFST columns [1, 2]. The confining stress will be activated only when the micro-cracking of concrete starts to form and the expansion of concrete exceeds that of steel tube. On the other hand, degradation of confining stress, strength and ductility will occur beyond the elastic stage due to the inelastic outward buckling of steel tube.

Previous experimental [1-5] and theoretical [6, 7] studies have proved that the deficiencies can be conquered and the potential of composite action can be fully utilized by providing various types of external confinement for circular CFST columns: rings [2, 3], ties [1], spirals [4] and steel jackets [5]. In confined circular CFST columns, attributable to the additional confining stress provided by additional confinement, the steel–concrete interface bonding has been improved and the inelastic outward buckling of steel tube has been prevented or at least delayed, resulting in superior uni-axial behaviour of CFST columns. However, the effects of steel tube yield strength (σ_{sy}), concrete cylinder compressive strength (f_c'), steel ratio and external confinement on the uni-axial behaviour of CFST columns were not clearly interpreted by the previous studies. For better understanding, an accurate theoretical model proposed by the authors [6] based on (1) an accurate hoop strain equation; (2) an actively confined concrete model by Attard and Setunge [8]; (3) a comprehensive three-dimensional steel model by Generalized Hooke's Law at the elastic stage and Prandtl-Reuss theory at the post-elastic stage; (4) Interaction of core concrete, steel tube and external confinement by free-body diagram was employed herein to perform a parametric study. Based on the numerical results obtained from the parametric study in this paper, the effects of σ_{sy}, f_c' and external confinement have been investigated much more clearly and quantitatively.

Besides, it is concluded that adding external confinement is more effective in improving the uni-axial behaviour of CFST columns than solely increasing the wall thickness of steel tube.

THEORETICAL MODEL

A theoretical model developed by the authors previously [6] was adopted to predict the uni-axial behaviour of the tested specimens in this paper. The model was verified with a large database, which included 422 test results from the authors' and other researchers' previous studies. Thus this model was proved to be accurate within a very wide range of different parameters: σ_{sy} varied from 186 to 853 MPa; f_c' varied from 15 to 125 MPa; The D_o/t ratio was from 15.9 to 220.9. This model also predicted the uni-axial behaviour of CFST columns with external confinement well, whilst the confinement schemes included rings, spirals, ties and steel jackets; the spacing of these confinement varied and the diameter of the confinement also varied within a wide range. The model consists of four main components: (1) an accurate hoop strain equation; (2) Constitutive model of confined concrete modified from Attard and Setunge [8] actively confined concrete model; (3) Full range constitutive model of steel tube under complicated stress-state using generalized Hooke's Law and Prandtl-Reuss theory; (4) Interaction of steel jackets, steel tube and external confinement by free-body diagram. Since the details of the proposed model have been introduced at the previous research [6], only key issues would present in this study.

Sign Convention and Perfect Bond Assumption

In this paper, compressive stress and strain are taken as positive; and vice versa. The bonding between the concrete and steel tube is assumed to be intact and thus the following equations are given:

$$\varepsilon_{cz} = \varepsilon_{sz} = \varepsilon_z \tag{1}$$

$$\varepsilon_{c\theta} = \varepsilon_{s\theta} = \varepsilon_\theta \tag{2}$$

where ε_{cz} and ε_{sz} are the axial strains of the concrete and steel tube; $\varepsilon_{c\theta}$ and $\varepsilon_{s\theta}$ are the hoop strains of the concrete and steel tube; ε_z and ε_θ are the axial and hoop strains of the CFST column, respectively.

Three Dimensional Stress-Strain Relationship of Steel Tube

For the CFST columns with very thin-walled steel tube, it is believed that local buckling would occur before yielding of steel tube. In this case, the following equation [9] is adopted to calculate the elastic buckling stress of steel tube, $\sigma_{sy,b}$:

$$\frac{D_o}{t} \le 90\sqrt{3}\left(\frac{235}{\sigma_{sy,b}}\right) \approx \frac{36632.9}{\sigma_{sy,b}} \tag{3}$$

$$\sigma_{syc} \le \sigma_{sy,b} \le \sigma_{syt} \tag{4}$$

where D_o and t are the outer diameter and thickness of steel tube, respectively; σ_{syc} and σ_{syt} are the yield stresses of steel tube compression test and steel tensile coupon test, respectively.

The three-dimensional stress-strain relationship of steel tube can be evaluated by the hoop-axial strain relationships with the aid of Prandtl-Reuss theory. In this study, to be conservative, no strain-hardening of steel tube is considered. Therefore, the uni-axial stress-strain curve of steel-tube in compression can be assumed as linearly-elastic-perfectly-plastic. In the initial elastic stage, according to generalized Hooke's Law (in incremental form):

$$\begin{Bmatrix} d\sigma_{sz}^i \\ d\sigma_{s\theta}^i \\ d\sigma_{sr}^i \end{Bmatrix} = \begin{bmatrix} K+\frac{4}{3}G & K-\frac{2}{3}G & K-\frac{2}{3}G \\ K-\frac{2}{3}G & K+\frac{4}{3}G & K-\frac{2}{3}G \\ K-\frac{2}{3}G & K-\frac{2}{3}G & K+\frac{4}{3}G \end{bmatrix} \begin{Bmatrix} d\varepsilon_{sz}^i \\ d\varepsilon_{s\theta}^i \\ d\varepsilon_{sr}^i \end{Bmatrix} \tag{5}$$

$$K = \frac{E_s}{3(1-\nu_s)} \tag{6}$$

$$G = \frac{E_s}{2(1+\nu_s)} \tag{7}$$

During the plastic stage, the famous Prandtl-Reuss equations are adopted:

$$\begin{Bmatrix} d\sigma_{sz}^i \\ d\sigma_{s\theta}^i \\ d\sigma_{sr}^i \end{Bmatrix} = \begin{bmatrix} K+\frac{4}{3}G - \omega S_z^2 & K-\frac{2}{3}G-\omega S_z S_\theta & K-\frac{2}{3}G-\omega S_z S_r \\ K-\frac{2}{3}G-\omega S_z S_\theta & K+\frac{4}{3}G-\omega S_\theta^2 & K-\frac{2}{3}G-\omega S_\theta S_r \\ K-\frac{2}{3}G-\omega S_z S_r & K-\frac{2}{3}G-\omega S_\theta S_r & K+\frac{4}{3}G-\omega S_r^2 \end{bmatrix} \begin{Bmatrix} d\varepsilon_{sz}^i \\ d\varepsilon_{s\theta}^i \\ d\varepsilon_{sr}^i \end{Bmatrix} \tag{8}$$

For perfectly-plastic material:

$$\omega = \frac{3G}{\sigma_{sy}^2} \tag{9}$$

$$S_z = \frac{1}{3}\left(2\sigma_{sz}^{i-1} - \sigma_{s\theta}^{i-1} - \sigma_{sr}^{i-1}\right) \tag{10}$$

$$S_\theta = \frac{1}{3}\left(2\sigma_{s\theta}^{i-1} - \sigma_{sz}^{i-1} - \sigma_{sr}^{i-1}\right) \tag{11}$$

$$S_z = \frac{1}{3}\left(2\sigma_{sr}^{i-1} - \sigma_{sz}^{i-1} - \sigma_{s\theta}^{i-1}\right) \tag{12}$$

where σ_{sz} and σ_{sr} refer to the axial and radial stresses of steel tube; K and G are bulk and shear moduli of steel tube; ν_s is the Poisson's ratio of steel tube taken as 0.3 in this study; ε_{sr} refers to the radial strain of steel tube; ω is the hardening parameter; S_z, S_θ and S_r refer to the deviatoric stresses in axial, hoop and radial direction. Lastly, i is the present stress or strain increment number. The yield surface of steel tube is determined by Von Mises yield criterion:

$$\sigma_{sy} = \frac{\sqrt{2}}{2}\sqrt{(\sigma_{sz}-\sigma_{s\theta})^2 + (\sigma_{sz}-\sigma_{sr})^2 + (\sigma_{s\theta}-\sigma_{sr})^2} \tag{13}$$

The yield stress of steel tube σ_{sy} is equal to $\sigma_{sy,b}$ if the local buckling occurred before yielding of steel tube.
The radial stress σ_{sr} is equal to the total confining stress, f_r:

$$\sigma_{sr} = f_r \tag{14}$$

Thus, the three-dimensional stress-strain history of steel tube can be evaluated using Eqs. (3)-(14).

The Constitutive Model of Confined Concrete

The following equation [6] is proposed to describe the relationship among ε_θ, ε_z, f_r and concrete cylinder strength f_c':

$$\varepsilon_z = LS\left(\frac{f_c'}{30}\right)^m \left\{ \varepsilon_{co}\left[1+0.75\left(\frac{-\varepsilon_\theta}{\varepsilon_{co}}\right)\right]^{0.7} - \varepsilon_{co}\exp\left[7\left(\frac{\varepsilon_\theta}{\varepsilon_{co}}\right)\right] + 0.07(-\varepsilon_\theta)^{0.7}\left[1+26.8\left(\frac{f_r}{f_c'}\right)\right] \right\} \tag{15}$$

$$LS = \frac{LS_2 - LS_1}{H-d}(S-d) + LS_1 \tag{16}$$

$$LS_1 = 0.6650 \tag{17}$$

$$LS_2 = 0.6466 \tag{18}$$

$$m = \begin{cases} 0 & f_c' \le 30 \\ -0.05 & f_c' > 30 \end{cases} \tag{19}$$

$$\varepsilon_{co} = \frac{4.11(f_c')^{0.75}}{4370(f_c')^{0.52}} = 9.405\times10^{-4}(f_c')^{0.23} \tag{20}$$

where LS is the parameter reflecting the effect of external confinement, from $LS_2 = 0.6466$ for unconfined CFST columns to $LS_1 = 0.6650$ for confined CFST columns with the centre-to-centre spacing of external confinement (S) equal to the width of external confinement; H is the total height of the specimen; m is the parameter considering the effect of concrete strength; ε_{co} is the strain corresponding to the unconfined peak concrete strength.

The axial stress-strain relationship of confined concrete is given by Attard and Setunge [8], which has been proven to be applicable to a broad range of concrete strength from 20 to 130 MPa:

$$\frac{f_{cc}}{f_{ccp}} = \frac{A(\varepsilon_z/\varepsilon_{cc}) + B(\varepsilon_z/\varepsilon_{cc})^2}{1 + (A-2)(\varepsilon_z/\varepsilon_{cc}) + (B+1)(\varepsilon_z/\varepsilon_{cc})^2} \tag{21}$$

$$\varepsilon_{cc} = \varepsilon_{co}\left[1 + (17.0 - 0.06 f_c^{'})\frac{f_r}{f_c^{'}}\right] \tag{22}$$

where f_{cc} is the confined concrete stress; f_{ccp} and ε_{cc} are the confined peak concrete stress and the corresponding axial strain of concrete under a constant f_r, respectively; A and B are parameters that govern the shape of the stress-strain curve .

In order to maintain the consistency to authors' previous research [1-3], f_{ccp} is defined as:

$$\frac{f_{ccp}}{f_c^{'}} = 1 + 4.1\left(\frac{f_r}{f_c^{'}}\right) \tag{23}$$

The Interaction amongst Concrete, Steel Tube and External Confinement

In a confined CFST column, the core concrete is confined by steel tube and also external confinement (rings, spirals, ties, steel jackets and FRP wraps). Thus, f_r is equal to the sum of the confining stress from the steel tube (f_{rS}) and external confinement (f_{rE}):

$$f_r = f_{rS} + f_{rE} \tag{24}$$

$$f_{rS} = -\frac{2t}{D_o - 2t}\sigma_{s\theta} \tag{25}$$

Firstly, for CFST columns confined by rings, spirals or steel jackets, the following formula for f_{rE} can be obtained from the free-body diagram [6]:

$$f_{rE} = -\frac{2nA_{ssE}}{H(D_o - 2t)}\sigma_E \tag{26}$$

Secondly, for tie-confined CFST columns, f_{rE} can be obtained using the virtual work principle [6]:

$$f_{rE} = -\frac{nd^2}{H(D_o - 2t)}\sigma_E \tag{27}$$

With:

$$\sigma_E = \begin{cases} \varepsilon_{ssE}E_{ssE} & \varepsilon_{ssE}E_{ssE} \le \sigma_{ssE} \\ \sigma_{ssE} & \varepsilon_{ssE}E_{ssE} > \sigma_{ssE} \end{cases} \tag{28}$$

where $\sigma_{s\theta}$ is the hoop stress provided by the steel tube; n is the number of external confinement (pair of tie bars); σ_E refers to the stress provided by the external confinement; A_{ssE} is the cross-section area of external confinement (ring, spiral or steel jacket); ε_{ssE}, E_{ssE} and σ_{ssE} are the average hoop strain, elastic modulus and yield stress of external confinement, respectively.

Axial Load against Axial Strain Curve of CFST Columns

Multiplying the axial stress of the steel tube σ_{sz} and core concrete f_{cc} by the respective contact area, A_s and A_c, the axial load carried by the steel tube (F_s) and the axial load carried by confined concrete (F_c) can be obtained. In this study, to be consistent with the authors' previous research [5, 6], the maximum axial strain adopted is 1.5% (around average hardening strain of steel tube in the authors' experiments). Thus, A_s and A_c can be assumed to remain unchanged. Then the total axial load of the CFST column, F_t can be calculated by using:

$$F_s = \sigma_{sz} A_s \tag{29}$$

$$F_c = f_{cc} A_c \tag{30}$$

$$F_t = F_c + F_s \tag{31}$$

The generation of the axial load-strain curves of CFST columns requires an iterative process. (1) A small increment of hoop strain $d\varepsilon_{s\theta}$ is given (-0.5 με in elastic stage and -5 με beyond elastic stage), with which the total hoop strain of the next step ε_θ^{i+1} can be renewed based on the total hoop strain of the current step ε_θ^{i}; (2) The total axial strain of the next step ε_{z1}^{i+1} is assumed and then σ_{sz}, $\sigma_{s\theta}$, σ_{sr} and f_r can be determined; (3) With f_r and ε_θ^{i+1}, another total axial strain ε_{z2}^{i+1} can be calculated. If ε_{z1}^{i+1} and ε_{z2}^{i+1} is close enough (Error < 0.1%), ε_θ^{i+1} and ε_{z1}^{i+1} converge. If not, an iterative process based on secant method is performed starting from step (2); (4) Once the converged values of ε_θ^{i+1} and ε_{z1}^{i+1} are determined, f_{cc}, F_c, F_s and F_t can be evaluated and a point on the axial load-strain curve is obtained; (5) Repeat Steps (1) to (4) to obtain the complete stress-strain curve until the total axial strain is larger than 1.5%, or when the load dropped to less than 85% of the maximum load (It is recommended that no more than 15% loss in strength is allowed to avoid abrupt failure of the column), whichever was earlier.

PARAMETRIC STUDY

A parametric study was conducted using the proposed model described earlier to investigate the effects of σ_{sy}, f_c', D_o/t ratio and external confinement on the uni-axial behaviour of CFST columns. In the parametric study, σ_{sy} was varied from 250 to 850 MPa and f_c' was varied from 20 to 120 MPa to cover normal- and high-strength materials. The range of D_o/t ratios was extended, which varied from 10 to 200, covering very thin-walled to relatively thick-walled section. External confinement in the form of steel jackets was assumed in the parametric study to investigate the effects of centre-to-centre spacing, cross-sectional area and yield stress of external confinement on the uni-axial behaviour of CFST columns. The total height of the specimen (H) is three time of D_o, with which, no slenderness effects should be considered. The Young's module of steel tube and steel jackets are set to 200 GPa.

A naming system was established to identify each of the specimens in the parametric study. The naming system for unconfined specimens consists of two alphabets and four numbers. To illustrate, CN-30-250-300-4 represents a CFST column ("C") without any external confinement ("N"). The in-filled concrete cylinder strength is 30 MPa (indicated by the first number after the alphabets, "30"). The steel tube yield stress is 250 MPa (indicated by the second number, "250"). The outer diameter and thickness of steel tube are 300 mm (indicated by the third number, "300") and 4 mm (indicated by the last number, "4"), respectively. For confined specimens, CJ(30-2*12-250)-30-250-300-4 represents the specimen confined by steel jackets ("J"). The numbers inside the parentheses are the number ("30"), thickness ("2"), width ("12") and yield stress of confinement ("250"), respectively. The numbers outside the parentheses are the same as the unconfined specimens.

Axial Load against Axial Strain Curve of CFST Columns

The differences between the maximum strength (F_{max}) of CFST columns, which is the maximum strength before 1.5% axial strain of the axial load-strain curves, and the nominal squash load of CFST columns F_o, defined as the sum of the load-carrying capacity of concrete and steel tube (in Eq. 32) with the same D_o/t (300/7) ratio and f_c' are plotted against σ_{sy} in Fig 1. It can be observed that the differences increase as σ_{sy} increases provided that the D_o/t ratio fulfils the slenderness limit in Eq. (3). This is because as σ_{sy} increases, the axial resistance and confining stress provided by the steel tube increase and thus enhancing F_{max}.

$$F_o = f_c^{'} A_c + \sigma_{sy} A_s \tag{32}$$

The differences between F_{max} and F_o of CFST columns with the same D_o/t (300/7) ratio and σ_{sy} are plotted against f_c' in Fig 2. With higher f_c', the differences increase. However, it can be observed from Fig. 2 that the improvement of differences becomes smaller for higher strength concrete, which implies that to obtain the same amount of enhancement, higher strength concrete needs larger confining stress, i.e. larger σ_{sy} or smaller D_o/t.

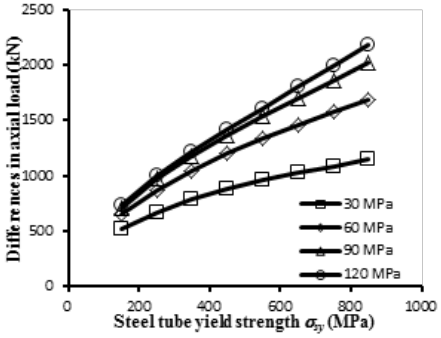

Fig 1 Effects of steel yield strength

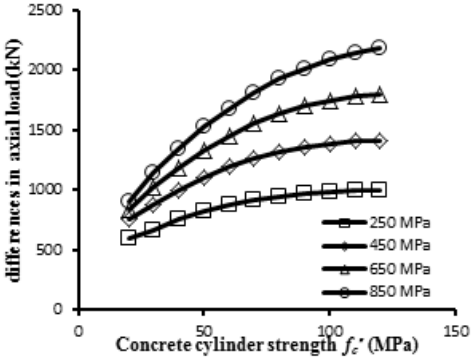

Fig 2 Effects of concrete strength

Effects of D_o/t ratio

The normalized maximum strength of CFST columns with the same σ_{sy} (250 MPa) and f_c' (30 and 90 MPa) are plotted against D_o/t ratio in Fig 3, in which F_{max} is normalized with F_o. It can be observed from this figure that the normalized strengths increase with decreasing of D_o/t ratio. This is attributed to the fact that at smaller D_o/t ratio, the confining effect is larger, resulting in larger enhancement and vice versa.

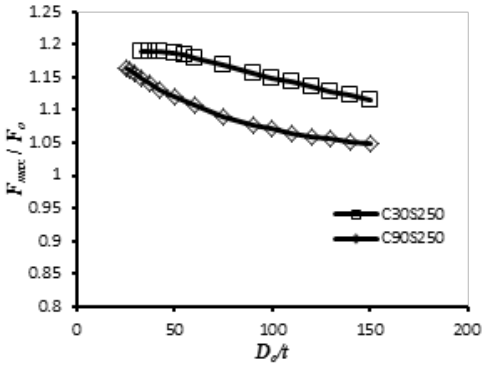

Fig 3 Effect of D_o/t ratio on F_{max} / F_o

Effects of Adding External Confinement

For the analysis in the following section, external confinement in the form of steel jackets is provided to enhance the strength and ductility of CFST columns with σ_{sy} = 250 MPa, f_c' = 60 MPa and D_o/t ratio of 60.

The normalized maximum strength (F_{max}/F_o) of the confined CFST columns is plotted against n, A_{sE} and σ_{ssE} of steel jackets in Figs 4-6, in which n varied from 5 (S = 180, with steel jackets far away from each other) to 75 (S = 12, with continuous arrangement of steel jackets); A_{sE} varied from 12 to 48 mm^2 (range of the authors' experimental studies) and σ_{ssE} was from 250 to 450 MPa (covering mild steel to high yield steel bar in traditional reinforced concrete columns). It can be observed from Figs 4-6 that F_{max}/F_o increases as n, A_{sE} and σ_{ssE} of steel jackets increase or S decreases. This is attributed to the fact that by increasing of n, A_{sE} and σ_{ssE} (or decreasing S), the steel jackets could provide larger and more uniform confining stress and hence improving the uni-axial strength of CFST columns, which is consistent with the authors' previous research [3, 4].

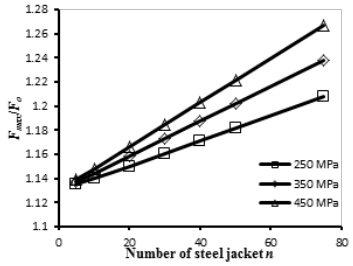

Fig 4 Effects of steel jacket no.

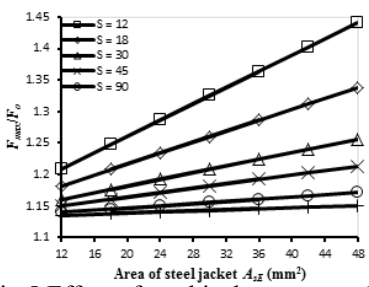

Fig 5 Effect of steel jacket area

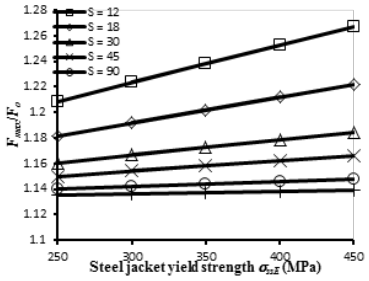

Fig 6 Effect of steel jacket yield strength

From the parametric study and the authors' previous research, it can be also seen that the providing of steel jackets can also improve the ductility of CFST columns. The uni-axial behaviour of specimen CN-60-250-300-5 can be improved in two ways: (1) By adding steel jackets, CJ(35-3*12-250)-60-250-300-5; (2) By solely increasing the steel tube thickness, CN-60-250-300-6.72. The comparison among these three specimens is shown in Fig 7. It can be seen that these two methods provide similar enhancements in strength and ductility of specimen CN-60-250-300-5. Compared CJ(35-3*12-250)-60-250-300-5 with CN-60-250-300-6.72, it can be found that the amount of materials required for steel jackets is 1187522 mm^3 in volume whilst that required for increasing the thickness of steel tube is 1401959 mm^3 (Compared with CN-60-250-300-5), which means the same level of ductility can be achieved by adding external confinement with 84.7% of material required for increasing the wall thickness. Moreover, F_{max} for CJ(35-3*12-250)-60-250-300-5 is 6348 kN and that for CN-60-250-300-6.72 is 6270 kN. From the above analysis, it can be concluded that adding external confinement is much more effective than increasing the wall thickness in strength and ductility improvements. This is attributed to the fact that by increasing the wall thickness of steel tube could not increase the interface bonding between steel tube and core concrete: Under uni-axial load, the steel tube will dilate more than core concrete in the initial elastic stage because of the variations in Poisson's ratios. This imperfect interface bonding will have unfavourable effect on the composite action by reducing the confining stress provided by the steel tube, or even causing negative confining stress [9]. By adding external confinement, the interface bonding can be improved and will become positive confining stress if adequate amount of external confinement is provided. Moreover, the steel tube will provide axial resistance and confining stress simultaneously, which may not be as effective as that of external confinement by providing lateral confining stress only.

\

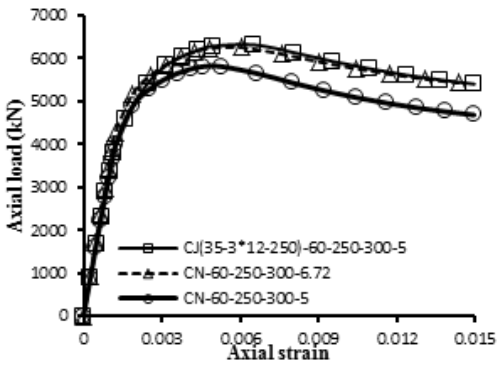

Fig 7 Effect of adding steel jackets

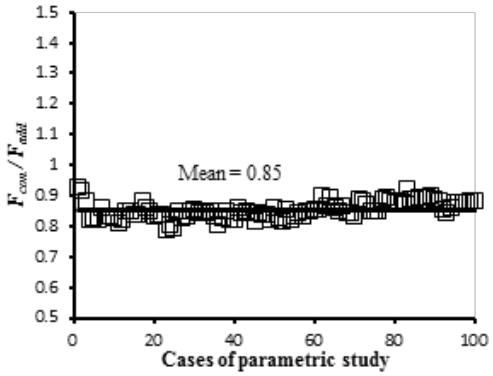

Fig 8 The ratio of F_{con} to F_{add}

Fig 8 shows the ratio of F_{con} to F_{add} when the same level of ductility and axial strength improvement are achieved by adding external confinement or increasing the wall thickness of steel tube, in which F_{con} and F_{add} are the equivalent force provided by the external confinement and force provided by the steel tube with added area compared to original steel tube, respectively (See Eqs. 33-36).

$$F_{con} = \sigma_{ssE} A'_{ssE} \tag{33}$$

$$F_{add} = \sigma_{sy} A_{add} \tag{34}$$

$$A'_{ssE} = A_{ssE} \pi D_o / S \tag{35}$$

$$A_{add} = A_{sT} - A_s \tag{36}$$

where A'_{ssE}, A_{add} and A_{sT} are the equivalent area of external confinement, added area of steel tube and area of steel tube by increasing the wall thickness, respectively. From Fig 8, it can be concluded that the same level of ductility and axial strength improvement can be achieved by adding external confinement with 85% of material required for increasing the wall thickness of steel tube (or F_{con} = 0.85 F_{add}), which again proves that providing external confinement is more effective than by just adding the wall thickness of steel tube.

CONCLUSIONS

From this study, the following conclusions can be drawn:

The maximum strength of CFST columns increases as the yield strength of steel tube increases or the concrete cylinder strength increases, or the diameter-to-thickness ratio of steel tube decreases.

The normalized strength of the confined CFST columns increases as the number, cross-sectional area and yield stress of steel jackets increase or spacing decreases.

Adding external confinement is much more effective than solely increasing the steel tube thickness in strength and ductility enhancements of CFST columns since the same level of ductility and axial strength improvement can be achieved by adding external confinement with 85% of material required for increasing the wall thickness of steel tube.

ENHANCED GUIDELINES FOR REINFORCEMENT AROUND OPENINGS

Tom Molkens [1,*]
[1] StuBeCo bvba, Hoevenstraat 155 - B 3900 Overpelt, Belgium.*Email: tom@stubeco.be

ABSTRACT

When designing concrete slabs, it is rather difficult to make a performant design that already takes the effect into account of unexpected openings. This is needed because it becomes unfortunately a common practice to add some openings at a final stage, which then requires rough time-saving rules. Even when the concrete is already casted some openings will be cut afterwards, certainly when a building gets refurbished in his life-time. Some standards require that if the reinforcement is designed for a homogeneous slab, the interrupted amount of reinforcement by the opening must be distributed around the opening. However, it is logical that for bigger openings, the flow of internal forces will be influenced by the opening itself. So it is clear that the previously-mentioned method can overestimates and, more dangerously, underestimates some reinforcements. To develop a more accurate design method, FEM analyses were conducted for different spans and opening sizes in slab areas with one- (central part) and two-way bearing (towards the edges) behaviour. Because flat slabs are much less sensible for openings, they are not included in this study. As result of this study, reduction and magnification factors were found which may be applied with an easy rule to obtain a better-performing method. These factors depend on the opening width/span ratio and must be normalized for the span in meters. In addition to the ultimate limit state, the service limit state was also verified. A magnification factor on the deformations must be applied, of the same order as that one on the lower reinforcement. This work was done in the scope of a new technical document about reinforcement for the Belgian Centre of Science and Technology for Construction Works.

KEYWORDS

Design and verification rules, reinforcement around openings, magnification factor.

INTRODUCTION

Openings are commonly added in the design, during the construction phase for technical equipment or changes in layout, such as transforming two apartments into a duplex. This is also the case when a structure is renovated. Openings in an existing concrete slab must also be added due to new regulations about ventilation, heating, minimal surfaces and so on.

Several standards (Tayebwa *et al*. 2015 & Ravindra 2006) specify how to deal with small openings, with dimensions of $1/16^{th}$ to $1/3^{th}$ of the shortest span. Extra reinforcement may be needed, depending on the structural systems of the slab and dimensions of the opening. All these rules begin from the assumption that the internal flow of forces will not be influenced by the opening, which will be the case starting from a certain point. It has already been shown (Molkens 2015) that flat slabs are less influenced by the presence of openings, so the focus was put on one- or two-way bearing slabs supported by line supports around the perimeter. This is typical for domestic buildings with masonry bearing walls, for example, or offices with a beam grid. For the sake of simplicity, we assume that the slab doesn't act as an upper part of a T-beam.

19 FEM-based slab analyses of different slabs, varying the dimensions of the slabs and the openings, were used in order to investigate how a slab would react to the presence of an opening. Geometry, loads, and materials of the study cases are discussed in the Sections 2 and 3. Verification and validation of the FEM model is done in Section 4, which compares the moments on the centre line of a 5x10 m slab with a 5x15 m slab and a beam model. Reinforcement results are discussed in Section 5.

GEOMETRY

To obtain results for practical applications, we've chosen three different slab dimensions which are frequently used in Northern Europe for domestic buildings: 5x10, 6x12, and 7x14 m . The shortest span-to-width ratio was always equal to two, both because it is most common in practice, and because Eurocode 2 (2004) specifies that the central part will act as a one-way span starting from this ratio. Bigger openings enter the two-way span area.

The thickness of the slab is governed by resistance, rigidity, and acoustic requirements. In Belgium, they require a minimum mass of 500 kg/m or a minimum thickness of 200 mm. As deformation criteria, we used a maximum deformation of span/500 after installation of the inner non-bearing partition walls (equal distribution presumed); this is why we've used 220 mm for the 7x14 m slabs. A time-dependent cracked calculation is therefore needed to account for creep and the following reinforcement:

- minimal reinforcement to avoid brittle fracture following EC2 in both directions (220 or 300mm /m),
- reinforcement needed to resist actions on the slab.

Most buildings use lattice girder slabs or plank floors with a thin (about 50 mm) reinforced concrete permanent formwork with integrated lower reinforcement and in situ concrete topping, which includes joint and upper reinforcement. To simulate the behaviour of such a composite floor, we worked with orthotropic plate characteristics with full thickness in the bearing direction and only the thickness of the concrete topping in transverse direction.

The FEM model is limited to three equal spans with one simply supported (hinge line) and one clamped end. Side borders are always simply supported. As openings, we introduced 5 different dimensions:

- 500x500 mm , which is a normal shaft for domestic buildings without high energy performance,
- 1000 or 1500x1000 mm , which is a normal shaft for domestic buildings with high energy performance, such as (high rise) passive buildings,
- 2000x1000 mm can be for a large shaft for smoke evacuation, or even suitable for a miller staircase,
- 3000x1000 mm , which is the minimum for a normal staircase (about 13 steps).

Openings are always located in the centre and against a line support (see Figure 1). The shortest span is divided into at least six for mesh generation of the finite elements. Calculations are done by Diamonds r02 FEM Kirchoff based software from Buildsoft (2015).

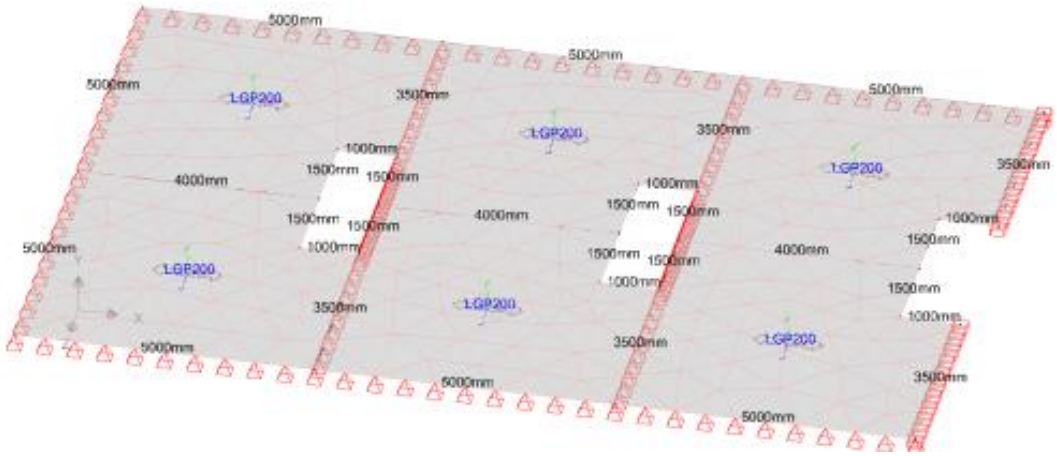

Figure 1 Summary view of smallest and biggest opening configurations.

LOADS AND MATERIALS

Load combinations mentioned in the calculation are derived from equations 6.10a and 6.10b from EN 1990 (2002) + CC2 (γ_G = 1.35 and γ_Q = 1.50). Class B EN 1991-1-1 (2002) is used for the mobile load combination factors for domestic buildings or offices. The following loads act on the slabs:

- Own weight of the slab at 25 kN/m , applied after 28 days = removing stamps,
- Permanent action of 1.20 kN/m for non-bearing partition walls of 3 kN/m, EN 1991-1-1 (2002). Applied after 60 days,
- Permanent action of 2 kN/m for the finishing, applied after 90 days,
- Mobile load of 2 kN/m acting on the structure after 150 days.
- REI60 as fire resistance.

Concrete used in the analyses has a C30/37 quality, with a α_{cc} value of 0.85 and a safety factor of 1.50. The reinforcing steel has a f_{yk} = 500 N/mm with a safety factor of 1.15. Supports are vertically rigid and function as a real hinge for rotational moments. It was assumed that supports are well-loaded to avoid uplift in the corners.

VERIFICATION AND VALIDATION OF FEM MODEL

To verify the accuracy of the FEM model (number of elements) and the one-way span behaviour of the central area of this slabs a validation was set up by the analytical solution for a 1 m wide slab part. The factors used in

this simple beam-model can be found in the Betonkalender (1991). We can compare the analytical values for a 1 m wide beam with those of 5x10 m slab without openings from the FEM model. The design load = greatest combination of loads from the following equations, look previous chapter:

- 1.35·(0.20·25+1.2+2) + 1.50·0.70·2 = 13.58 kN/m (Eq. 6.10a NBN EN 1990)
- 0.85·1.35· (0.20·25+1.2+2) + 1.50·2 = 12.40 kN/m (Eq. 6.10b NBN EN 1990)

For the first, second and third span, the field moment of a 1 m wide continuous beam model would be: 0.078·13.58·5 = 26.47 kNm; 0.033·13.58·5 = 11.20 kNm and 0.042·13.58·5 = 14.25 kNm. For the first, second and third span, the moment above the supports of a 1 m wide continuous beam model would be: 0.105·13.58·5 = 35.63 kNm; 0.079·13.58·5 = 26.81 kNm and 0.083·13.58·5 = 28.17 kNm.

*Disequilibrium on top of support in FEM, mean value as reference

The most significant deviation can be found in the first span, as it is there that the torsional stiffness still plays an important role. Just to check, we adapted the model to a ratio $L_y/L_x = 3$ instead of 2. The results fit very well in the first span, but there was more scatter above the supports. We therefore concluded that the accuracy of the model with $L_y/L_x = 2$ is acceptable and results will be reliable.

RESULTS

A summary of the results can be found in Table 3. Several results are represented here and will be discussed later on. It is important to follow the legend in order to understand the table:

- Aix (mm /m) = Lower reinforcement in principal bearing direction of the slab at centre line = line exactly in the middle of the width through the opening
- Aiz (mm /m) = Lower transverse reinforcement at centre line
- ΣAiz (mm) = Sum of lower transverse reinforcement on centre line for one span (inclined represented)
- Width L (m) = Width of additional lower reinforcement needed above a slab without opening
- Additional L (mm) = Triangular integration of extra reinforcement over the Width L next to opening
- Aix FEM/wo (1) = Ratio of principal reinforcement with opening to principal reinforcement without opening.
- Hatch = lower transverse reinforcement stays under the one needed to avoid brittle fracture.
- Hatch = lower peak against opening becomes most important and 0 against apposite support.
- Asx (mm /m) = Maximum reinforcement above support next to opening
- ΣAsx (mm) = Sum of upper principal reinforcement over half support line
- Asz (mm /m) = Upper transverse reinforcement at centre line
- Width U (m) = Width of additional upper reinforcement needed above a slab without opening
- Additional (mm) = Triangular integration of extra reinforcement over the Width U 2x next to opening
- Aix FEM/DR (1) = Ratio of extra principal reinforcement to that following from the design rule, half width opening multiplied by reinforcement needed without opening.

Lower principal reinforcement A_{xi}

The lower principal reinforcement is in the direction of the lattice girders or plank profiles. For spans 1, 2 and 3, quite accurate and easy linear approximations are possible, governed by the opening size and almost independent of slab size. With O = opening width in m, the perpendicular principal bearing direction becomes:

- First span: $A_{xi,extra,1stspan} = 1+0.017\ O$, (1)
- Second span: $A_{xi,extra,2ndspan} = 1+0.090\ O$, (2)
- Third span: $A_{xi,extra,3rdspan} = 1+0.057\ O$. (3)

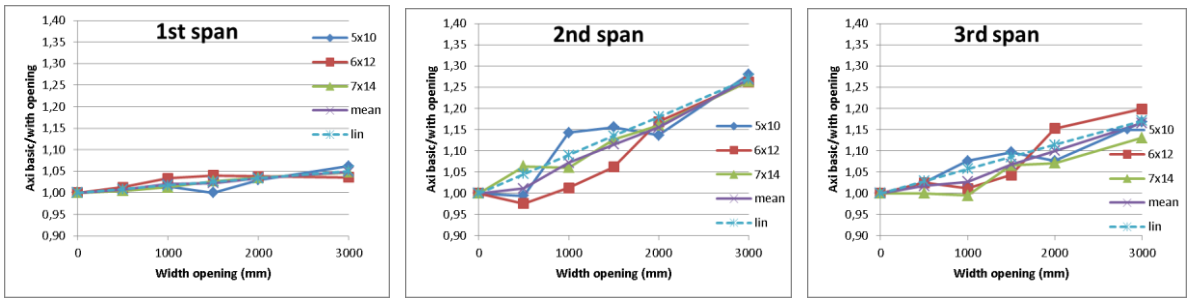

Figure 4 Variation of lower principal reinforcement for first, second and third span

It can be seen that in only the first span, the extra reinforcement becomes more or less stable for bigger openings in bigger spans. This figure does not show the possibility of activating a second bearing direction. Extra reinforcement stays even, with large openings limited to about 30% for the second span.

Lower reinforcement in transverse direction A_{zi}

In the first span, the maximum values for the lower transverse reinforcement are even more stable than for the principal reinforcement, but this is due to the torsional moment in this span. On the other hand, a serious increase can be seen for the second and third span. For opening widths of up to about 1 m, the reinforcement needed to avoid brittle fracture is enough to cover the extra amount of reinforcement for the opening in the second span. For the third span this applies for openings of up to 2 m.

If we're looking to integrate the reinforcement over the centre line, it can be seen that the total amount of reinforcement stays stable, almost independent of the span number and highly dependent on the opening size, Figure 5.

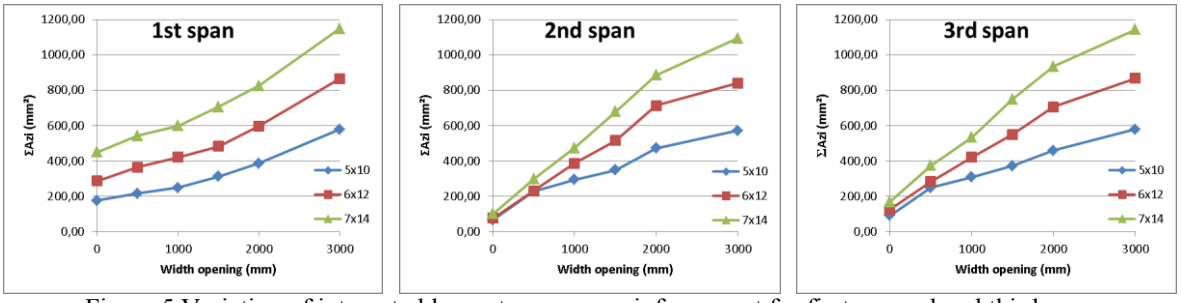

Figure 5 Variation of integrated lower transverse reinforcement for first, second and third span

It is common practice to locate this reinforcement beside the opening in the field. Based on the models, it seems that this is only sufficient for the really big 3 m openings (Table 3). For smaller openings (up to 1 m), in contradiction with this easy applicable rule of thumb it seems that the biggest demand for extra reinforcement is against the support line, which can be explained as follows:

- Due to the negative moment on top of the support, the slab becomes very stiff and seeks equilibrium for the peak values in the moments,
- There is thus a kind of virtual support before forces reach the support line beside the opening. Extra lower transverse reinforcement must be located beside the support!

From 1.5 to 2.0 m, extra reinforcement must be evenly distributed next to the opening and beside the support.

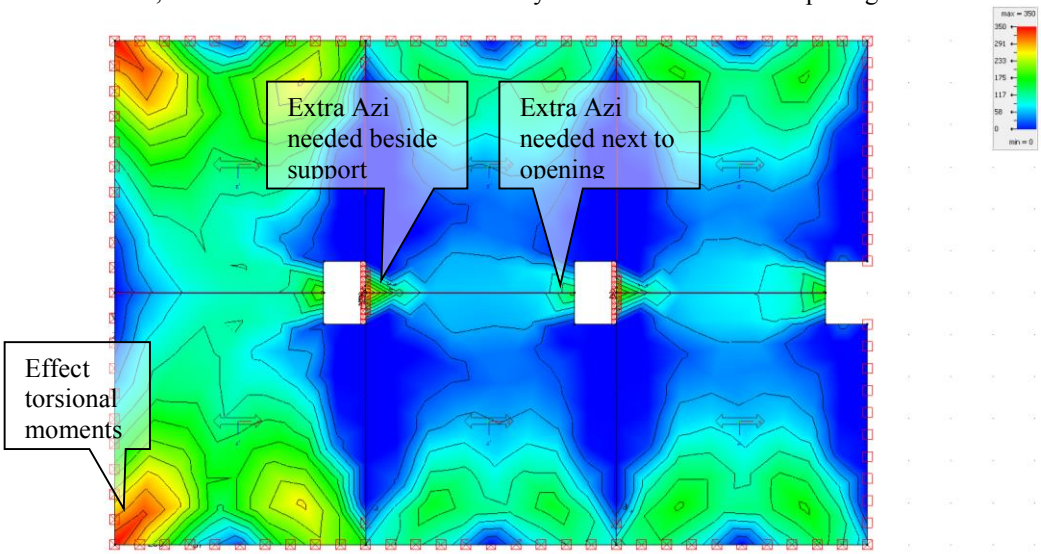

Figure 6 Location of lower transverse reinforcement for a 6x12 m slab and 1000x1500 mm opening

Upper principal reinforcement A_{xs}

Based on the location of the opening in the centre and next to the support line, it can be expected that the influence will be concentrated in the lower transverse reinforcement and principal upper reinforcement for negative bending moments. By considering maximum values of this reinforcement, it becomes clear that we must deal with high peak values. Here, the integration of the total reinforcement seems to be the most interesting issue (Figure 7).

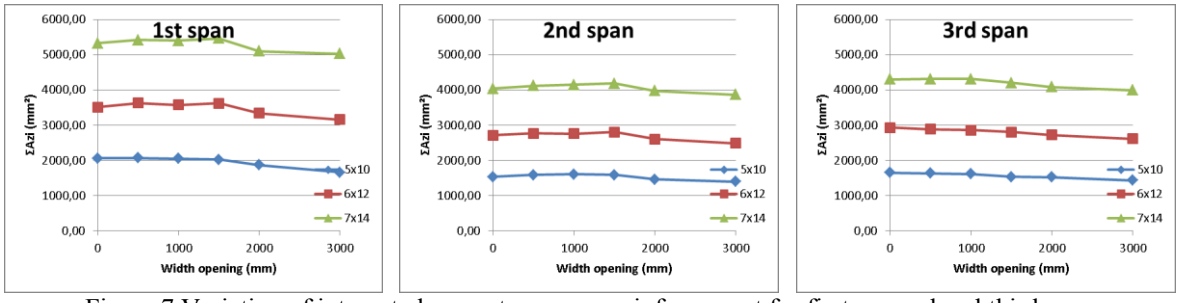

Figure 7 Variation of integrated upper transverse reinforcement for first, second and third span

A slight decrease in reinforcement can be seen for openings of at least 2 m perpendicular to the bearing direction, due to activation of the second bearing direction. But practical the total amount of reinforcement stays more or less the same in an initial approximation. It would be really interesting if we could divide this total quantity into one which must be provided next to the opening, and a part that can be evenly distributed along the line support. Table 3 includes a ratio between the integration of the peak reinforcement ($A_{xs,peak}$ triangular shape), the product of the upper reinforcement without opening with half the opening width = reinforcement which was cut by the opening ($A_{xs\ design\ rule}$). We've repeated this for the three different spans (Figure 8).

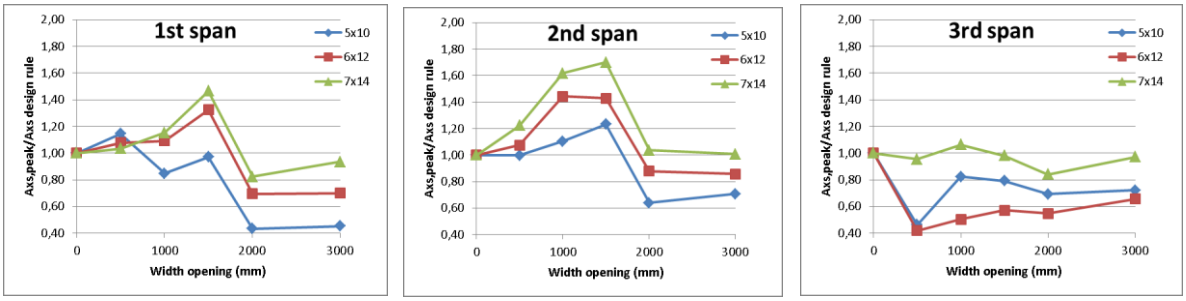

Figure 8 Variation of upper extra principal reinforcement for first, second and third span in relation with design rule out of code

We see similar forms for each span, but the easy design rule (putting the quantity of reinforcement which was cut next to the opening) is only conservative for very small openings (< 500 mm), large openings of 2 m or more, and in the third span. In between, this rule can strongly underestimate the amount of peak reinforcement, up to a factor of 1.70.

Upper reinforcement in transverse direction A_{zs}

This reinforcement is already very low without opening and quickly (> 500 mm) becomes zero at the centre line.

DESIGN RULES

It can be useful or even necessary to build robustness into the floor system. A maximum opening width (or diameter) must be defined after discussion with the client, and the reinforcement can be optimised by following design rules to avoid delays due to recalculation.

Lower reinforcement

Some magnification factors are already given in the previous chapter for the lower principal reinforcement A_{xi}, depending on the span number, in this case with the opening O in m. The graphs presented in Figure 5 for A_{zi} suggest that the demand for the total amount of transverse reinforcement varies linearly, and the curves have the same shape. Those figures can be normalized by multiplying them by a factor of (5/span) . The total amount of lower transverse reinforcement can be calculated using Eq. 4 with the width of the opening in m (see Figure 7). 200 mm is the mean value of the sum of the lower reinforcement over the centre line for slabs without openings, and the factor 133 is the result of curve fitting.

$$\sum A_{zi} = \max\left[span \cdot \frac{0.26}{f_{ctm}} f_{yk} bd;\ (200 + 133(width\ opening)) \cdot \left(\frac{span}{5}\right)^2\right] \quad (4)$$

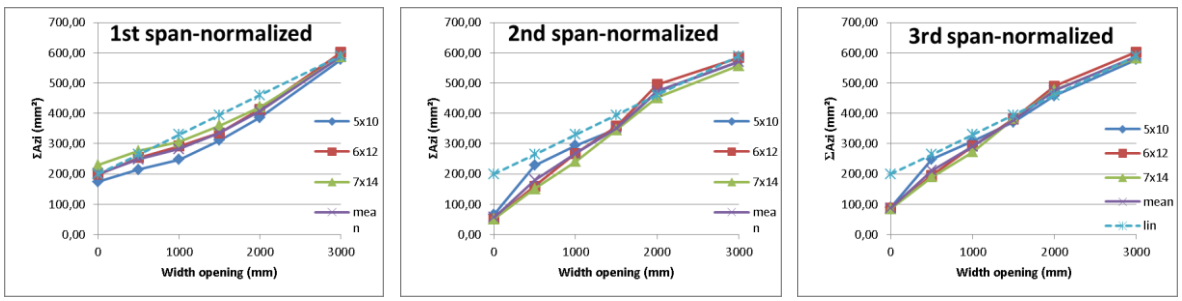

Figure 9 Variation of lower transverse reinforcement for first, second and third span - normalized

For the location of the reinforcement, consult the guiding rules in the previous chapter: < 1 m = beside the support next to the opening, 1.5 -2 = evenly distributed, and > 3 = beside the opening only. The maximum width

of the opening without reinforcement can be defined by setting the minimal reinforcement in Equation 1 as equal to the second part of the formula.

Upper reinforcement

The total amount of reinforcement stays equal, so we want to provide an opening with a width of O so that the mean reinforcement per meter will increase to (Width slab)/(Width slab – Opening) times the amount without opening. If we can derive the peak reinforcement which must be placed next to the opening, then we will also know the surplus. Figure 8 makes clear that we only can work within an envelope to obtain a safer approximation than before; even normalized for the span (multiplied by 5/span), 3 different factors must be used (Equation 5).

$$A_{xs,peak} = \gamma_{opening} \cdot (\frac{span}{5}) \cdot (\text{through opening cut-away reinforcement } A_{xs,without\ opening}) \quad (5)$$

$\gamma_{opening}$ can be smaller, equal to, or bigger than unity:

- First span: $\gamma_{opening}$ = 1 without opening, $\gamma_{opening}$ = 1.15 for O between 500 and 1500 mm, and $\gamma_{opening}$ = 0.80 for O >2000. Linear interpolation can be used for values in between.
- Second span: $\gamma_{opening}$ = 1 without opening, $\gamma_{opening}$ = 1.25 for O between 1000 and 1500 mm, and $\gamma_{opening}$ = 0.80 for O >2000. Linear interpolation can be used for values in between.
- Third span: $\gamma_{opening}$ = 1 without opening, $\gamma_{opening}$ = 0.80 for O at least 500. Linear interpolation can be used for values in between.
- Take 1,20 and you cover almost everything, applicable as easy design rule or first approach.

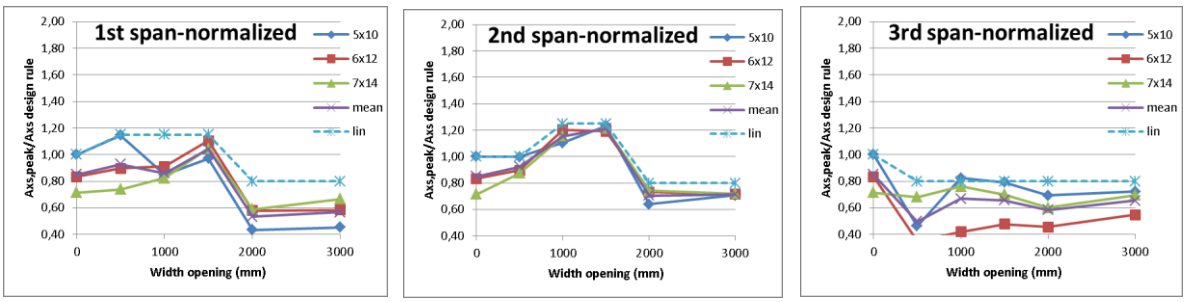

Figure 10 Variation of lower transverse reinforcement for first, second and third span - normalized

VERIFICATION RULES

If the slab is already completed, previous formulas can be used backwards to see what is possible without needing to strengthen the slabs. In the past, the transverse reinforcement is mostly only a Poisson's fraction (0.20 - 0.25) of the principal reinforcement; at that point, the effective reinforcement must be used in the formulas.

The end of the previous chapter also shows why cracks can appear even with what is, at first glance, properly designed extra peak reinforcement. When cracks appear, plastic yielding will occur, and there will be never a static problem, because the total reinforcement is always respected even with the simple design rule. To limit crack width, the reinforcement may need to be enlarged by a higher factor, such as the previous $\gamma_{opening}$.

DEFORMATIONS

With equal spans, it is obvious that only the first span will be the most critical one. Maximum time dependent deformations of the slab increase up to about 30%. This is a much bigger effect than would be presumed based on the influence of the lower principal reinforcement. Linear interpolation can be used (Equation 6).

$$\text{Influence of opening on deformation in first span} = 1 + 0.103\ O \text{ with O in m} \quad (6)$$

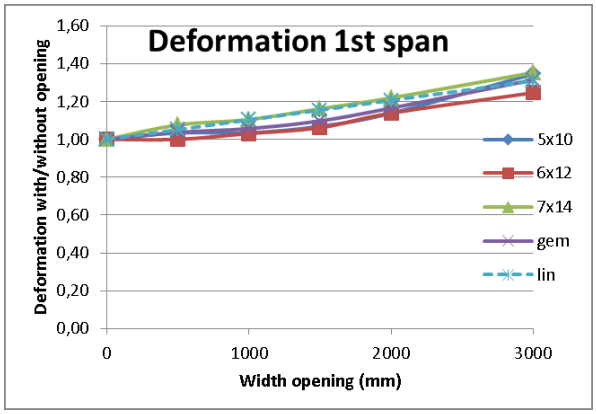

Figure 11 Variation of total impacts for different sections

CONCLUSIONS

Based on this study of practical slab dimensions, we can distill design rules which estimate when and how much additional lower and upper reinforcement will be needed, when the second direction of the slab gets activated, and how we can improve robustness. All the given formulas start from slab information without openings, which greatly improves the numerical stability of FEM models for global analyses.
The given design rules are currently only valid for rectangular shapes with a width/span ratio of 2 or higher. An unexpected location of lower transverse reinforcement could be shown.
At this point, we could only find a dependency of the opening width, perpendicular to the principal bearing direction. Slab thickness and span are not involved.

AKNOWLEDGE

ABSTRACT

The nonlinear long-term behavior of slender high-strength concrete (HSC) panels in two-way action is investigated in this paper. A theoretical model that considers the geometric nonlinearity and creep of concrete is developed based on a time-stepping analysis. A rheological material model that is based on the generalized Maxwell chain is adopted to model the concrete creep. Von Karman plate theory is used to derive the incremental governing equations. The equations are solved numerically at each time step based on a Fourier series expansion of the deformations and loads in one direction, and using the numerical multiple shooting method in the other direction. The capabilities of the model are demonstrated through a numerical example and a parametric study. The numerical study shows that the model can effectively predict the time-dependent behavior of two-way HSC panels, where the out-of-plane deflection and internal bending moments increase with time as a result of the combined effects of creep and geometric nonlinearity. These effects may ultimately lead to creep buckling failures. A parametric study is carried out to investigate the effects of in-plane load level, load eccentricity and slenderness ratio. It is revealed that the long-term behavior of two-way HSC panels is very sensitive to these parameters.

KEYWORDS

Buckling, creep, panel, high strength concrete, time-dependent.

INTRODUCTION

High-strength concrete panels in two-way action have attracted numerous research interests in the past decades. Slender two-way concrete panel may undergo increasing in-plane and out-of-plane deformations with time under eccentric sustained in-plane and/or out-of-plane loads due to the combined effects of geometric nonlinearity and creep of concrete. This may cause excessive deflection and cracking when the structure is in serviceable state or may eventually lead to creep buckling failure of the panel.

Studies that focus on the buckling failure behavior of two-way panels under the influence of creep and shrinkage, regardless of normal-strength concrete (NSC) or HSC panels, cannot be found in the open literature. However, a significant amount of studies have been undertaken to investigate the nonlinear behavior of two-way reinforced concrete (RC) panels under short-term loads, in which many of them focus on NSC wall panels. Swartz et al. (1974) tested 24 NSC panels that were subjected to uniaxial compressive loads along their short edges and simply supported along all four edges. The panels in the test failed due to buckling where the compressive stress levels varied from 51% to 87% of the concrete compressive strength. The paper also presented a formula, which was explained in details in Swartz and Rosebraugh (1974), for predicting the buckling load of RC panels. Saheb and Desayi (1990) tested 24 rectangular reinforced NSC wall panels loaded eccentrically in two-way action and simply-supported along four edges. It was found that the ultimate strength of wall panels in two-way action increased linearly with the increase of the aspect ratio as well as the vertical reinforcement. On the other hand, it reduced nonlinearly with the increase in thinness or slenderness ratios. Aghayere and Macgregor (1990a) reported test results on 9 concrete plates, simply supported along four edges and subjected to combined uniform in-plane compression and uniform transverse loading. Based on the test results, it can be concluded that in most axially loaded specimens, buckling of the reinforcement adjacent to the compression face took place at failure and all final failures were compression failures due to crushing of the concrete. Ghoneim and MacGregor (1994a) tested 19 two-way RC plates that were subjected to combined in-plane compressive and transverse loads. The test results indicated that the slenderness of the plate and the loading sequence mainly determined the effect of the in-plane load on the lateral load capacity of RC plates. Both material failure including crushing of concrete and yielding of the tension steel and stability failure occurred in the RC plates tested under combined

loads. Sanjayan and Maheswaran (1999) carried out experiments on 8 HSC concrete walls loaded eccentrically. It was found that the load capacity of the wall was significantly influenced by the eccentricity of in-plane loading, while it was insensitive to the concrete strength.

A number of theoretical analyses have also been carried out to study the behavior of two-way HSC panels (Aghayere and MacGregor 1990b; Massicotte et al. 1990; Ghoneim and MacGregor 1994b; Attard et al. 1996). Yet, their emphasis was placed on the short-term response where creep was not accounted for in the models.

Theoretical and experimental studies were conducted by Huang and Hamed (2013) and Huang (2015) to examine the time-dependent response of HSC panels in one-way actions. In this paper, a new theoretical model that utilizes the mechanics of thin plates is developed for the long-term analysis of HSC panels. A time-stepping analysis is used to account for the effect of creep. A rheological material model is adopted, which is based on the generalized Maxwell chain. In order to highlight the effect of creep only, a linear viscoelastic material behavior is assumed for concrete. The incremental governing equations are solved numerically at each time step based on a Fourier series expansion of the deformations and loads in one direction, and using the numerical multiple shooting method in the other direction. The mathematical formation of the model is presented first, followed by numerical and parametric studies.

MATHEMATICAL FORMULATION

The general governing equations derived here are applicable to any combination of external loads and boundary conditions. An incremental time-stepping analysis is implemented in order to account for the time-dependent change of the internal stresses and the increase of the deformations of the structure with time due to creep. For this, the time of concern t, which is measured from the time of first loading, is subdivided into n_t discrete time steps with $\Delta t_r = t_r - t_{r-1}$ ($r = 1, 2, \ldots, n_t$). The sign conventions for the coordinates, loads and displacements are shown in Figure 1. The middle plane of the panel is taken as the xy plane, where the x and y axes are directed along the edges. The z axis is taken normal to the middle plane and measured positive downwards. The forces and bending moments at the boundaries as well as the lateral loads are also presented in Figure 1. The torsional moments at the boundaries are not shown in the figure for brevity and clarity.

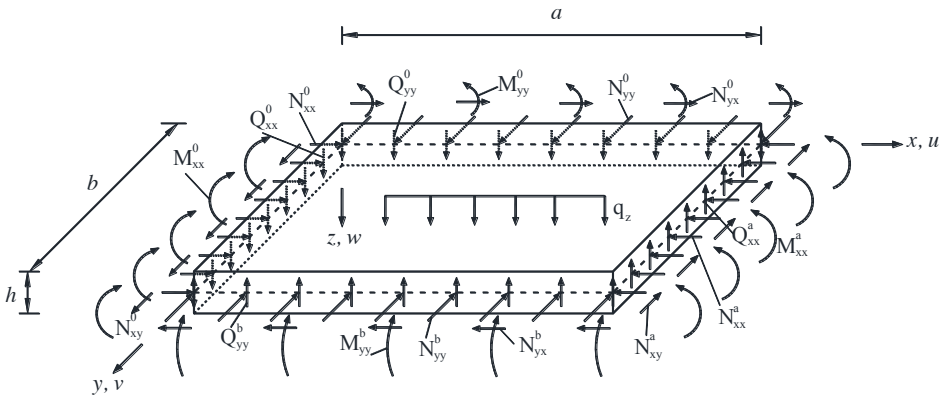

Figure 1 Sign conventions of the investigated panel

Kinematic Relations

In typical HSC panels, the dimensions in the z direction are much smaller than those in the other two directions. Therefore, a plane stress condition is adopted, where the stresses in the z direction including the normal and shear stresses are equal to zero. The theoretical model is based on Von Karman plate with large displacements. The incremental kinematic relations of the plate read

$$\Delta\varepsilon_{xx}(t_r) = \frac{\partial \Delta u(t_r)}{\partial x} + \frac{1}{2}\left(\frac{\partial \Delta w(t_r)}{\partial x}\right)^2 + \frac{\partial w(t_{r-1})}{\partial x}\frac{\partial \Delta w(t_r)}{\partial x} - z\frac{\partial^2 \Delta w(t_r)}{\partial x^2}$$

$$\Delta\varepsilon_{yy}(t_r) = \frac{\partial \Delta v(t_r)}{\partial y} + \frac{1}{2}\left(\frac{\partial \Delta w(t_r)}{\partial y}\right)^2 + \frac{\partial w(t_{r-1})}{\partial y}\frac{\partial \Delta w(t_r)}{\partial y} - z\frac{\partial^2 \Delta w(t_r)}{\partial y^2} \quad (1)$$

$$\Delta\gamma_{xy} = \frac{\partial \Delta u(t_r)}{\partial y} + \frac{\partial \Delta v(t_r)}{\partial x} - 2z\frac{\partial^2 \Delta w(t_r)}{\partial x \partial y} + \frac{\partial w(t_{r-1})}{\partial y}\frac{\partial \Delta w(t_r)}{\partial x} + \frac{\partial w(t_{r-1})}{\partial x}\frac{\partial \Delta w(t_r)}{\partial y} + \frac{\partial \Delta w(t_r)}{\partial x}\frac{\partial \Delta w(t_r)}{\partial y}$$

where ε_{xx} and ε_{yy} are the total normal strains in the x and y directions; γ_{xy} is the total shear strain in the xy planes. Each total strain has two components: the instantaneous strain and creep strain. u and v are the in-plane displacements along x and y directions, and w is the out-of-plane deflection along z axis, and $\partial/\partial x$ and $\partial/\partial y$ denote the partial derivative with respect to x and y, respectively; Δ represents the incremental operator and note that any displacement that appear without the Δ operator are the accumulated known quantity from the previous time step.

Equilibrium Equations

The variational principle of virtual work is used to derive the nonlinear incremental equilibrium equations along with the boundary conditions, where

$$\delta U + \delta W = 0 \tag{2}$$

with δU and δW as the internal virtual work and external virtual work and δ is the variational operator. The incremental equilibrium equations read

$$\frac{\partial \Delta N_{xx}}{\partial x} + \frac{\partial \Delta N_{xy}}{\partial y} = 0; \qquad \frac{\partial \Delta N_{yy}}{\partial y} + \frac{\partial \Delta N_{xy}}{\partial x} = 0 \tag{3}$$

$$\begin{aligned} &N_{xx}\frac{\partial^2 \Delta w}{\partial x^2} + \Delta N_{xx}\frac{\partial^2 w}{\partial x^2} + \Delta N_{xx}\frac{\partial^2 \Delta w}{\partial x^2} + N_{yy}\frac{\partial^2 \Delta w}{\partial y^2} + \Delta N_{yy}\frac{\partial^2 w}{\partial y^2} + \Delta N_{yy}\frac{\partial^2 \Delta w}{\partial x^2} \\ &+2N_{xy}\frac{\partial^2 \Delta w}{\partial x \partial y} + 2\Delta N_{xy}\frac{\partial^2 w}{\partial x \partial y} + 2\Delta N_{xy}\frac{\partial^2 \Delta w}{\partial x \partial y} + \frac{\partial^2 \Delta M_{xx}}{\partial x^2} + \frac{\partial^2 \Delta M_{yy}}{\partial y^2} + 2\frac{\partial^2 \Delta M_{xy}}{\partial x \partial y} + q_z = 0 \end{aligned} \tag{4}$$

where N_{xx} and N_{yy} are the internal axial forces in the x and y directions and N_{xy} are the internal shear force in the xy plane; M_{xx} and M_{yy} are the internal bending moments along x and y axes and M_{xy} is the internal torsional bending moment; q_z is the out-of-plane distributed load applied perpendicular to the top surface of the panel throughout the whole area. The general boundary conditions at $x = 0$ and $x = a$ are given by

$$\Delta N_{xx} + \Delta N^i_{xx} = 0 \quad \text{or} \quad \Delta u = \Delta \bar{u}; \qquad \Delta N_{xy} + \Delta N^i_{xy} = 0 \quad \text{or} \quad \Delta v = \Delta \bar{v}; \qquad \Delta M_{xx} - \Delta M^i_{xx} = 0 \quad \text{or} \quad \frac{\partial \Delta w}{\partial x} = \frac{\partial \Delta \bar{w}}{\partial x}$$

$$\begin{aligned} &N_{xx}\frac{\partial \Delta w}{\partial x} + \Delta N_{xx}\frac{\partial w}{\partial x} + \Delta N_{xx}\frac{\partial \Delta w}{\partial x} + N_{xy}\frac{\partial \Delta w}{\partial y} + \\ &\Delta N_{xy}\frac{\partial w}{\partial y} + \Delta N_{xy}\frac{\partial \Delta w}{\partial y} + \frac{\partial \Delta M_{xx}}{\partial x} + 2\frac{\partial \Delta M_{xy}}{\partial y} + \Delta Q^i_{xx} = 0 \qquad \text{or} \qquad \Delta w = \Delta \bar{w} \end{aligned} \tag{5}$$

where $\bar{u}$, $\bar{v}$, and $\bar{w}$ are the external deformations at the edges; and $i = 0$ at $x = 0$ and $i = a$ at $x = a$. The general boundary conditions at $y = 0$ and $y = b$ are given by

$$\Delta N_{yy} + \Delta N^i_{yy} = 0 \quad \text{or} \quad \Delta v = \Delta \bar{v}; \qquad \Delta N_{xy} + \Delta N^i_{yx} = 0 \quad \text{or} \quad \Delta u = \Delta \bar{u}; \qquad \Delta M_{yy} - \Delta M^i_{yy} = 0 \quad \text{or} \quad \frac{\partial \Delta w}{\partial x} = \frac{\partial \Delta \bar{w}}{\partial x}$$

$$\begin{aligned} &N_{yy}\frac{\partial \Delta w}{\partial y} + \Delta N_{yy}\frac{\partial w}{\partial y} + \Delta N_{yy}\frac{\partial \Delta w}{\partial y} + N_{xy}\frac{\partial \Delta w}{\partial x} + \\ &\Delta N_{xy}\frac{\partial w}{\partial x} + \Delta N_{xy}\frac{\partial \Delta w}{\partial x} + \frac{\partial \Delta M_{yy}}{\partial y} + 2\frac{\partial \Delta M_{xy}}{\partial x} + \Delta Q^i_{yy} = 0 \qquad \text{or} \qquad \Delta w = \Delta \bar{w} \end{aligned} \tag{6}$$

where $\bar{u}$, $\bar{v}$ and $\bar{w}$ are the external deformations at the edges; and $i = 0$ at $y = 0$ and $i = b$ at $y = b$.

Constitutive relations

As mentioned before, the concrete is considered as linear viscoelastic, and the steel reinforcement is modelled as elastic. A rheological model which is based on the generalized Maxwell chain is used to formulate the long-term constitutive relations of concrete (Bažant and Wu 1974). The relaxation moduli can be approximated as follows:

$$R_{xx}(t,t') = \frac{E_c}{(1-\nu)\left[1+\varphi(t,t')\right]}; \qquad R_{yy}(t,t') = \frac{E_c}{(1-\nu)\left[1+\varphi(t,t')\right]}; \qquad R_{xy}(t,t') = \frac{G_c}{1+\varphi(t,t')} \tag{7}$$

where $R_{xx}(t,t')$, $R_{yy}(t,t')$ and $R_{xy}(t,t')$ are the relaxation moduli in x and y directions and xy plane; $\varphi(t,t')$ is the creep coefficient of the concrete at time t for a load applied at time t' ; E_c and G_c are the elastic and shear moduli of concrete and ν is the Poisson's ratio, which is assumed to be time-independent (Bazant 1988). Thus, due to the lack of experimental data regarding the creep behavior of concrete in shear, the latter is assumed to be similar to the creep behavior under normal stresses. The relaxation moduli can be expanded into Dirichlet series as follows:

$$R_{xx}(t,t') \approx \bar{R}_{xx}(t,t') = \sum_{\mu=1}^{m} E_\mu e^{-(t-t')/\tau_\mu} + E_{m+1} \quad ; \quad R_{yy}(t,t') \approx \bar{R}_{yy}(t,t') = \sum_{\mu=1}^{m} E_\mu e^{-(t-t')/\tau_\mu} + E_{m+1} \tag{8}$$

$$R_{xy}(t,t') \approx \bar{R}_{xy}(t,t') = \sum_{\mu=1}^{m} G_\mu e^{-(t-t')/\tau_\mu} + G_{m+1} \tag{9}$$

where $\bar{R}_{xx}$, $\bar{R}_{yy}$ and $\bar{R}_{xy}$ are the approximated relaxation moduli; E_μ and G_μ are the moduli of the μth spring in the Maxwell chain for the modelling in the normal and shear directions; m is the number of units; τ_μ is the relaxation time of the μth unit. Note that in this study, m and τ_μ are assumed to be identical in the normal and shear directions for simplicity. The incremental constitutive relations of plane stress state can be formulated as follows based on numerical time integration

$$\Delta\sigma_{xx}(t_r) = \frac{E''(t_r)}{1-\nu^2}\left[\Delta\varepsilon_{xx}(t_r) - \Delta\varepsilon''_{xx}(t_r) + \nu\left(\Delta\varepsilon_{yy}(t_r) - \Delta\varepsilon''_{yy}(t_r)\right)\right] \tag{10}$$

$$\Delta\sigma_{yy}(t_r) = \frac{E''(t_r)}{1-\nu^2}\left[\Delta\varepsilon_{yy}(t_r) - \Delta\varepsilon''_{yy}(t_r) + \nu\left(\Delta\varepsilon_{xx}(t_r) - \Delta\varepsilon''_{xx}(t_r)\right)\right]; \quad \Delta\sigma_{xy}(t_r) = G''(t_r)\left(\Delta\gamma_{xy}(t_r) - \Delta\gamma''_{xy}(t_r)\right) \tag{11}$$

where $E''_c(t_r)$ and $G''(t_r)$ are the pseudo normal and shear moduli, and $\Delta\varepsilon''_{xx}(t_r)$, $\Delta\varepsilon''_{yy}(t_r)$ and $\Delta\gamma''_{xy}(t_r)$ are the incremental prescribed normal strains in x and y directions and shear strain in the xy plane that includes the effect of creep. These are given by

$$E''(t_r) = \sum_{\mu=1}^{m}\left(1-e^{-\Delta t_r/\tau_\mu}\right)\frac{\tau_\mu}{\Delta t_r}E_\mu + E_{m+1}; \quad G''(t_r) = \sum_{\mu=1}^{m}\left(1-e^{-\Delta t_r/\tau_\mu}\right)\frac{\tau_\mu}{\Delta t_r}G_\mu + G_{m+1} \tag{12}$$

$$\Delta\varepsilon''_{xx}(t_r) = \frac{1}{E''(t_r)}\sum_{\mu=1}^{m}\left(1-e^{-\Delta t_r/\tau_\mu}\right)\left[\sigma_\mu^{xx}(t_{r-1}) - \nu\sigma_\mu^{yy}(t_{r-1})\right] \tag{13}$$

$$\Delta\varepsilon''_{yy}(t_r) = \frac{1}{E''(t_r)}\sum_{\mu=1}^{m}\left(1-e^{-\Delta t_r/\tau_\mu}\right)\left[\sigma_\mu^{yy}(t_{r-1}) - \nu\sigma_\mu^{xx}(t_{r-1})\right]; \quad \Delta\gamma''_{xy} = \frac{1}{G''(t_r)}\sum_{\mu=1}^{m}\left(1-e^{-\Delta t_r/\tau_\mu}\right)\sigma_\mu^{xy}(t_{r-1}) \tag{14}$$

$$\sigma_\mu^{xx}(t_r) = e^{-\Delta t_r/\tau_\mu}\sigma_\mu^{xx}(t_{r-1}) + \frac{E_\mu}{1-\nu^2}\left[\Delta\varepsilon_{xx}(t_r) + \nu\Delta\varepsilon_{yy}(t_r)\right]\left(1-e^{-\Delta t_r/\tau_\mu}\right)\frac{\tau_\mu}{\Delta t_r} \tag{15}$$

$$\sigma_\mu^{yy}(t_r) = e^{-\Delta t_r/\tau_\mu}\sigma_\mu^{yy}(t_{r-1}) + \frac{E_\mu}{1-\nu^2}\left[\Delta\varepsilon_{yy}(t_r) + \nu\Delta\varepsilon_{xx}(t_r)\right]\left(1-e^{-\Delta t_r/\tau_\mu}\right)\frac{\tau_\mu}{\Delta t_r} \tag{16}$$

$$\sigma_\mu^{xy}(t_r) = e^{-\Delta t_r/\tau_\mu}\sigma_\mu^{xy}(t_{r-1}) + G_\mu\Delta\gamma_{xy}(t_r)\left(1-e^{-\Delta t_r/\tau_\mu}\right)\frac{\tau_\mu}{\Delta t_r} \tag{17}$$

where σ_μ^{xx}, σ_μ^{yy} and σ_μ^{xy} are the stresses in the μth Maxwell unit. $G''(t_r)$ and G_μ are given by $G''(t_r) = E''(t_r)/[2(1+\nu)]$ and $G_\mu = E_\mu/[2(1+\nu)]$.

The constitutive relations at the cross-section level of the panel are determined using the classical definition of stress resultants and using the constitutive relations (Eqs 10 and 11) and the kinematic relations (Eq. 1) as follows:

$$\Delta N_{xx}(t_r) = C''\left[\frac{\partial\Delta u}{\partial x} + \frac{1}{2}\left(\frac{\partial\Delta w}{\partial x}\right)^2 + \frac{\partial w(t_{r-1})}{\partial x}\frac{\partial\Delta w}{\partial x} + \nu\left(\frac{\partial\Delta v}{\partial y} + \frac{1}{2}\left(\frac{\partial\Delta w}{\partial y}\right)^2 + \frac{\partial w(t_{r-1})}{\partial y}\frac{\partial\Delta w}{\partial y}\right)\right] - \Delta\bar{N}_{xx}(t_r) \tag{18}$$

$$\Delta N_{yy}(t_r) = C''\left[\frac{\partial\Delta v}{\partial y} + \frac{1}{2}\left(\frac{\partial\Delta w}{\partial y}\right)^2 + \frac{\partial w(t_{r-1})}{\partial y}\frac{\partial\Delta w}{\partial y} + \nu\left(\frac{\partial\Delta u}{\partial x} + \frac{1}{2}\left(\frac{\partial\Delta w}{\partial x}\right)^2 + \frac{\partial w(t_{r-1})}{\partial x}\frac{\partial\Delta w}{\partial x}\right)\right] - \Delta\bar{N}_{yy}(t_r) \tag{19}$$

$$\Delta N_{xy}(t_r) = \frac{1-\nu}{2}C''\left[\frac{\partial\Delta u}{\partial y} + \frac{\partial\Delta v}{\partial x} + \frac{\partial w(t_{r-1})}{\partial x}\frac{\partial\Delta w}{\partial y} + \frac{\partial w(t_{r-1})}{\partial y}\frac{\partial\Delta w}{\partial x} + \frac{\partial\Delta w}{\partial x}\frac{\partial\Delta w}{\partial y}\right] - \Delta\bar{N}_{xy}(t_r) \tag{20}$$

$$\Delta M_{xx}(t_r) = -D''\left(\frac{\partial^2\Delta w}{\partial x^2} + \nu\frac{\partial^2\Delta w}{\partial y^2}\right) - \Delta\bar{M}_{xx}(t_r); \qquad \Delta M_{yy}(t_r) = -D''\left(\frac{\partial^2\Delta w}{\partial y^2} + \nu\frac{\partial^2\Delta w}{\partial x^2}\right) - \Delta\bar{M}_{yy}(t_r) \tag{21}$$

$$\Delta M_{xy}(t_r) = -(1-\nu)D''\frac{\partial^2\Delta w}{\partial x\partial y} - \Delta\bar{M}_{xy}(t_r) \tag{22}$$

where C'' and D'' are axial and flexural viscoelastic rigidities of the two-way panel; $\Delta\bar{N}_{xx}(t_r)$, $\Delta\bar{N}_{yy}(t_r)$ are the incremental effective axial forces in the x and y directions and $\Delta\bar{N}_{xy}(t_r)$ is the incremental effective shear force in

the *xy* plane; $\Delta\bar{M}_{xx}(t_r)$ and $\Delta\bar{M}_{yy}(t_r)$ are the incremental effective bending moments along *x* and *y* axis and $\Delta\bar{M}_{xy}(t_r)$ is the incremental effective torsional bending moment. Note that the forces and bending moments are defined as the distributions of these quantities per unit width. The viscoelastic rigidities, which account for the internal reinforcement, are given by

$$C'' = \frac{E''}{1-\nu^2}\left[h + (n-1)A_s / b + (n-1)A_s' / b\right]; \quad D'' = \frac{E''}{1-\nu^2}\left[\frac{h^3}{12} + (n-1)A_s z_s^2 / b + (n-1)A_s' z_s'^2 / b\right] \tag{23}$$

where *h* is the thickness of the panel; $n = E_s / E''$, E_s is elastic modulus of steel reinforcement; A_s and A_s' are the areas of the steel reinforcements at the inner and outer faces of the panel; z_s and z_s' are the locations of the corresponding reinforcements measured from the mid-thickness of the panel. For simplicity, A_s and A_s' are taken as the minimum reinforcement ratios between *x* and *y* directions. The effective forces and bending moments are given as

$$\Delta\bar{N}_{xx}(t_r) = \sum_{\mu=1}^{m}\left(1-e^{-\Delta t_r/\tau_\mu}\right)N_\mu^{xx}(t_{r-1}) + \int_{-\frac{h}{2}}^{\frac{h}{2}} \frac{E''(t_r)}{1-\nu}\Delta\varepsilon_{sh}\mathrm{d}z; \quad \Delta\bar{N}_{yy}(t_r) = \sum_{\mu=1}^{m}\left(1-e^{-\Delta t_r/\tau_\mu}\right)N_\mu^{yy}(t_{r-1}) + \int_{-\frac{h}{2}}^{\frac{h}{2}} \frac{E''(t_r)}{1-\nu}\Delta\varepsilon_{sh}\mathrm{d}z \tag{24}$$

$$\Delta\bar{N}_{xy}(t_r) = \sum_{\mu=1}^{m}\left(1-e^{-\Delta t_r/\tau_\mu}\right)N_\mu^{xy}(t_{r-1}) + \int_{-\frac{h}{2}}^{\frac{h}{2}} \frac{E''(t_r)}{2(1+\nu)}\Delta\varepsilon_{sh}\mathrm{d}z; \quad \Delta\bar{M}_{xx}(t_r) = \sum_{\mu=1}^{m}\left(1-e^{-\Delta t_r/\tau_\mu}\right)M_\mu^{xx}(t_{r-1}) + \int_{-\frac{h}{2}}^{\frac{h}{2}} \frac{E''(t_r)z}{1-\nu}\Delta\varepsilon_{sh}\mathrm{d}z \tag{25}$$

$$\Delta\bar{M}_{yy}(t_r) = \sum_{\mu=1}^{m}\left(1-e^{-\Delta t_r/\tau_\mu}\right)M_\mu^{yy}(t_{r-1}) + \int_{-\frac{h}{2}}^{\frac{h}{2}} \frac{E''(t_r)z}{1-\nu}\Delta\varepsilon_{sh}\mathrm{d}z; \quad \Delta\bar{M}_{xy}(t_r) = \sum_{\mu=1}^{m}\left(1-e^{-\Delta t_r/\tau_\mu}\right)M_\mu^{xy}(t_{r-1}) + \int_{-\frac{h}{2}}^{\frac{h}{2}} \frac{E''(t_r)z}{2(1+\nu)}\Delta\varepsilon_{sh}\mathrm{d}z \tag{26}$$

Governing Equations

The incremental governing equations are formulated by substitution of the stress resultants (Eqs 18-22) into the equilibrium equations (Eqs 3 and 4), noting that terms of higher product of the incremental displacements and forces are neglected due to the use of sufficiently small time increments. The incremental governing equations are partial differential equations in terms of the unknown displacements:

$$\psi_p\left(\Delta u,\ \Delta v,\ \Delta w\right) = 0 \qquad \left(p = 1,\ 2,\ 3\right) \tag{27}$$

where ψ_p consists of differential operators. For brevity, the explicit form of these equations is not presented here. The equations and the boundary conditions (Eqs 5 and 6) are reduced to a set of ordinary differential equations by a separation of variables and expansion into the truncated Fourier series (Hong and Teng 2002; Hamed et al., 2010).

$$\left\{\Delta u(x,y),\ \Delta v(x,y),\ \Delta w(x,y)\right\} = \sum_{m=1}^{2F}\left\{\Delta u_m(x),\ \Delta v_m(x),\ \Delta w_m(x)\right\}g_m(y) \tag{28}$$

where F = (F_u, F_v, or F_w) is the number of terms in the relevant Fourier series. The initial state or previous accumulated displacements and the external loads along the panel and at the boundaries take the following form

$$\left\{u(x,y),\ v(x,y),\ w(x,y)\right\} = \sum_{m=1}^{2F}\left\{u_m(x),\ v_m(x),\ w_m(x)\right\}g_m(y) \tag{29}$$

$$\begin{Bmatrix} Q_{xx}^0(x,y),\ Q_{xx}^a(x,y), N_{xx}^0(x,y), \\ N_{xx}^a(x,y), M_{xx}^0(x,y),\ M_{xx}^a(x,y) \end{Bmatrix} = \sum_{m=1}^{2F}\begin{Bmatrix} Q_{xxm}^0(x),\ Q_{xxm}^a(x), N_{xxm}^0(x), \\ N_{xxm}^a(x), M_{xxm}^0(x),\ M_{xxm}^a(x) \end{Bmatrix} g_m(y)$$

$$\begin{Bmatrix} Q_{yy}^0(x,y),\ Q_{yy}^b(x,y), N_{yy}^0(x,y), \\ N_{yy}^b(x,y), M_{yy}^0(x,y),\ M_{yy}^b(x,y) \end{Bmatrix} = \sum_{m=1}^{2F}\begin{Bmatrix} Q_{yym}^0(x),\ Q_{yym}^b(x), N_{yym}^0(x), \\ N_{yym}^b(x), M_{yym}^0(x),\ M_{yym}^b(x) \end{Bmatrix} g_m(y) \tag{30}$$

$$q_z(x,y) = \sum_{m=1}^{2F} q_{zm}(x)g_m(y)$$

The functions $g_m(y)$ are

$$g_m(y) = \begin{cases} \sin\left(\dfrac{m\pi}{b}y\right) & m = 1, 2, \ldots, F \\ \cos\left[\dfrac{(m-F)\pi}{b}y\right] & m = F+1, F+2, \ldots, 2F \end{cases} \tag{31}$$

By minimizing the errors due to the truncated Fourier series by the Galerkin procedure with trigonometric weighting functions, the partial differential equations are converted into linear ordinary differential equations in the x direction:

$$\Psi_p^m(x) = \int_0^b \psi_p\left(u,\ v,\ w\right) g_m(y)\mathrm{d}y \qquad \left(p = 1,\ 2,\ 3;\ \ m = 1, 2, ..., 2F\right) \tag{32}$$

The governing equations along with the boundary conditions are solved through the use of the multiple shooting method at each time step (Stoer and Bulirsch 2002). The analysis presented here is also conducted up to a certain time (the critical time) where the deformations of the system exceed a prescribed limit (Hoff 1958; Bažant and Cedolin 1991). A proper time step is selected for a given load level in the way that the difference between the predicted critical times of creep buckling for the selected time-step and one-half of it is of minor significance.

NUMERICAL STUDY

The governing equations derived in Eq. 27 and the solution procedures proposed in Eqs 28-31 are generally applicable for any combinations of loading scenarios and boundary conditions. Here, a square panel that is simply-supported on four edges and subjected to an in-pane eccentric compression load in the x direction only, as shown in Figure 2, is investigated. For this particular case, only the first term of the Fourier series is considered.

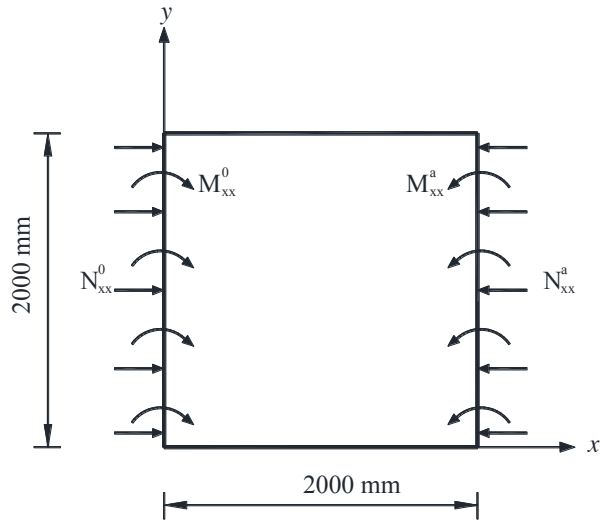

Figure 2 HSC panel used in numerical study: simply-supported on four edges and loaded by uniformly distributed eccentric compression forces in the x direction

The thickness of the panel is 100 mm. There are two layers of steel reinforcement in both orthogonal directions, placed at top and bottom of the specimen. The reinforcement ratios in the x and y directions (ρ_x and ρ_y), where $\rho_x = (A_{sx} + A'_{sx})/bh$ and $\rho_y = (A_{sy} + A'_{sy})/ah$, are both 0.2% and the reinforcement at the top and bottom layers in each direction are equal. The concrete cover is 20 mm and the elastic modulus of the steel is 200 GPa, respectively. The panel is assumed to be loaded at the age of 28 days after casting with $N^0_{xx} = N^a_{xx} = 20.3$ kN/mm. The applied load equals to 60% of the instantaneous classical buckling load (P_{cr} = 33.9 kN/mm), that is determined as follows (Dym and Shame 2013):

$$P_{cr} = \frac{4D''\pi^2}{b^2} = \frac{4\pi^2}{b^2}\frac{E_c}{1-\nu^2}\left[\frac{h^3}{12} + (n-1)A_s z_s^2 / b + (n-1)A'_s z'^2_s / b\right] \tag{33}$$

The load eccentricity is $e = h/6 = 16.7$ mm, which results in edge moments of $M^0_{xx} = M^a_{xx} = 339$ kNm/m (Figure 2). The development with time of the creep coefficient is calculated according to AS3600 (2009) as follows

$$\varphi(t) = \frac{1.45t^{0.8}}{t^{0.8} + 17} \tag{34}$$

The number of Maxwell units (m) used to model the viscoelastic behavior of concrete is taken as five in this example with $\tau_\mu = 5^{\mu-1}$ (days). The spring constants in the Maxwell model obtained by the least squares methods are E_1 = 1684 MPa, E_2 = 7537 MPa, E_3 = 8674 MPa, E_4 = 4050 MPa, E_5 = 1199 MPa, E_6 = 16287 MPa.

The time-dependent variation of the out-of-plane deflection and the bending moments at the center of the panel are shown in Figure 3. The time t is measured from the time of first loading. The deflection is normalized with respect to the thickness of the panel h. It can be seen that the deflection of the panel and hence the bending moments M_{xx} and M_{yy} increase with time as a result of the combined effects of creep and geometric nonlinearity. Similar to the one-way panel, the out-of-plane deflection as well as the bending moments exhibit unlimited asymptotical increase beyond a certain time. The criterion for critical time of buckling failure adopted here is when the normalized out-of-plane deflection (w/h) reaches a given limit (Hoff 1958; Bažant and Cedolin 1991). The limit in this numerical study is taken as 4 and the corresponding time, referred to as the critical time, equals 1400 days in this case. As indicated in Figure 3d, the ratio of M_{xx}/M_{yy} also increases with time, which implies that stress redistribution occurs with time and the influence of the geometric nonlinearity becomes more pronounced in the x direction than in the y direction.

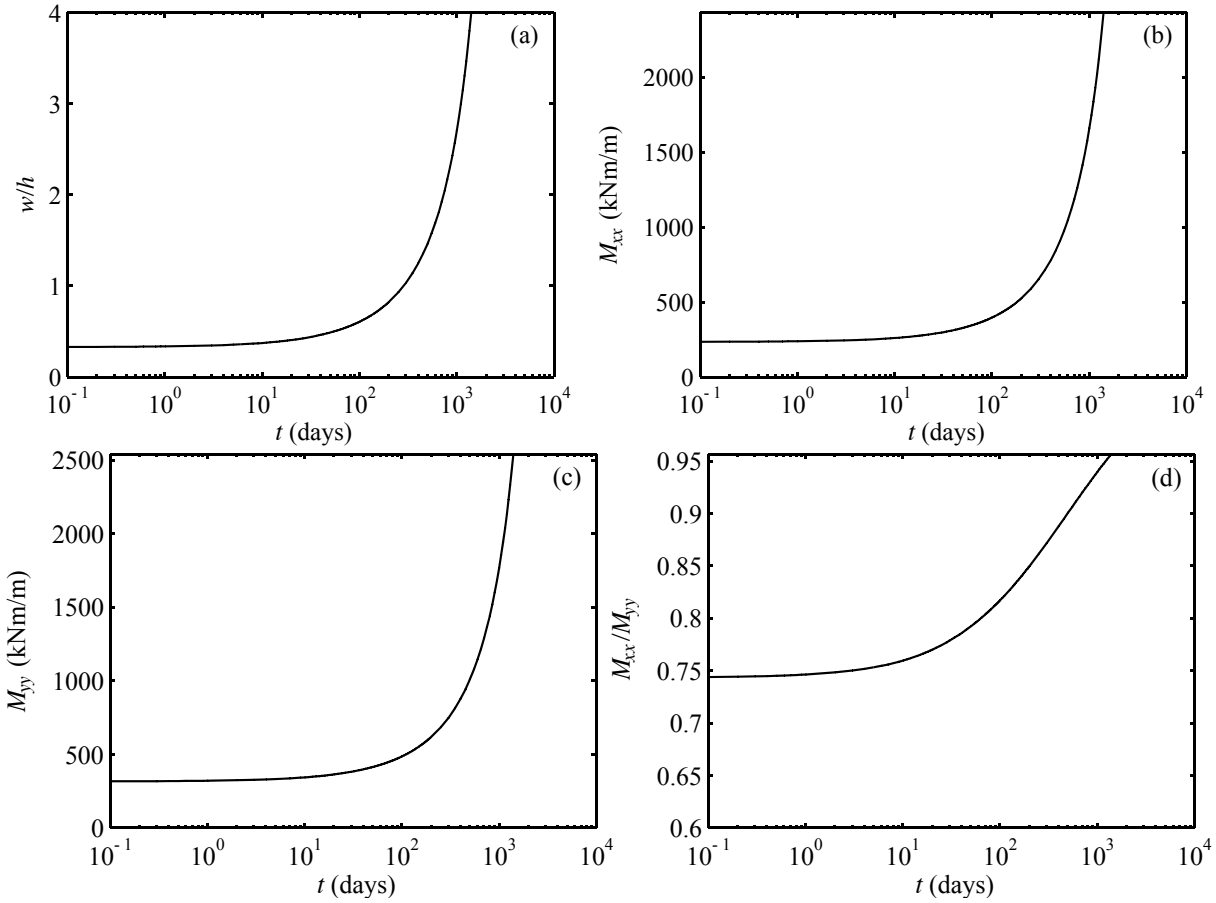

Figure 3 Variation with time of the (a) out-of-plane deflection; (b) bending moment M_{xx}; (c) the bending moment M_{yy}; (d) the ratio of M_{xx}/M_{yy} at the center of the panel

A parametric study is conducted here to examine the effects of key parameters on the time-dependent response of HSC panels. The parameters include the magnitude and eccentricity of the sustained in-plane load (N_{xx}^{0}) and the slenderness ratio defined as a/h. The panel investigated in the numerical example is used as a reference and the reinforcement ratio is constant.

Figure 4 presents the influence of the level of the sustained load on the time-dependent behaviour. It can be seen that the increase of the imposed load level leads to earlier occurrence of buckling (shorter critical time). It can also be observed that the panel studied here is stable in the long run under a load level that is lower than 50% of the elastic buckling load P_{cr}, as the increase in the out-of-plane deflection becomes insignificant after a certain time, which can be critical for the design of HSC panels. The minimum load level to cause creep buckling for the examined panel is 51% of its elastic buckling load. This result is in accordance with that obtained using the simplified Effective Modulus Method (EMM), where E_c in Eq. 33 is replaced with $E_c / \left[1+\varphi(t,t')\right]$.

Nevertheless, if cracking is taken into account or biaxial loading scenarios are considered, the simplified effective modulus method might lead to inaccurate results.

Figure 5 reveals the change of the out-of-plane deflection at the centre of the square panel with time under the in-plane compression load with different eccentricities. The load is equal to 52% of the elastic buckling load. As seen in the figure, the time-dependent behaviour is very sensitive to the eccentricity. Thus, it is essential in the design to consider different load scenarios as small inaccuracy in estimating the actual load eccentricity may result in catastrophic buckling failure in the long term.

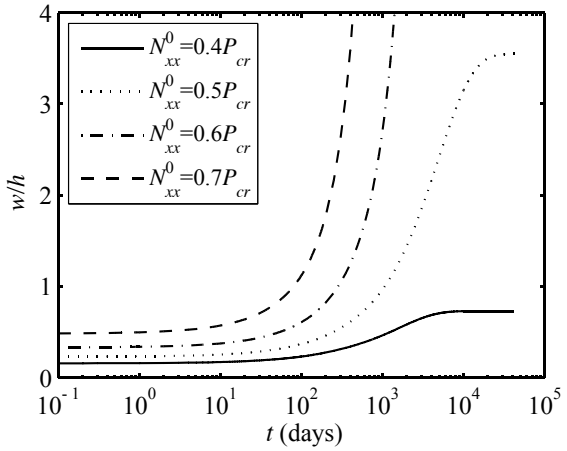

Figure 4 Influence of load level ($e = h/6$, $[\rho_x, \rho_y] = 0.2\%$, $a \times b \times h = 2000 \times 2000 \times 100$ mm)

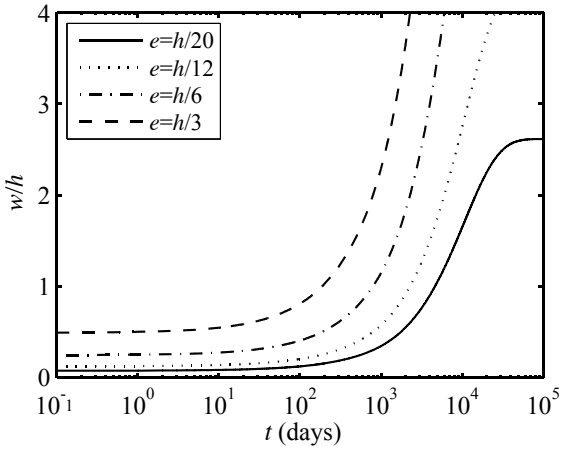

Figure 5 Influence of load eccentricity ($N^0_{xx} = 0.52P_{cr}$, $[\rho_x, \rho_y] = 0.2\%$, $a \times b \times h = 2000 \times 2000 \times 100$ mm)

The normalized deflection at the center of the panels with various thicknesses is plotted against time in Figure 6 for investigating the effect of slenderness of the panel. The load level, the eccentricity as well as the reinforcement ratios in both orthogonal directions are $0.6P_{cr}$, $h/6$, and 0.2%, respectively, where P_{cr} is the elastic buckling load corresponding to the panel with 100 mm thickness in order to keep the load unchanged for the three different cases. The slenderness ratio is defined as a/h. Three different thicknesses 90 mm, 100 mm and 120 mm are investigated, which yield slenderness ratios of 22.2, 20 and 16.7, respectively. It can be seen that under the same magnitude of sustained load, the panels that are 90 mm and 100 mm thick are unstable whereas the panel with 120 mm thickness exhibits stable behavior. For the unstable panels, the critical time increases with increasing the thickness. Therefore, in practical design and use of two-way panels, the creep buckling failure can be potentially prevented by slightly increasing the thickness of the panel.

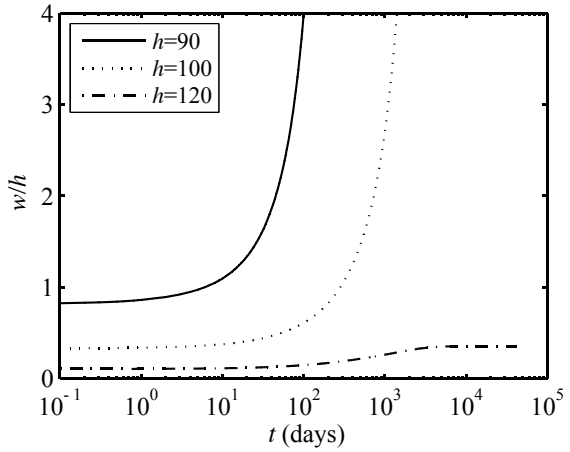

Figure 6 Influences of slenderness ($N_{xx}^{0} = 0.6P_{cr}$, $e = h/6$, $[\rho_x, \rho_y] = 0.2\%$, $a \times b = 2000 \times 2000$ mm)

CONCLUSIONS

A theoretical model is developed in this paper for the time-dependent analysis of two-way HSC panels. Creep of the concrete is accounted for through a rheological viscoelastic model. The model considers the geometric nonlinearity and describes the variation of the internal stresses with time through a step-by-step time analysis. It has been shown in the numerical study that the increase of out-of-plane deflection and the internal bending moments may lead to creep buckling failures under axial sustained loads that are as low as 50% of the instantaneous classical buckling load. The parametric study reveals that the creep buckling response of HSC panels is very sensitive to key parameters including the load level and eccentricity as well as the slenderness ratio.

ABSTRACT

This paper describes the behaviour of selective steel storage racking systems in the cross-aisle direction. Steel storage racks are regular kind of equipment; these systems are developed for enhancing the storage of load units in diverse weights and sizes. In most cases in this study, the boundary conditions assumed fixed on their fundamental state, to prevent from any possible moment – rotation and uplift effects on uprights. Finite element method (FEM) modeling was used to analyze and evaluate the natural frequency of diagonally k-braced frame at cross-aisle direction. This report takes advantage of capabilities of two well-known structural analysis software for FEM modeling: Abaqus and Strand7. The objective is to predict and determine the eigenvalues and natural frequencies of selective steel storage racks in the cross-aisle direction. Taking the fact into account that the reaction of the structure under seismic loads is vitally important at this critical direction, this paper will provide a better view for designing these type of structures in the future. The novelty of this paper is to classify conditions where we could avoid creating any possible resonance in the structure.

KEYWORDS

Selective steel storage racks, natural frequency, cross-aisle direction, structural optimization, finite element analysis.

INTRODUCTION

Steel storage racking systems are facilities used in approximately 40% of the manufacture, distribution and consumption cycle of all products, these systems are developed for enhancing the storing load units in diverse weights and sizes. Selective rack systems are very cost-effective and offer suitable accessibility of all stored goods for all periods of time during their life-cycle. It is an ideal system where full selectivity and speed of operation are the key objectives, with the added advantages of ease of customization and adjustability. These features made selective racks the most common type of storage racks in use today. However, there is a problem with these systems, their natural frequency is relatively high when seismic loading applies and limited guidelines for their design is available. Racks are challenging to design because they are built as lightly as possible,but are very heavily loaded, and they can fail and collapse for a range of reasons. This paper aims to determine the forces leading to these collapses and providing a better view for the design of these structures accordingly. A standard selective storage racking system is illustrated in Figure 1.

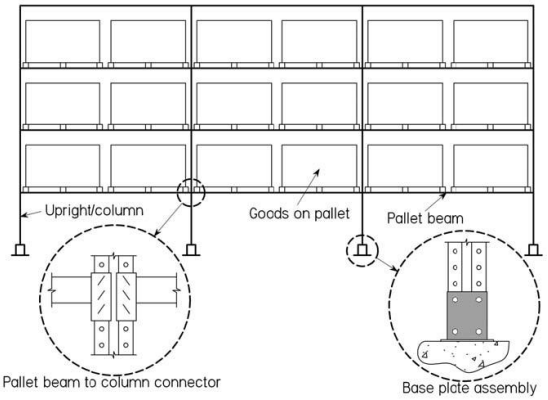

Figure1 Standard selective storage rack (Gilbert and Rasmussen 2012)

Uprights at racking systems are typically made of thin-walled cold-formed steel sections that contain ranges of holes along the longitudinal axis of the member. The perforations can be assumed as a kind of undesirable features which has to be supposed in addition to the other type of imperfections. Therefore, a perforated section

is further ‘‘imperfect’’ over an unperforated one (Crisan et al. 2012). Uprights and load beams are the main parts of selective pallet racks. The upright capacity needs to be higher than the overall capacities of the load beams in a “bay” or section of rack, and is a factor of the type of steel, and the depth and height of the upright. The standard height of an upright frame starts from 3 meters to 12 meters, and covers the working compression load from 7.5 to 12.5 tons per frame. Similarly, there is a wide range of standard working load for beams from 1 to 4 tons per level (Australian Standard AS 4048 2012).

Selective racks are free standing assemblies that carry gravity loads, placement and impact forces and possibly seismic forces. In the cross-aisle direction (lateral direction), the uprights are linked together by bracing members. It is highly possible for the uprights to be influenced by lateral forces and consequently deflect and fail sideways. In the down-aisle direction (longitudinal direction), the frame is normally designed as a moment resisting frame. Since steel storage racks are typically unbraced in the down-aisle direction, the stability relies heavily on the beam to column joints and the connection at the point of base plate (Freitas et al. 2010). It was found that the capacity of energy dissipation and ductility for storage racks is much greater in the down-aisle moment-resisting direction in comparison to cross-aisle braced frame direction (FEMA 460 2005).

In steel storage racking systems, lateral stiffness in the down-aisle direction is ordinarily provided by beam-to-column joints and base-plate connections. Baseplate joints have great influence on the overall rack response and, therefore, more tests should be conducted on the behaviour of the column base restraint to achieve more data. In most cases, joints should be modeled as hinges (Baldassino and Bernuzzi 2000). Trouncer carried out several experimental investigations on uprights, and according to the nature of the buckling tests and defined pinned boundary conditions for the major principal axis, it was discovered that overall buckling was the dominant failure mode, regardless of the length of the specimen tested. However for the shorter sections, both local and distortional buckling typically occurred well before overall buckling, meaning that there was an interaction between the buckling modes which lead to a reduction in the upright’s axial stiffness (Trouncer 2013).

The objective of this paper is to attain a better view on the behaviour of steel storage rack structure in cross-aisle direction, with the main focus on evaluating the natural frequency and the overall response of the system, which could be the most critical direction for any failure in these types of structures. This will provide better solutions for designing these types of structures in the future.

METHODOLOGY

Finite Element Modelling of Selective Steel Storage Rack

To attain “Natural Frequency” and different modes of the structure in free vibration condition, two finite element method (FEM) modeling software were used for analyzing and evaluating behaviour of the rack frame in cross-aisle direction, respectively Abaqus and Strand 7. Boundary conditions assumed fixed for preventing from any moment – rotation and uplift effects on uprights in both of Abaqus and Strand 7 software. To study the natural frequency of the structure through FEM, the step for analysis defined as “Linear Perturbation – Frequency” in Abaqus. However, the solver assumed “Static Solver” for doing analysis in Strand 7.

Model Geometry and Element Types

The units for modeling considered SI units, newton (N) and meter (M) throughout all modeling. The length of upright at all models assumed generally 5.8 m for RF9015 standard section. Howerver, The length of bracing considered 1176 mm for diagonal bracing and 992 mm for horizontal bracing. The side view of rack model illustrates at Figure 2.

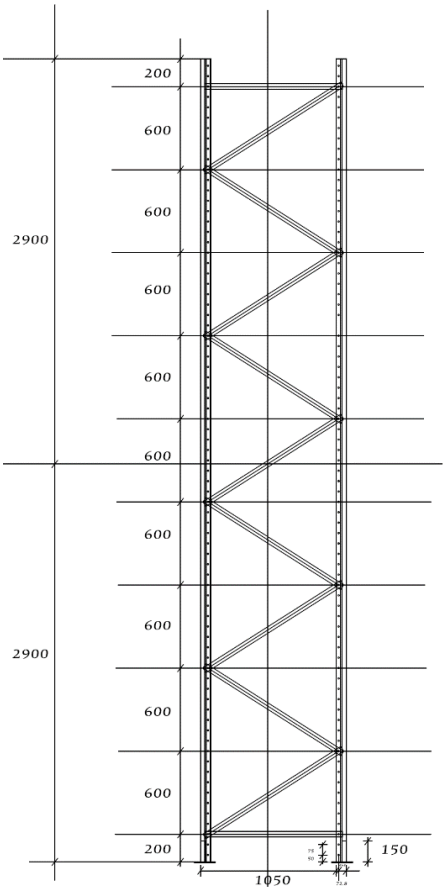

Figure 2 Side view of model

In Abaqus modeling, uprights and bracing defined as “Shell Element”. Similarly, in Strand 7 modeling, upright defined as “Shell Element”, while bracing is considered as “Beam Element”. In a whole rack system analysis in Strand 7, the distance between two frames assumed 2.4 m, while 1.5 m assumed as a constant distance between two diaphragms.

Materials and Sections Properties

Table 1 presents section properties for upright used in modeling.

Table 1 Upright with lip stiffener section properties

Name	Depth (mm)	Width (mm)	Lip (mm)	Thickness (mm)
RF9015	88.5	72.8	15.5	1.5
Area (mm^2)	$I_{Principal-axis}$ ($10^6 \times mm^4$)	$I_{Minor-axis}$ ($10^6 \times mm^4$)	J (mm^4)	I_w ($10^6 \times mm^6$)
413	0.0435	0.0284	310	59.2

Table 2 determines section properties for bracing cee section used in modeling.

Table 2 Cee section properties

Name	Depth (mm)	Width (mm)	Lip (mm)	Thickness (mm)
Cee Section	40	23	7	1.5

Table 3 indicates material properties for different elements in modeling.

Table 3 material properties

Element Type	E (MPa)	Poisson’s Ratio	ρ (kg/m^3)
Upright	225E3	0.25	7850
Bracing	200E3	0.25	7850

Since the main focus of this study was evaluating the overall response of steel storage rack structure systems, in case of modeling and analysis in the Strand 7 software, uprights modeled without any perforation details which seems to have minor effect on natural frequency analysis results of the structure.

RESULTS AND DISCUSSIONS

The finite element method is a powerful numerical technique that uses variations and interpolation methods for modeling and solving boundary value problems associated with distributed-parameter vibration problems. This method is also extremely useful for complicated structures with unusual geometric shapes such as trusses and frames (Inman 2013).

Free vibration occurs when a mechanical system is set off with an initial input and then allowed to vibrate freely. Natural frequency is the frequency at which a system naturally vibrates once it has been set into motion, a key aspect of structural dynamic analysis concerns the behaviour of a structure at "resonance". Resonance occurs when the forced vibration of an object matches the natural frequency of the self-weight of the structure. In general, the total value of any response is the combination of the contributions of all the vibration modes. Mass and stiffness are two important factors for determining the natural frequency. Moreover, length of structural elements and speed of vibration wave has a great impact on the natural frequency of a structure (Randall 1987). The first modes should always consider as the most critical mode for designing rack structures.

The results for natural frequency analysis are entirely conservative and could just be considered as a starting point for getting more familiar with the behaviour of the steel storage rack systems. These results clarify some possible vibration modes and approximate deformation of the structure under self-weight free vibration condition.

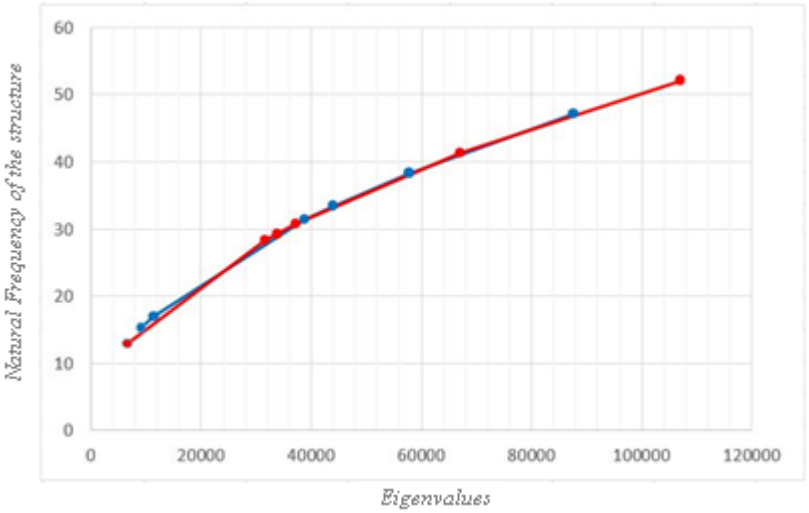

Figure 6 Eigenvalue and natural frequency diagram

Figure 6 illustrates that there is a logarithmic relation between eigenvalues and natural frequencies of the rack structures. The blue line illustrates In-plane restraint frame analysis and red line indicates values for whole rack system analysis , which coincide with each other, this resemblance confirms the validity and accuracy of the results. And generally shows that both of value increases with each other in a logarithmic trend which indicates upper limits for designing the rack structure.

The friction force between pallets and rail beams makes pallets act as links to connect adjacent rack uprights, so the pallets are beneficial factors to increase the lateral stiffness of storage racks. Compared with unloaded racks, the natural frequencies of loaded racks are smaller (Cheng and Wu 2013).

The vibration response can be reduced by achieving certain spacing between two adjacent natural frequencies. For instance, when the excitation frequency lies between two natural frequencies, the suitable design is to maximize the distance between the excitation frequency and the nearest higher and the nearest lower frequency. The natural frequencies of structures can be modified by different methods such as changing the boundary conditions and adding internal supports, adding auxiliary structures, such as masses and springs and changing the structural geometry, thickness and modulus of elasticity (Bendsoe and Olhof 1985).

Lower frequencies means the structure takes more time to return to its initial (pre excited) situation which means that the structure is in a more vulnerable situation to seismic load and have more capacity of critical fracture, deformation and displacement. One of the main limitation is the material capacity to deform plastically without any fractures or cracks.

It is vitally significant to find resilient design solutions for shifting a natural frequency of the structure, to avoid a coincidence between an excitation and a modal response. Reaching higher range of frequency at last modes for a structure means that the structure has a greater natural potential for damping lower frequencies and applied

forces which put the structure in a safer situation in terms of structural stability, strength and steadiness. The Period and frequency of a structure had a reverse relationship with each other, it means that structure with lower natural frequency has longer one cycle vibration period. We cannot change a lot on the quantity of mass of the structure, but we can optimize the damping and internal stiffness of a structure for a better sustainable and desirable design.

All Structures undergo some shape changes under load. In stable structure the deformations induced by the load are typically small, and internal forces are generated in the structure by the action of the load that tend to restore the structure to its original shape after the load has been removed (Schodek and Bechthold 2014).

Lack of restraining causes relatively low frequency which means higher possibility of torsion, bending and huge dispalement , which could ultimately resulted in catastrophic deformation and buckling in the structure. The natural frequency analysis for in-plane restraint single perforated upright could be consider as an example for this case, that behave like a cantilver beam.

Bracing an upright changes its buckling mode and consequently its effective length. The more an upright is braced, the shorter its effective length becomes and the greater the load that is required to cause buckling. Bracing is usually more effective when placed symmetrically (Schodek and Bechthold 2014).

The bracing configuration plays a great role in the natural frequency of rack structures, plan bracings at the top and spine bracings at the back of the rack can change the load transfer through the rack framework, strengthen the initial lateral stiffness of racks, but only back spine bracings can affect the natural frequency and damping ratio of racks (Gilbert and Rasmussen 2009). Furthermore, using x-bracing or double bracing ideas could be so hepful for imporving seismic behaviour of rack structures in the cross-aisle direction.Experimental studies revealed that the seismic response of rack systems in the down-aisle direction is greatly influenced by nonlinear moment-rotation response of the beam to upright connections. However, the seismic response in the cross-aisle direction relies on the specifications of the bracing members used in the truss arrangement (FEMA 460 2005).

As a general rule in structural analysis, higher stiffness at structure results in higher and more critical natural frequencies. So it is beneficial to decrease the natural frequency of rack structures through having a relatively ductile base plates, allowing a bit uplift at the base point of uprights and improving the overall response of the frame in the cross-aisle direction under high seismic loads.

The Natural frequency of vibration increases by structural stiffness and steadiness. The greater the displacements, the greater the stresses that are developed in the framing members and connections of the structure. Reinforcing the structure and uncoupling the vibration sources are the two main options to correct those problems which greatly reduce the vibration amplitude by stiffening the structure (Schodek and Bechthold 2014).

It is highly essential to damp out the mechanical motions through flexible competent structural design and using damping equipment. For instance, perforation in steel storage rack structure's upright plays a great role for flexibility of uprights for deforming and absorb and damp seismic energy beside the main role that have on the adjustability of setting a desirable configuration for racks. However, they are currently considered as a structural imperfection. Taking the fact into account that, this kind of design shouldn't pass the boundaries of strength and affects the ideal performance of the structure. This topic should be considered as a real concern and boundary for future design optimization of steel storage racks.

One of most common procedures for decreasing effects of seismic loads is base isolation, which diminishes the horizontal acceleration in structures. Filiatrault et al. accomplished tests on anchored and base-isolated steel pallet storage racks. The instrument operated in the tests provided base isolation in the cross-aisle direction, while the down-aisle direction had similar restraint conditions as the conventional ones. The structures with cross-aisle base isolation showed better seismic performance by reducing the cross-aisle absolute accelerations and inter-story drifts (Filiatrault et al. 2006). More experimental and numerical studies should conduct for revealing capability and weakness of these structures for damping forced vibrations. The natural frequency and damping ratio are not only important in free vibration, but also characterize how a system will behave under forced vibration. If no damping exists, there is nothing to dissipate the energy and therefore theoretically the motion will continue to grow on into infinity (Schodek and Bechthold 2014).

This study evaluated the natural frequency of the structure in the cross-aisle direction, for the first time through FEM modeling that could be the main strength of this research. Which it was not possible through analytical and experimental procedures.

CONCLUSIONS

This paper could suggest a simplified method to predict the natural frequency of the rack system. By considering author's knowledge, currently there are quite limited number of published papers that predicted natural frequency of rack structures. The novelty of this paper is to classify conditions where we could avoid creating any possible resonance in the structure. Accuracy was the first priority of the author in these series of modeling. At every step of modeling, it was hardly tried that come up with models that be accurate as much as possible. Furthermore, geometry and properties defined as closest as possible to the real case situation.

This kind of calculation of natural frequency for rack systems could be useful to find out critical vibration modes of the structure and provide a better overall view for the design of this type of structure. This would prevent conditions that could lead to the resonance phenomenon of the structure due to external forces or seismic loading.

This paper also could be helpful to recognize the location of the week points at the structure and improve the design guidelines in that area to optimize behavior of structure under seismic loads and providing better structural solutions. This method of modeling could be extended to the full selective rack systems on larger scales and also could be useful for the studies on behaviour of drive-in rack systems.

Ductility and flexibility as a general idea could be a great solution for improving the overall response of these structures. In turn, this will decrease the quantity of the natural frequency during free vibration of these structures.

From a writer's point of view, some complementary modelling and numerical analysis should be conducted for validating and improving the accuracy of results for design guidelines. It is also highly recommended that the results compare and get updated with some possible corresponding experimental and analytical analyses to attain better views on the topic. Some of natural frequency modes (combination of flexural and torsional condition) are still vague and needs to further researches undertaken in this area.

It is also recommended that other damping possibilities should studied at rack systems for near resonance vibrations to provide some solutions for decreasing natural frequencies. This effect naturally occurs through deflection of members in the absence of any damping equipment such as base isolation and viscous damper ideas at general steel structures. Furthermore, Hand calculating critical value for buckling either as single columns or as a group of columns needs to be taken into account for further studies.

ABSTRACT

Despite many papers on the structural response of thin circular sections, the effect of large imperfections – largely imposed due to damage, collisions, etc. – still leaves many open questions. Over the past few years however, there has been a significant body of tests on steel members with large imperfections, conducted by the authors at the *University of Tasmania*, with a particular focus on circular hollow sections under different loading conditions. The effect of geometrical irregularities of such structures was examined and subsequently presented in several papers. This paper incorporates these new advances into an organized summary, including key findings of the mentioned experimental data on the effect of local damages on the capacity of different structures with various geometrical features. Discussions are presented on the topic and some general recommendations made in relation to real structures in practice.

KEYWORDS

Steel, thin shells/tubes, damage, dent imperfection.

INTRODUCTION

Numerous papers have investigated the effect of different types of imperfections on steel structures. Prabu et al. studied buckling of dented steel cylindrical shells under axial compression (Prabu, Raviprakash et al. 2010), showing an adverse effect of the dent imperfection. Gavrilenko and V. L. Krasovskii studied the effect of a single local dent on steel cylindrical shells (Gavrilenko and Krasovskii 2004). The proposed method in this study was found to be effective to estimate the capacity of the dented structures within a specific range of the geometry. Furthermore, Karroum et al. studied indentation of thin cylinders in which wedge-shaped indenters were employed (Karroum, Reid et al. 2007). FE and experimental methodologies were conducted to identify the failure. Paik studied the residual stress of dented elements (Paik 2014), in which FE computations and test observations were thoroughly discussed on the models.

Lately, 27 specimens were tested by the authors where the buckling behavior of thin cylindrical shells was evaluated under compression (Ghanbari Ghazijahani, Jiao et al. 2014). The capacity decrease of such structures was also set forth in this research. The authors examined the bending capacity of damaged CHS tubes (Ghanbari Ghazijahani, Jiao et al. 2015), wherein the effect of dent imperfection was thoroughly studied. Further studies investigating dented shell structures subject to pressure can be seen in Refs. (Ghanbari Ghazijahani and Showkati 2013, Rathinam and Prabu 2013, Ghanbari Ghazijahani, Jiao et al. 2014), in which the capacity reduction was obtained for the imperfect models. Plastic buckling of locally damaged steel tubes was investigated by the authors (Ghanbari Ghazijahani, Jiao et al. 2015). The effect of the damage imperfections and the results of this study will be discussed in detail in the coming sections.

Fabrication type imperfections mostly under axial compression are found in numerous paper, e.g. (Hutchinson, Muggeridge et al. 1971, Brush and Almroth 1975, Calladine 1989, Deml and Wunderlich 1997, Holst, Rotter et al. 1999, Holst 2011, Ghanbari Ghazijahani and Showkati 2012, Ghanbari Ghazijahani and Showkati 2013) in which the capacity and failure modes of different structures were expounded upon. Two innovative methods were proposed to investigate imperfect shells (Gavrilenko 2003), wherein even a single dent was found to strongly affect the buckling load. Hambly and Calladine (Hambly and Calladine 1996) experimentally investigated damaged cylindrical shells subject to axial compression. The detrimental effect of the dent imperfection in nearly perfect specimens was obtained in this research.

This paper aims to incorporate the results of the recent experimental studies on the effect of locally damaged steel circular hollow sections into organized discussions and recommendations. The discussions will lead to

useful tips on the adverse effects of the dent in the mentioned studies, which can be significantly employed in practice. Figure 1 illustrates a schematic view of the dent imperfection and the specimens.

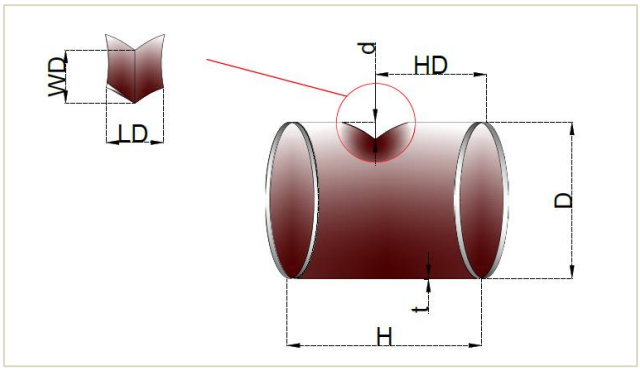

Figure 1 Typical schematic view of the dent imperfection.

LARGE IMPERFECTIONS AND PLASTIC BUCKLING UNDER COMPRESSION

Description of experiments

Steel circular hollow tubes with a moderate ratio of diameter to thickness of 47.6 were studies experimentally (Ghanbari Ghazijahani, Jiao et al. 2015). Indentation was conducted using an *Avery Universal Testing Machine* and a V-shape indenter. Dent imperfections with different geometries, inclinations and distances from the end edges were adopted in this study. Full descriptions about the experimentation can be found in (Ghanbari Ghazijahani, Jiao et al. 2015).

Failure mode and capacity

The tubes were thick enough to behave plastically, i.e. the yield governed the failure for these specimens (Ghanbari Ghazijahani, Jiao et al. 2015).The failure mode for the dented specimens was similar to the undented reference specimens, wherein the side of the tubes opposite the dents buckled in an elephant foot mode. As well, failure was accompanied by the enlargement of the dented zone and geometrical development of the deformations to the areas of the vicinity of the dents. Overall, the deformations were concentrated in the end areas of the tubes and the dented zone itself (Figure 2).

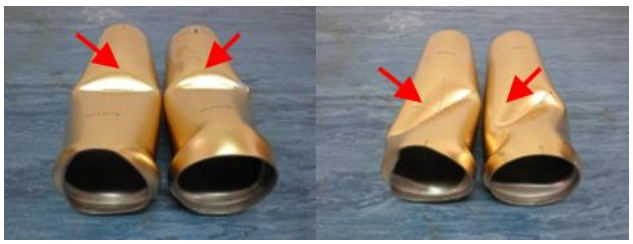

Figure 2 Failure mode of the tube specimens with different dent shapes under compression.

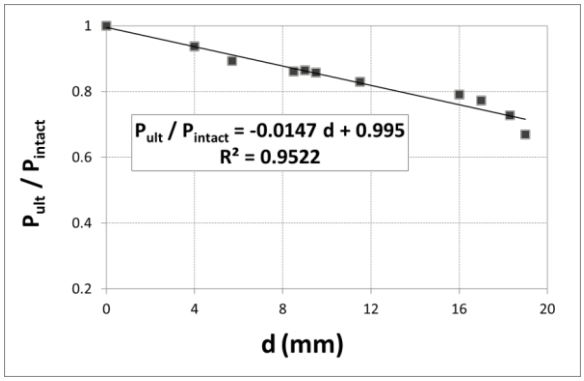

Figure 3 Capacity ratio of the dented to the intact tubes under compression.

In this study the ultimate axial load (P_{ult}) was obtained for each specimen when the peak load was reached after a nonlinear plastic load displacement trend. Figure 3 shows the capacity ratios of the dented to intact tubes for different specimens, which was plotted against the depth of the dent (d). As observed from the graph, a moderate decreasing effect of the dent imperfection is plainly seen, where the more the depth of the dent the more the reduction of the ultimate axial capacity. The location of the dents and the orientation turned out to be of a lesser significance.

SLENDER CIRCULAR HOLLOW SECTION AND THE IMPOSED DAMAGES AGAINST COMPRESSION

Thin shell specimens and experimental method

Very thin specimens were investigated by the authors in which the dent shape damage were exerted to the body of the shells (Ghanbari Ghazijahani, Jiao et al. 2014). The indentation was performed by a round edge indenter. The creation of the dents was followed by applying the controlled compression over the surface of the shells. The diameter to the thickness ratio (D/t) was different for the specimens so that the specimens were categorized into two groups: (i) $D/t = 604$, and (ii) $D/t = 340$. Thus, the slenderness of the first group was two times more than the second category.

Failure mode and Impact of the dent on the capacity

The failure predominantly formed as a diamond mode – a typical buckling form for slender shells – which was seen both for intact and dented specimens. Figure 4 shows typical failure modes for the specimens under axial compression. Note that the area around the top edge was the most susceptible zone to buckling. For some of the dented specimens the failure was initiated from the dented area or end area or concurrently. The bifurcation type of failure was observed, wherein the second bifurcation point was detected after the first drop of load was seen in the load displacement curves (Ghanbari Ghazijahani, Jiao et al. 2014). It is fitting to mention that the same failure was observed for both groups with different geometries.

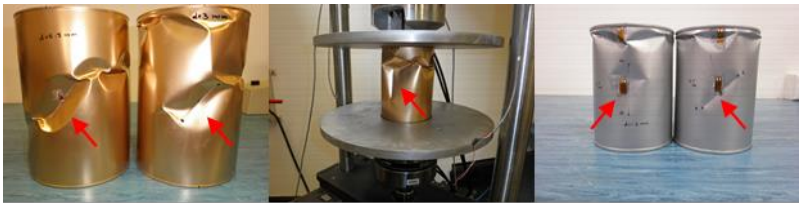

Figure 4 Specimens under compression with different dent imperfections after failure

Figure 4 shows the impact of local damages on the capacity of the mentioned thin specimens. The effect of the damage for SCC specimens ($D/t = 604$) was greater than their less slender counterparts indicating that the dent seems more detrimental for the slenderer specimens against axial compression. Although this conclusion may not necessarily be simply extrapolated to a wide range of geometries, sufficient experimental data is still required to draw definitive conclusions.

EXTERNALLY PRESSURIZED DENTED THIN CIRCULAR SHELLS

Geometry of specimens and experimental method

The same specimens as described for the previous section were employed for this program. The method of indentation was also the same as the dented specimens under compression, which were discussed earlier. The boundary conditions were simply supported which was conducted through the circular grooves machined at the end plates. Dented thin circular shells of revolution were used while they were subjected to the peripheral pressure (Ghanbari Ghazijahani, Jiao et al. 2014).

Failure modes and influence of the dent shape irregularities on the buckling load

The sensitivity of these structures to the local large imperfections – capacity wise and buckling mode wise – was assessed in this study. As can be found in the mentioned reference, the failure mode was initiated from the areas adjacent to the dent imperfection especially for the larger dents, whereas for the smallest dents the occurrence of the initial lobe of the buckling may or may not be affected by the dent. This is attributed to the fact that the dominance of the fabrication related imperfections could affect the onset of buckling. Thus we hypothesize that there is an interaction between the normal fabrication-related imperfections and the smaller dents. Indeed, the distribution and/or the amplitude of the normal imperfections can critically affect the initiation of buckling, which can definitely correlate with the depth and the width of the damages.

When it comes to the larger dents, different inclinations of the dents affected the buckling mode. As an instance, a large longitudinal dent can lead the yield lines to form nearby the dented area. It is worth mentioning that the overall buckling in the dented specimens, i.e. complete formation of several lobes around the circumference, took place by the same mechanism as the undented specimens.

Figure 7 shows the decreasing trend of the capacity (critical buckling load) as the depth of the dent increases. A moderate effect of the dent imperfection is seen through the figure. Given the capacity reduction of the equivalent specimens under compression discussed in the last section, the specimens under external pressure behaved structurally steadier when they were exposed to the external pressure. This response can be attributable to the geometry of a typical dent against external pressure and axial compression, i.e. the direction of the stresses for both load cases relative to the dent imperfection can suggest this capacity differences.

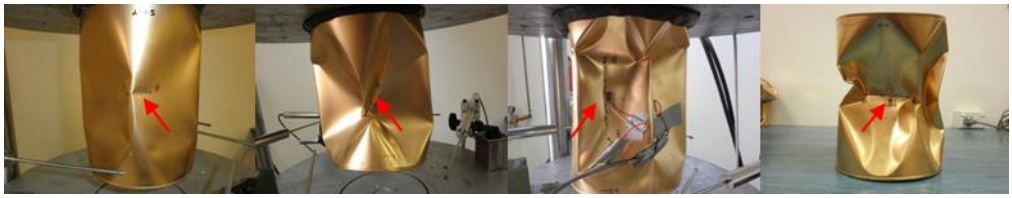

Figure 6 Specimens under external pressure with different dent imperfections after failure.

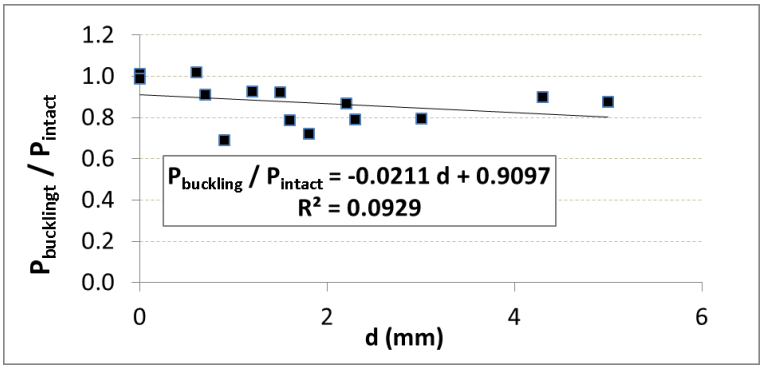

Figure 7 Capacity ratio of dented to intact thin shells under external pressure

COMPARISONS AND DISCUSSIONS

The decreasing trend for the specimens with plastic buckling under axial load was in large part, linear. Less scatter of the data was seen as the regression value indicated a magnitude very close to the unity (Figure 3). This demonstrates a steadier response of the thicker circular hollow sections in which the yield phenomenon prevails rather than the local instabilities in the pre-yielding zone.

It is quite evident that the scatter of the data for the thinner specimens subjected to the axial compression was far more sizable than the thicker tubes presented before (Figure 5). This definitely implies more certainties in the response of the thicker specimens as pre-yielding local instabilities were not prevalent in thicker tubes.

Comparing the specimens under external pressure with equivalent specimens under compression, the scatter of the data for the specimens under external pressure was higher, which suggests more certainty of the response of the dented specimens under axial compression than external pressure.

Figure 8 Recommended tolerances for the imperfections by three different codes, also available in: (Fatemi, Showkati et al. 2013).

Quite a few codes tolerated allowable values for the ordinary fabrication imperfections as provided in ESSC (2008), ENV (1993) and DIN 18800 (1990). It is reiterated that the results of the mentioned experiments in this paper necessitate further evaluations in the future updates of the mentioned codes to include the large local imperfections in the design codes. This is proposed thanks to the fact that in some cases the effect of large imperfections is not as large as they would be imagined.

CONCLUSIONS

The effect of large imperfections caused by damage or physical collisions in the service life of the thin-walled circular hollow sections was investigated in this study. Experimental data were evaluated to organize the experimental findings on the mentioned structures under axial load and external pressure. The findings were incorporated into a set of organized results to present and compare the effect of dent imperfections in different applications. Comparisons demonstrated that the effect of the dent imperfection was greater for the specimens under axial loading compared to the cases subject to the external pressure. It is believed that the results of this study fairly necessitate reconsideration of the present available codes to include the effect of imperfection in order that the available tolerances are updated. This is indeed due to the fact that in some cases the dents beyond the tolerated magnitudes may still have some little effects on the capacity of different structures.

ON THE SYSTEM-BASED DESIGN FOR STEEL FRAMES USING INELASTIC ANALYSIS

Hao Zhang*, Haoyu Liu, and Kim J.R. Rasmussen
School of Civil Engineering, The University of Sydney, NSW, Australia
*Email: hao.zhang@sydney.edu.au

ABSTRACT

Design by inelastic analysis of overall system behaviour is permitted in several steel design specifications worldwide (e.g., the American Specification AISC360-10 and the Australian Specification AS4100-1998). Advanced inelastic analysis is better able to capture the system behavioural characteristics as they currently are understood. This paper presents a case study of the design of three planar steel structures using different design methods, including the Direct Analysis method in AISC360-10, the inelastic design method in AISC360-10, and the inelastic method ("advanced analysis") in AS4100. The effects of structural ductility (capacity of load redistribution) and failure modes on the design results are discussed.

KEYWORDS

Inelastic analysis, elastic analysis design, steel structures, nonlinear frame analysis, system-based design.

INTRODUCTION

The traditional steel design methods focus on the limit states of individual components and connections, based on elastic structural analysis. In the design process, the system effects are addressed only implicitly through the use of effective length factors. The design philosophy (except for seismic design) generally is based on a "first-hinge" approach, i.e., the strength limit state of the frame is defined when one or more members develops a fully plastic hinge. The effective length factor approach cannot predict the true interactions between members of a large structural system accurately. Moreover, the beneficial system effects such as load redistribution cannot be captured by elastic analyses. The recent increases in computing power and sophisticated inelastic structural analysis make it possible to predict the behaviour of complex steel structural systems quite accurately, including the effects of material nonlinearity (yielding), geometric nonlinearity, initial geometric imperfections, residual stresses etc.

With the advent of inelastic analysis, it is now possible to design a steel frame on the system level. The system strength can be directly assessed from the analysis without the need for checking the member-based design specification provisions. System-based inelastic design may also lead to more economic design than the first-hinge elastic approach by explicitly incorporating beneficial system effects such as load redistribution (Ziemian et al., 1992).

The most significant advantage of design by inelastic analysis, however, is that engineers can better understand the system behavioural characteristics. This advantage is especially important in the new paradigm of performance-based design, which is closely coupled to the issue of system behaviour. Since inelastic analysis can explicitly indicate the failure modes, it becomes possible to consider different performance objectives in design (e.g., first yielding or hinge, incipient system instability, etc.), and associate with each a specific reliability goal. Take the wind design for instance, the owner may choose "first hinge" or "collapse prevention" as the performance objective. The former is the current wind design objective. If the owner accepts a lower performance objective of "collapse prevention", the system is required to maintain sufficient stiffness to prevent collapse, but certain members (with adequate ductility) are permitted to enter the inelastic range. Such a design methodology is founded on rigorous nonlinear system analysis, which is no longer a formidable task from the structural analysis point of view.

The objective of this paper is to compare the designs of three planar streel structures using different design methods, including the Direct Analysis Method (DAM) in AISC360, and the two inelastic design methods in the American Specification AISC360-10 and the Australian Specification AS4100. The three methods are briefly introduced. The merits of system-based design by inelastic analysis are demonstrated through the examples. The roles of structural ductility (capacity of load redistribution) and failure modes on the design results are discussed.

DESIGN METHODS

Direct Analysis Method (AISC360-10)

The Direct Analysis Method in AISC360-10 requires a rigorous second-order elastic analysis with modelling of initial geometric imperfection (either by direct modelling or by applying notional loads) and application of a reduction factor of 0.8τ to the nominal elastic stiffness in structural analysis. Internal actions are obtained from the second-order elastic analysis and the strengths of components are checked using an effective length factor of unity for compression members. The limit state of in-plane flexural buckling is checked according to the interaction equation:

$$\frac{P_u}{\phi P_n} + \frac{8}{9}\left(\frac{M_u}{\phi M_n}\right) \leq 1.0, \text{when } \frac{P_u}{\phi P_n} \geq 0.2, \qquad (1)$$
$$\frac{P_u}{2\phi P_n} + \frac{M_u}{\phi M_n} \leq 1.0, \text{when } \frac{P_u}{\phi P_n} < 0.2,$$

where P_u and M_u are the required strengths (design actions), calculated from second-order analysis under the design loads; and P_n and M_n are the nominal compression and bending strengths, calculated in the plane of the frame. ϕ is the resistance factor for reliability consideration. With member and system instability being checked by the second-order analysis, the equation based design checks only need to be completed at the cross-sections. Compared to the traditional load and resistance design using the effective length procedure, the DAM greatly simplifies the assessment of frame stability by using the actual member length. However, the DAM still represents the member-based, "first hinge" design philosophy.

System-based design by inelastic analysis in AISC360-10

Appendix 1 of AISC360-10 allows, in principle, the use of inelastic analysis to supersede the member-based design equations in the Specification, provided that (1) the limit states covered by the Specification equations are detected by the inelastic analysis; (2) members and connections with elements subject to yielding have adequate ductility; and (3) a comparable or higher level of structural reliability is provided by the inelastic analysis than by member-based design. If a certain limit state cannot be modeled by the inelastic analysis, it needs to be verified by the corresponding Specification equation. To ensure adequate ductility of members and connections, two general methods can be used: (a) limiting the factors that affect the inelastic deformation capacity of components, such as the slenderness of cross-sectional elements and the unbraced length, and (b) limiting the inelastic deformation demands to be less than or equal to their (predefined) inelastic deformation capacities.

The AISC 360-10 approach to ensuring structural reliability is to reduce both the strength and stiffness of all members and connections by a factor of 0.9. The 0.9 factor on stiffness makes sure that the strength of a frame with slender members failing elastically will be factored downward. The AISC 360-10 commentary acknowledges that the factor of 0.9 has its origin in the AISC LRFD resistance factors of tension and flexural members that yield; its use in system-based design, although ''deemed acceptable'', is not based on system reliability analysis.

Design by inelastic analysis in AS4100-1998

The Australian Specification for steel structures AS4100 (1998) is one of the first specifications that permit the use of inelastic analysis to verify the integrity of structural systems. The cross-section must be compact and members must be fully braced against flexural-torsional buckling. One needs to check the integrity of the frame under factored loads, using (unfactored) nominal values of structural stiffness and strength. In addition to that, the section capacity and connection capacity need also to be checked according to the specification equations. For compact section, the section capacity check is given by:

$$\frac{P}{\phi P_y} + \frac{M_x}{\phi M_{px}} + \frac{M_y}{\phi M_{py}} \leq 1 \qquad (2)$$

in which ϕ = the member resistance factor (0.9 in AS4100), P = design axial force under factored loads, P_y = nominal axial yield strength. M_x and M_y are design bending moments about the major principal x-axis and minor principal y-axis, respectively, M_{px} and M_{py} are nominal section plastic moments about x-axis and y-axis, respectively. AS4100 allows the internal actions (P, M_x and M_y) to be determined by inelastic analysis but still requires section capacity to be checked by specifications. As will be seen later in this paper, the need for separate section capacity check negates efficiencies to be gained by using inelastic analysis for system-based structural design.

EXAMPLE STEEL FRAMES

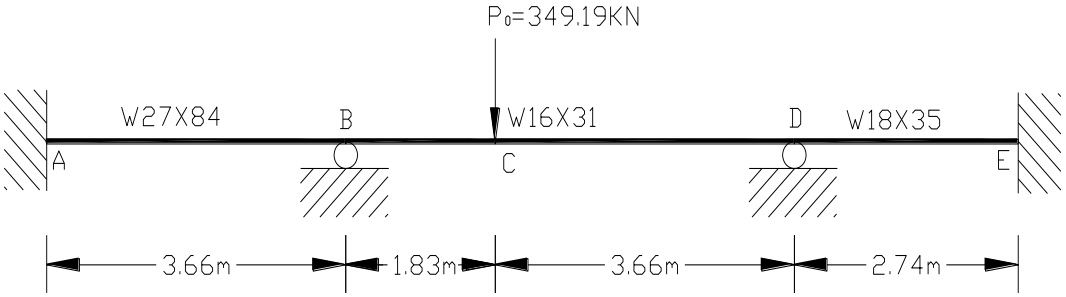

Figure 1 Example 1: 3-span continuous beam.

Three examples were adopted from the literature. The first example is a 3-span continuous beam as shown in Figure 1. This example was adopted from Ziemian and McGuire (2007). The nominal yield strength and modulus of elasticity for the members are 345 MPa and 200 GPa, respectively. The reference load P_0 = 349.19 kN.

The second example, shown in Figure 2, is a 2-bay, 2-storey unsymmetrical frame subjected to gravity load. The distributions of loads at different levels are as shown in the figure. The frame was adopted from (Ziemian et al., 1992). The nominal yield stress and modulus of elasticity for the members are 248 MPa and 200 GPa, respectively. The frame has an initial out-of-plumbness of 1/500 towards the right. The reference load P_0 is 147.11kN/m.

Example 3 is a portal frame adopted from Ziemian and McGuire (2007). The two columns are oriented for minor-axis bending. The nominal yield stress and modulus of elasticity for the members are 345 MPa and 200 GPa, respectively. The frame has an initial out-of-plumbness of 1/500 towards the right. The reference load P_0 = 484.86kN.

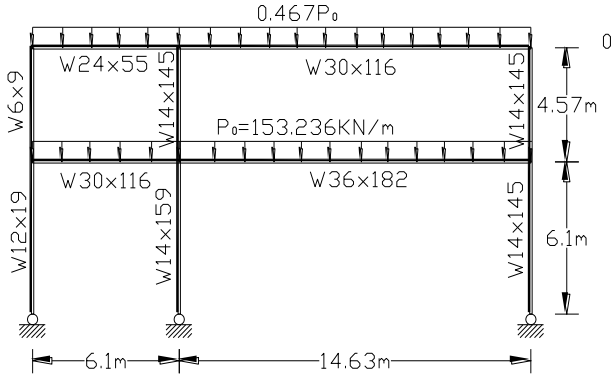

Figure 2 Example 2: 2-bay, 2-storey unsymmetrical frame.

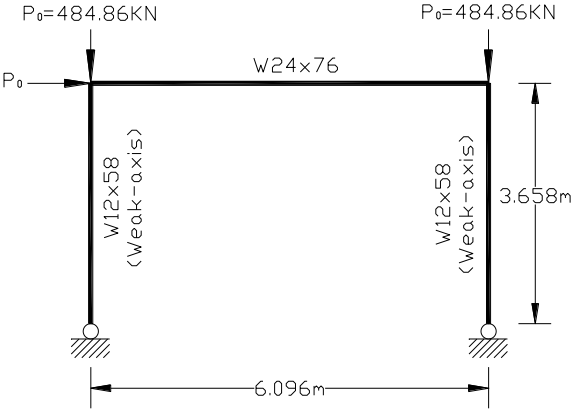

Figure 3 Example 3: slender portal frame.

In all examples, all beams and columns are compact and laterally braced so that the plastic capacity of each section can be achieved without local buckling. Connections are assumed to be fully rigid; compliance of the connections is not considered.

Second-order elastic/inelastic analyses were performed using the software OpenSEES. Initial geometric imperfections were modeled directly in the analysis by offsetting the relevant nodes from their nominal positions. For the inelastic analysis, displacement-based, fibre-type beam elements were used to model the spread of plasticity throughout the cross-sections and along the members. The stress–strain curve is assumed to be elastic-perfectly plastic. Residual stresses are assumed to distribute according to the pattern suggested in (Galambos and Ketter, 1961), i.e., linearly varying across the flanges and constant tension in the web. In the analyses, the loads applied on the structures are incrementally increased; a load scaling factor λ is used to (proportionally) increase the reference loads P_0.

Failure behaviour: Example 1

Inelastic analysis shows that significant yielding occurred first at Point C and that the second plastic hinge developed at Point B. Eventually, the third plastic hinge appeared at Point D; at which point, the continuous

beam reached its load-carrying limit. Figure 4(a) plots the load scaling factor versus the vertical displacement at Point C when the member yield stress and modulus of elasticity are at 0.9 times their nominal values. The first plastic hinge developed at $\lambda = 1.0$. It can be seen that the ultimate load factor (λ_u) is 1.29. Figure 4(b) shows the sections with significant yield ratio (percentage of yielded cross-sectional area) at the ultimate limit point λ=1.29.

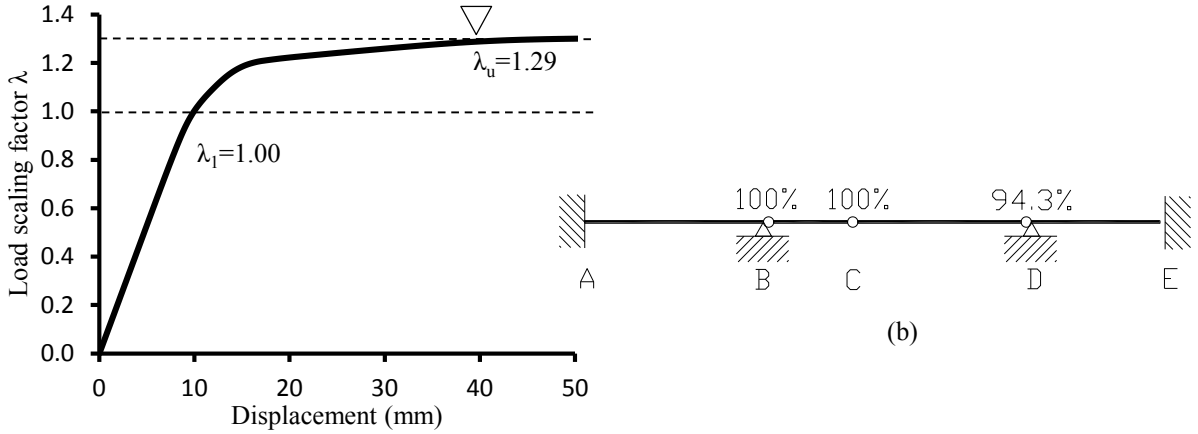

Figure 4 Example 1: (a) load-displacement at Point C, and (b) section yield ratios at $\lambda_u = 1.29$.

Table 1 compares the strength of the continuous beam determined by four different methods: 1) DAM, 2) (traditional) plastic design method, 3) inelastic method in AIS360-10, and 4) inelastic method in AS4100. The traditional plastic design of continuous beams is based on the plastic mechanism loads, and a factor of 0.9 is applied to the plastic moment capacities of all members. Table 1 shows that the ultimate load factors from the plastic design method and the inelastic method in AISC360 are identical, i.e., λ_u =1.29, which is 29% higher than the DAM. This suggests that there is 29% remaining strength to sustain further loading after first yielding. This example also shows that for this simple continuous beam, the traditional plastic analysis method and the inelastic method in AISC360 give the same results. This is to be expected. On the other hand, the λ_u given by the inelastic method of AS4100 is 0.99, which is essentially the same as the DAM, and is significantly conservative compared to the inelastic method of AISC360. As AS4100 requires a section yield capacity check, the system ultimate limit point is reached at the first plastic hinge. This negates any post-yield strength that could be gained by using inelastic analysis for a system-based design.

Table 1 Ultimate load factor (λ_u) from different design methods, Example 1.

Design Method	λ_u
DAM	1.00
Plastic design	1.30
Inelastic (AISC360)	1.30
Inelastic (AS4100)	0.99

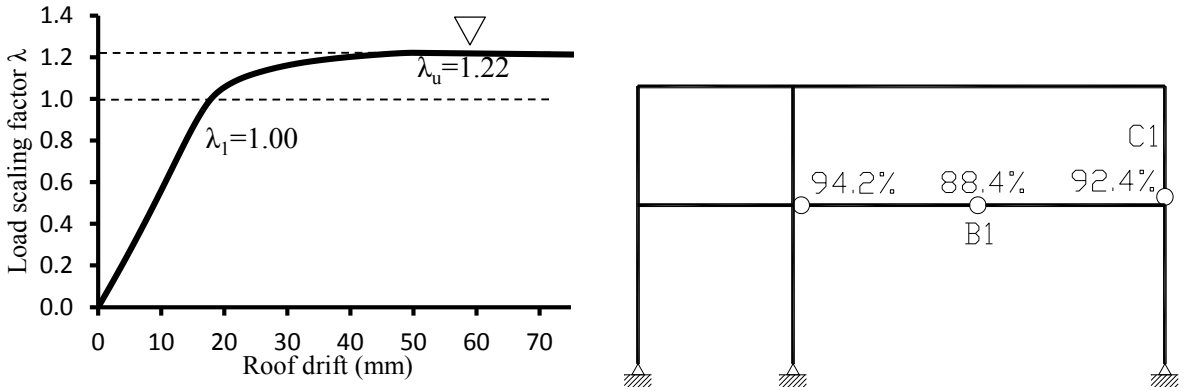
Table 2 Ultimate load factor (λ_u) from different design methods, Example 2.

Design Method	λ_u
DAM	1.00
Inelastic (AISC360)	1.22
Inelastic (AS4100)	1.00

Failure behaviour: Example 2

For the second example, the inelastic method of AISC360 indicates that beam B1 developed two plastic hinges, firstly at the left end of B1, then in the middle. The load scaling factor associated with the occurrence of the first plastic hinge is λ=1.0. Further increasing the load to λ=1.22, the third plastic hinge occurred at the bottom end of column C1. At this point, the system reached its load carrying capacity and is in a state of incipient instability. Figure 5 shows the load-roof drift response and the section yield ratios at the limit point for Example 2. The analysis is based on values of yield stress and elastic modulus of 0.9 times their nominal values.

Table 2 presents the system strengths given by three different methods: 1) DAM, 2) inelastic design method in AIS360-10, and 3) inelastic design method in AS4100. Similar observations were made as in Example 1. The inelastic method of AS4100 and the DAM gave the same results of λ_u = 1.0, which corresponds to the load when the first plastic hinge was developed. The "true" ultimate strength given by the system-based inelastic method-AISC360 is 1.22, which is 22% greater than that based on the first hinge approach.



(a) (b)

Figure 5 Example 2: (a) load-roof drift behaviour, and (b) section yield ratios at λ_u = 1.22.

Failure behaviour: Example 3

The slender portal frame fails essentially elastically. Figure 6 plots the load-drift response from the inelastic method of AISC360-10 based on values of yield stress and elastic modulus of 0.9 times their nominal values. At the ultimate point, the top ends of the two columns are partially yielded, with a yield ratio of about 55%. Other parts of the structure are in the elastic range. Table 3 summarizes the ultimate load factors from the DAM, the inelastic method in AISC360 and the inelastic method in AS4100. It can be seen that the DAM and the inelastic method in AISC360 predict the same system strength. This is not surprising since the structure behaves largely in its elastic range when the slender columns buckle elastically. From Table 3, it can be seen that the inelastic method in AS4100 over-predicted the system strength by 4%. The inelastic method in AS4100 stipulates a section yield capacity check with the section axial and moment capacities reduced by a resistance factor of 0.9. This practice is equivalent to performing inelastic frame analysis with a reduced yield stress $0.9F_y$ and nominal values of stiffness for all members. Since the structure fails due to elastic buckling of the slender columns, reducing F_y only will not have correct effect on this slender structure. In this example, using a reduced yield surface does not sufficiently factor down the nominal system strength. In comparison, the inelastic method in AISC360 reduces both the strength and stiffness of all members by a factor of 0.9. The 0.9 factor on stiffness ensures that the strength of a frame with slender members failing elastically will also be factored downward.

Table 3 Ultimate load factor (λ) with different analysis methods in example 3.

Design Method	λ_u
DAM	1.00
Inelastic (AISC360)	1.00
Inelastic (AS4100)	1.04

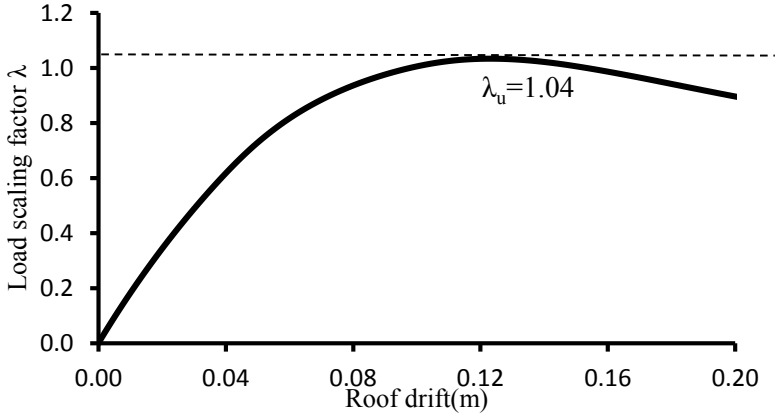


Figure 6 Example 3: load-roof drift behaviour at $\lambda_u = 1.04$.

DISCUSSIONS AND CONCLUSIONS

This paper presents a comparison of the design strengths of three steel structures using the DAM, the inelastic method in AISC360, and the inelastic method in AS4100. The three structures exhibit different ductility (capacity of load redistribution) and failure modes.

The continuous beam and the two-bay two-storey frame have significant capacities of load redistribution after first yielding. Using the inelastic method in AISC360 could gain significant post-yield strength; the system strengths are 20-30% larger than those from the DAM. In the continuous beam example, the result from the inelastic method in AISC360 agrees with that from the traditional plastic design method for continuous beams which is based on the plastic mechanism loads. For these two examples, the inelastic method in AS4100 gives the same system strength as the DAM. This is because AS4100 requires a section yield capacity check. As a result, the system ultimate limit point is reached at the first plastic hinge. This negates any post-yield strength that could be gained by using inelastic analysis for a system-based design. If the inelastic analysis is only used to obtain member forces for use in member/section capacity checks, the main benefits of using inelastic analysis cannot be fulfilled.

Because the slender portal frame fails essentially elastically, the inelastic method in AISC360-10 and the DAM give the same system strength. In this example, the inelastic design method does not lead to more economic design (compared to the member-based DAM). On the other hand, the inelastic method of AS4100 over-predicted the system strength. This is because AS4100 only reduces the strength of all members, which has no effect on slender structures failing elastically.

The inelastic design provisions in AS4100 appear to be problematic, for the two reasons summarized above, whereas the inelastic design method of AISC360-10 is more rational. It represents a system-based design methodology, and may give more economic design than the traditional member-based first plastic hinge design approach. The gain of post-yield strength by using system-based inelastic design depends on the nature (ductility and redundancy) of the system.

ABSTRACT

Steel plate shear walls are lateral load resisting systems consisting of vertical steel plate infills connected to the surrounding beams and columns. One of the parameters affecting the behavior of steel plate shear wall system under lateral load is characteristic of surrounding members. Since there are lots of experimental and analytical studies on steel plate shear walls with I-shaped surrounding members, this research is an experimental study carried out on a one-third scale steel plate shear wall system with box-shaped columns along with further analytical studies. The objectives were to calculate the stiffness, strength and energy dissipation capacity of the specimen and compare them with a very similar system constructed with I-shaped columns. Cyclic loading protocol of ATC-24 was used for test. Obtained experimental results showed a good conformity between box and I-shaped specimens. It is shown that the system can provide good initial stiffness and high ultimate capacity and remain intact under seismic effects. Some analytical studies on failure modes of system with box-shaped columns were also conducted using finite-element software confirming that the columns bottom connections and their flange buckling at that point are one of the most common modes of failure and a triangular reinforcing plate at that point can improve columns connection behavior effectively.

Steel plate shear wall, Box-shaped column, Cyclic behavior, Energy dissipation.

INTRODUCTION

According to the researches in recent decades, steel plate shear walls (SPWs) can be used as lateral load resisting system in high seismic hazard areas. The studies have revealed that this system has high initial stiffness, high elastic strength and behaves in a ductile manner (Driver *et al*. 1997; Caccese *et al*. 1993; Sabelli and Bruneau 2007) This system has been used in numerous buildings before advent of design requirements. The steel plate shear wall consists of steel plate surrounded by beams and columns; the most usual kind of this system is unstiffened walls recognized as special plate shear wall in AISC341 and ASCE7; the compression strength of these walls is very low so the shear buckling happens under low shear force and the lateral forces are carried by forming the tension field of the infill plate. Prior to key research in 1980s, the design limit state for SPW was considered to be out of plane buckling of the infill panel to prevent buckling; engineers designed SPW with heavily stiffened infill plates. At that time several analytical and experimental studies (Timler and Kulak 1983; Tomposch and Kulak 1987) showed that the post buckling strength and ductility of slender-web SPW can be substantial. This post buckling behavior is referred to as tension field action.

Thorburn *et al*. (1983) developed a simple analytical strip model to represent the tension field action of a thin steel wall under shear load. This mechanism can be described as follows: When lateral load is applied to a steel plate shear wall, it is assumed that the shear panel just experiences the shear deformation so the shear infill plate is subjected to essentially pure shear with principle stresses (compression and tension) oriented at a 45 angle to the direction of load; as the slenderness of the plate (depth to the thickness ratio and width to the thickness ratio) is high, the buckling strength of the plate is very low, furthermore the plate will not be straight or flat initially due to the fabrication and erection tolerances so the plate buckles at low level of the force then lateral loads are transferred through the plate by principal tension stresses. Timler and Kulak (1983) verified and refined the strip model.

The steel plate shear wall system which is designed properly and has specific details is so ductile and dissipate great amount of energy; the boundary element must be designed in such a way that allow formation of the tension field of the infill plate and its attainment to maximum capacity; so they play a key role in the accurate

performance of the system. The behavior of thin steel plate shear walls regarding frame members was studied by Alinia and Dastfan (2006); the results showed that the flexural stiffness of surrounding members has no significant effects, either on elastic shear buckling or on the post-buckling behavior of shear walls. The torsional rigidity has a significant effect only on the elastic buckling load, and the extensional stiffness slightly affects the post-buckling capacity.

In addition to gravity loads, the boundary columns on the sides of a steel plate shear wall resist the bulk of overturning moment and also provide an anchor point for tension field action. In structures with relatively large columns, these elements can also transfer a considerable amount of story shear. So the behavior of steel plate sheer walls under the effects of lateral loads depends on the surrounding columns.
In this study two one-third scaled, single bay-single story SPW were studied. Specimens were both similar in web plate thickness and other specification but different in column type as boundary element; one with boxed-shaped columns and the other one with I-shaped columns. Both specimens are tested in laboratory under quasi-static loading.

EXPERIMENTAL PROGRAM

Specimen specifications

The experimental program consists of a two one-third scaled, single bay-single story specimens with box-shaped and I-shaped columns called "SPW-1" and "SPW-2", respectively. Specimens were designed according to high seismic design provisions of AISC Design Guide 20 requirements. For preliminary design it is assumed that web plate resists the entire shear of the system and the angle of the tension stress which varies between 30 to 60 degrees is assumed to be 45 degrees. By these assumptions the nominal stress can be calculated as:

$$V_n = 0.42 f_y t_w L_{cf} \sin(2\alpha) \quad (1)$$

Where f_y is the infill panel yield stress, t_w is the thickness of the infill plate, L_{cf} is the clear distance between Vertical Boundary Elements (VBEs) flanges, α is the inclination angle of the tension field. The ultimate strength of a steel panel is fully developed only when the corresponding frame members are sufficiently stiff and strong to anchor the tension diagonals. For VBEs it has been recommended that moment of inertia should be calculated as:

$$I_c \geq 0.00307 t_w h^4 / L \quad (2)$$

In which h is height of panel. The same equation by swapping h and L is applicable to Horizontal Boundary Elements (HBEs). Regarding limitations on size of specimens and maximum allowable load, specimens are designed. To calculate the portion of the shear resisted by the web plate ABAQUS finite element (FE) software was used. From the analysis it was conducted that 35% of lateral load was resisted by the web plate. Details of designed specimens are shown in Figures 1-4.

As shown in Figure 3, built-up sections are used for beams and columns. In order to establish complete rigid connection, the connection of each column to bottom beam was developed utilizing complete penetration groove welds of flanges and fillet weld of web. For top beam connection, similar detail was used. In order to prevent the out of plane movement of top beam, two beams were applied as lateral support in top level of each specimen in both sides. Lateral support locations are shown in Figures 1,2.

Bottom beam flanges of specimens are connected to strong floor girder of the laboratory using M24 high strength bolts. The arrangements of these bolts are shown in Figure 4.

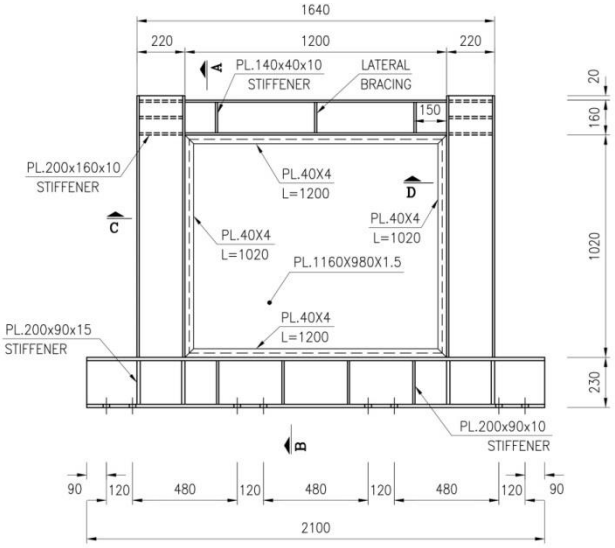

Figure 1 Specification of SPW-1 specimen (mm)

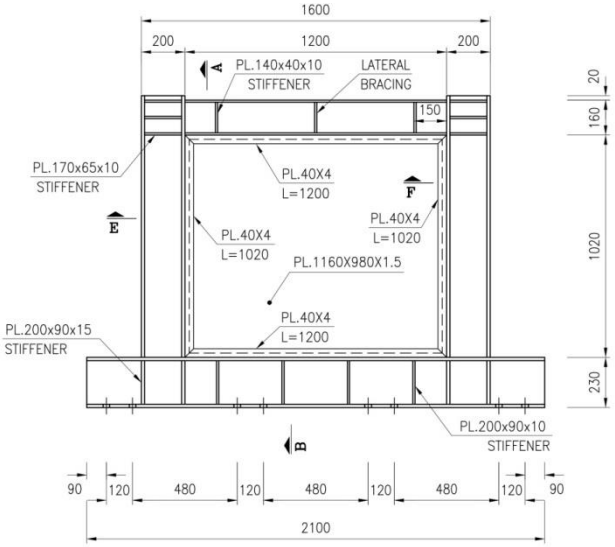

Figure 2 Specification of SPW-2 specimen (mm)

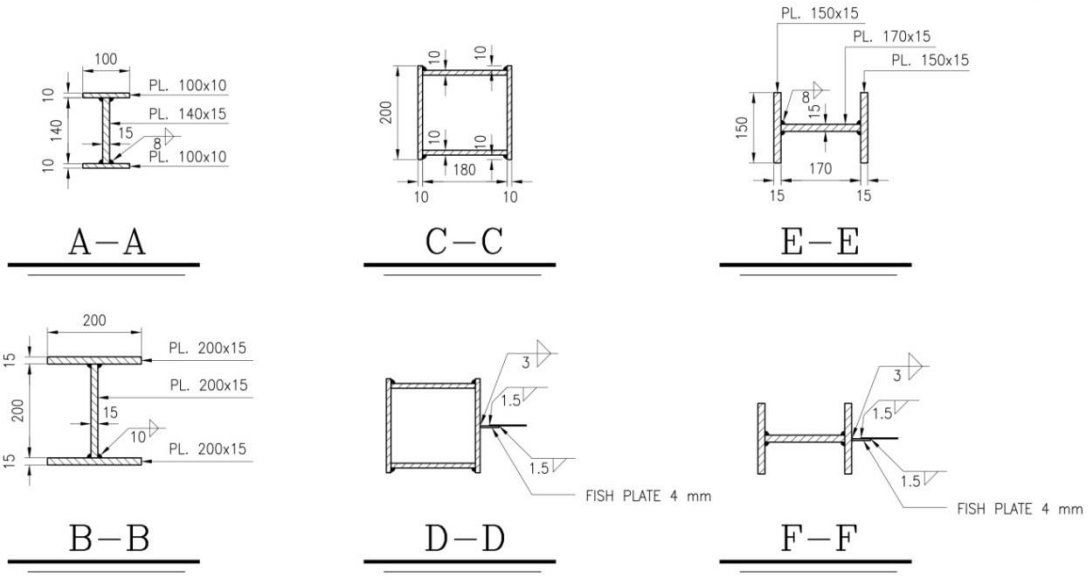

Figure 3 Beam and column sections (mm)

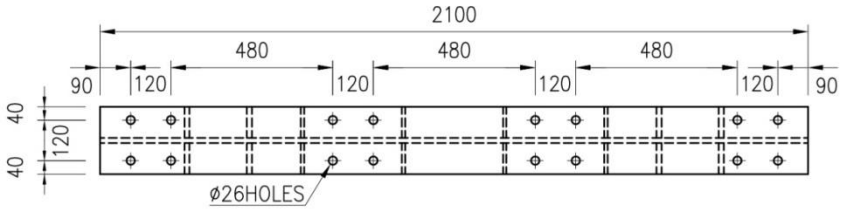

Figure 4 Bottom beam connection details (mm)

From construction point of view it is not easy to fit the web plate in the boundary frame, Therefore in steel plate shear walls, the connection of web plate to boundary frame is done using fish plates. In the above described specimens, fish plates with dimension of 40x4 mm were used. Noticing the low thickness of web plate, using bolts to connect the web plate to fish plates could result in high bearing stresses which could damage the plate. Hence it was decided to use welds to connect web to fish plates in all specimens.

Material Properties

The material of web plates and boundary frames were ST12 and ST37 steel, respectively, according to DIN standard. The strength of web plates was selected such that it was lower than the strength of boundary frames; which made the advantage of using smaller boundary elements. Mechanical properties of the steel plates used in the construction of the specimens were tested which are reported in Table 1. For each plate thickness, two samples were cut out from the plate, one in longitudinal direction of plate roll and one in transverse direction. The mechanical properties were determined by coupon test performed according to ASTM A370-12. In Table 1, ST12 and ST37 are comparable to A36 structural steel in the US.

Table 1 Mechanical properties of steel materials used for plates from tension coupon test

Type	Steel grade in DIN Germany Standard	Young's Modulus E (GPa)	Yield Stress f_y (MPa)	Ultimate Stress f_u (MPa)	f_u/f_y	Elongation (%)
Web plate (Pl. 1.5 mm)	ST12	200	222	315	1.42	42
Column and Beam (Pl. 10 mm)	ST37	200	254	383	1.51	43
Column and beam (Pl. 15 mm)	ST37	200	280	423	1.51	43
Diagonal and fish plate (Pl. 4 mm)	ST37	200	313	450	1.44	38

Test setup

Figures 5,6 Show the fabricated and installed specimens, SPW-1 and SPW-2, prior to testing, respectively. The specimens were painted with whitewash. Water was added to hydrated lime until a workable mixture was formed. The whitewash was left overnight prior to testing. The whitewash provided a good visual indicator of the specimen behavior.

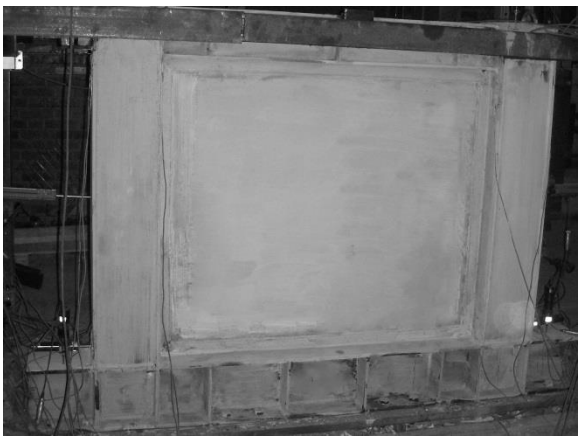

Figure 5 SPW-1 prior to testing

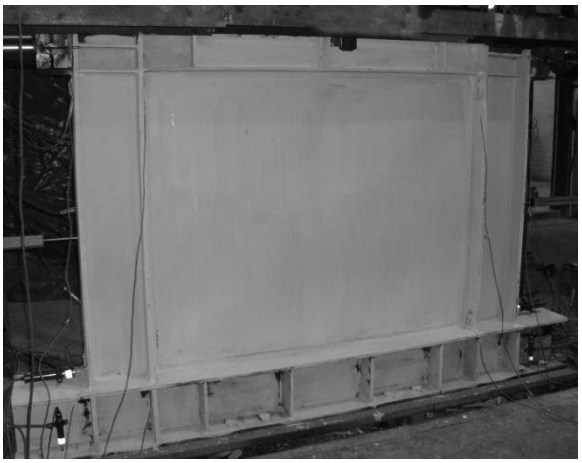

Figure 6 SPW-2 prior to testing

Loading and measurements

To simulate earthquake load and to investigate the cyclic behavior of the specimens, quasi-static loading was employed. Lateral loading was applied by two horizontal hydraulic jacks at the top beam level using ATC-24 protocol (1992). In this protocol it is required to determine the yield force and displacement. As was formerly described, ABAQUS software was used to simulate the test to predict these values. Monotonic analysis of specimens was applied to determine the yield displacements (Δ_{yield}) of specimens which were measured as 8mm. Displacement control lateral load was applied to specimens according to the following procedure:

- The first nine cycles consisted of fully reversing displacements of 25%, 50% and 75% of Δ_{yield}, three of each.
- The next three cycles consists of displacements equal to Δ_{yield}.

Loading is followed by three cycles of 200%, 300%, 400% of Δ_{yield} and so on until the maximum stoke of hydraulic jacks are achieved. The loading protocol is shown in Figure 7.

The loading history was interrupted with small cycles after each three cycles of loading with displacement equal to or larger than Δ_{yield} based on ATC-24 recommendation. These small cycles were force control, using a peak value of 0.75 yield force, which is the force that causes yielding to occur.

Also it is worth mentioning that because the displacement at the top of the specimens was monitored as the control point and there were some slipping and rotation at base connection, it was not possible to precisely achieve the target drifts, particularly at low drift levels. The actual drifts attained were always lower than the target drifts. All the drift values reported in the next sections are actual drift values.

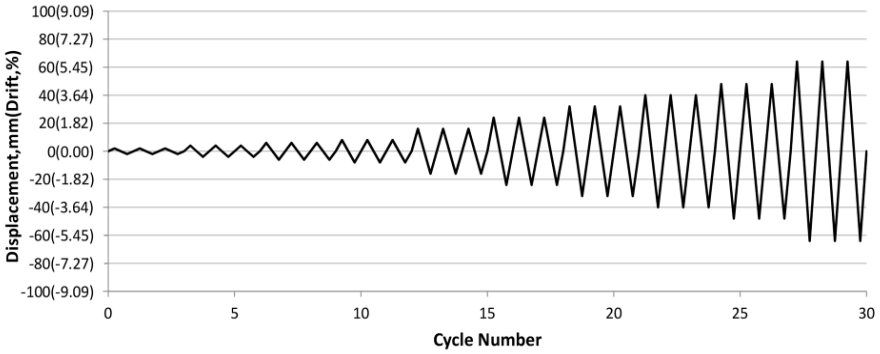

Figure 7 Quasi-static displacement control loading sequence

During the loading, the value of applied load and the amount of displacement at the top of the specimens were continuously measured using load cells and LVDTs. Besides, LVDTs and strain gauges were used to measure the amount of deformation and strain at other points of the specimens where all of the measurements were recorded by a data logger. The positions of the LVDTs and strain gauges are shown in Figure 8.

EXPERIMENTAL RESULTS

Difference in mechanical characteristics and properties including stiffness, energy dissipation, ultimate strength and failure mode distinguish the seismic behavior of different configuration of steel plate shear walls. The test procedures and results are described and discussed in the following sections.

Behavior of Specimens during loading

Specimen SPW-1

In the first 6 cycles of loading (up to drift 0.6%) there were no significant yielding lines on the infill plate, however web plate buckling was observed in the early cycles of loading. Web plate yielding occurred during cycle 7 when drift reached 7.12mm (0.64%). In this cycle the stain gauge's stress on the plate exceeded the yielding limits of the plate. In cycle 13 with 16mm (1.44%) drift several bangs were heard due to the deformation of the infill plate. post buckling waves were clearly observed and the first tear was detected in the top left corner of the infill plate (Figure 9(a)). In cycle 14 with the same lateral load, the second and third tears were observed at two other corners of the web plate which grew larger by increasing the loading amplitude in the subsequence cycles. In cycle 17 with 24mm (2.16%) drift a tiny crack in the right column bottom groove weld was detected and at the same time buckling of the column flange happened. By continuing the loading sequences the connection of the other column also cracked. In cycles 19 and 20, groove weld distortion as well as beam column connection distortion progressed and the tears increased thoroughly and finally in cycle 21 the loading was terminated (Figure 9(b)).

Total number of cycles applied to the specimen was 21. The ultimate story displacement was 50 mm and the ultimate load carried by the specimen was 820 KN at 2.2% drift

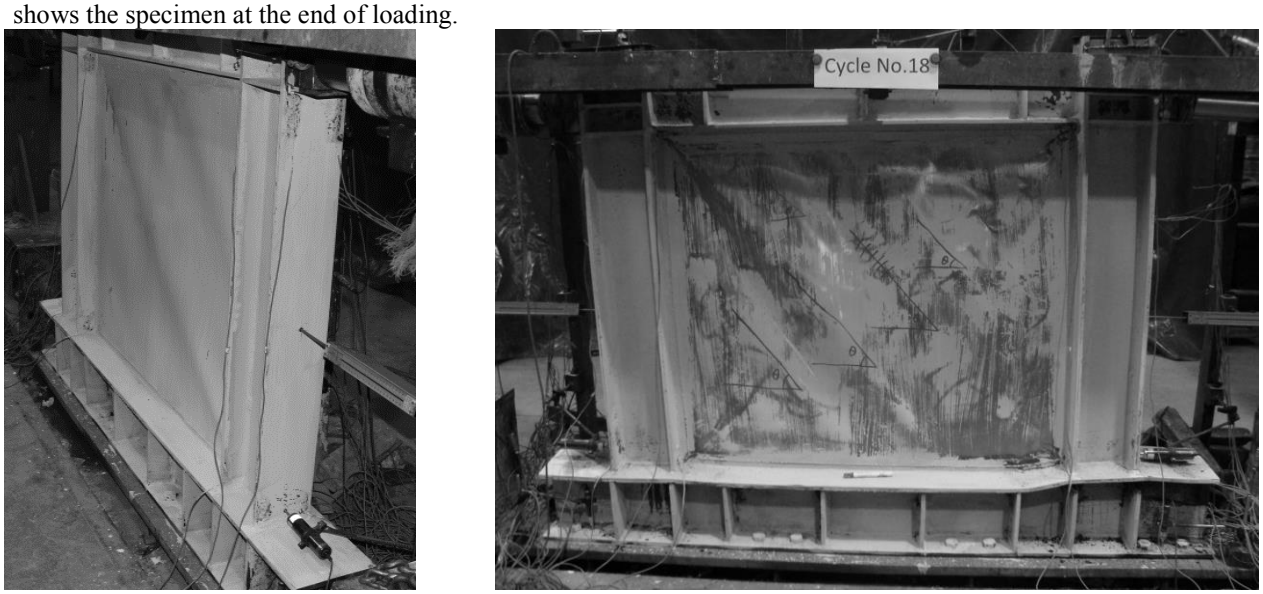
(a) (b)

Figure 9 Specimen SPW-1 during test: (a) at 1.44% drift; (b) at the end of the test

Specimen SPW-2

In was observed that the infill web plate underwent elastic buckling during the first cycle of loading when the drift was 2.55 mm (0.23%). The loading continued until in cycle 10 when the drift reached 9.31 mm (0.84%), the web plate experienced permanent out of plane deformation (Figure 10(a)) while yielding occurred at the bottom of the outer flange of columns according to data recorded by data logger. As it was expected, the boundary

element yielding happened after complete yielding of the web plate. By continuing and increasing the applied load, the web and flange of the bottom beam were cut out right under the columns during cycle 14 when the drift was 20.03 mm (1.82%). The loading was terminated in cycle 18 at the drift of 31.5 mm (2.86%). Figure 10(b) shows the specimen at the end of loading.



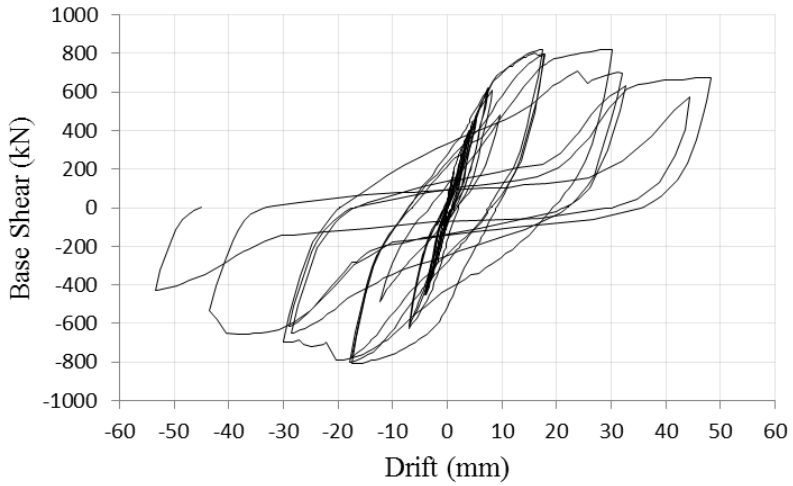
(a) (b)

Figure 10 Specimen SPW-0 during test: (a) at 0.84% drift; (b) at end of the test

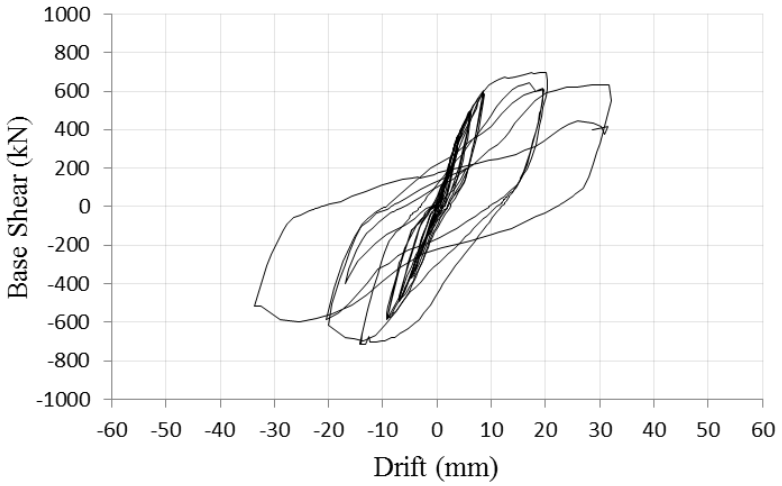
The maximum shear capacity of the specimen was observed to have reached 714 kN during cycle 13 at 20.36 mm (1.85%) drift.

Hysteresis behavior and structural properties of the specimens

Hysteresis curves of tested specimens are shown in Figure 11. The quantitative comparisons are proposed in the following sections.



(a)



(b)

Figure 11 Hysteresis curves of tested specimens: (a) SPW-1; (b) SPW-2

Because the ability of dissipating input energy is one of the main characteristics of a reliable structural lateral resistance system, the amount of cumulative dissipated energy is calculated and for different drift levels. As mentioned earlier, since the actual drift applied by the electrohydraulic jacks are different than the target drifts, it does not make sense to calculate and compare the cumulative dissipated energies by the specimens at each individual cycle of hysteresis, so these amounts are shown and compared at different drift levels. The absorbed energy by SPW-1 at 1 and 2 percent drift is 18.3 and 38.2 kN.m respectively while the absorbed energy by SPW-2 at 1 and 2 percent drift is 14.3 and 30.1 kN.m respectively. It shows that the amount of energy absorbed by SPW-1 is 27% more than SPW-2 at 2 percent drift which shows better behavior of this specimen due to more rigidity of boundary elements.

Initial stiffness of specimens are 89.9 and 96.3 kN/mm for SPW-1 and SPW-2, respectively which shows specimens are very similar regarding stiffness.

Comparative study of the results about strength of specimens shows 15% increase in maximum base shear capacity by using box-shaped columns as boundary elements.

Finite element modeling

Model Description

Finite element models of tested specimens were developed for comparison with experimental results. Frame members were modeled explicitly as built-up sections of plate elements to capture plastic hinging and local buckling observed in the specimens during testing. Due to the narrow width, FE modeling of the fish plates which were used to connect the infill plate to the boundary elements was ignored; instead a direct connection was used to model this connection, an approximation whose effects on analysis results were found to be negligible (Driver 1997). Since the bottom beam connection to rigid floor beam was established using some bolts and it was not practically possible to connect them entirely, there are some points to be considered for base connection; at bolt locations, springs are used with stiffness equal to AE/L of each bolt in which A, E and L represent area, modules of elasticity and grip of each bolt, respectively. At other points of bottom beam and rigid floor beam connection, springs with theoretically infinite stiffness in compression and zero stiffness in tension are defined and used.

Both the infill plate and boundary elements were modeled using the four-noded S4R element, a general purpose shell with reduced integration to avoid shear locking.

Nested surface model provided within ABAQUS known as kinematic hardening was used to represent the stress-strain behavior of infill panel and the frame member materials for plastic behavior. Kinematic hardening considers shifting of the yield surface without expansion during plastic straining and is proper for pushover analysis. The kinematic hardening component of the material model is considered using true stress (Cauchy stress) and logarithmic strain, σ_{true} and ε_{ln}, respectively.

Loading and imperfection modeling

To implement lateral load and to investigate the behavior of the specimens, in the lab, lateral loading was applied by horizontal hydraulic jack at the top beam level using ATC-24 protocol. For FE modeling, load was applied to the models through monotonic top beam displacement.

The initial shape of each specimen infill panel was not recorded prior to testing, although in general, small out of plane deformations (deviation from perfect flatness) due to fabrication process, welding distortion and assemblage were present which led to buckling of the infill plate. These imperfections need to be considered in FE analysis of the specimens. To account for the initial imperfections, an eigenvalue buckling analysis was performed to determine the first infill panel buckling mode prior to pushover analysis of each specimen model. The first panel buckling mode multiplied by a small displacement amplitude (10 mm) was applied as the initial conditions of the three specimens for pushover analysis. The magnitude of the imperfection was found to have a negligible effect as buckling of the plate occurred as soon as the system pushed.

Comparison of Results

Figure 12 shows the deformation shape of SPW-1 model a lateral displacement corresponding to 3% interstory drift and contours representing the magnitude of the von Mises stress in MPa. For SPW-2 is also similar deformation shape.

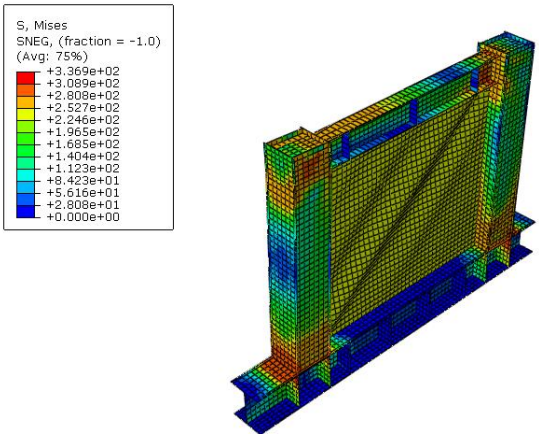


Figure 12 Deformed shape and stress distribution of SPW-1 FE models at 3% drift

The stress concentration at the beam-column connection, column bottom connection and bottom beam web at column connection zone is consistent with those observed during testing (by flaking of white wash as a qualitative measure of yielding).

Presented in Figure 13 is a comparison between the analytically predicted results for the SPW-1 and SPW-2 and the test result observed in the lab. As it can be seen good agreement between analytical and experimental results are held.

CONCLUSIONS

This study presented the procedure and results from an experimental and analytical investigation on seismic behavior of steel plate shear walls. Two 1/3-scaled one story single bay specimens denoted by SPW-1 and SPW-2 with box-shaped and I-shaped vertical boundary elements, respectively, were designed and built for the testing program. Through a parametric study the characteristics, advantages and drawbacks of system with box-shaped columns compared to system with I-shaped columns.

The hysteretic behavior of the specimens showed that the envelope curves of the SPW-1 has formed a more spindle shape and is richer than SPW-2 as it was verified by comparing energy dissipation of these two specimens in the past section. The results of comparative studies indicated that box-shaped columns improve some of the structural properties of steel plate shear walls. For example, the energy dissipation of SPW-1 at 2% drift is 27% greater than SPW-1; moreover maximum base shear capacity of SPW-1 is 15% higher.

Finite element study of specimens using ABAQUS software was also conducted and good agreement between analytical and experimental results for both models was observed.

According to these findings, it is concluded that using box-shaped columns as vertical boundary elements in steel plate shear wall system can improve its characteristics as these elements have a good torsional rigidity.

ABSTRACT

The design of engineering structures for deconstructability can reduce the energy and cost required for their demolition and the disposal of their construction waste, and it also enhances the sustainability of a building by allowing for easy dismantling and the reuse or recycling of structural components and construction materials at the end of the service life of the building. In addition, using high performance materials such as High Strength Steel (HSS) can improve the sustainability of a structure by providing for higher design stresses and accordingly reducing the self-weight of the structure. This paper describes the results of four full-scale beam-to-column deconstructable composite joints with HSS S690 flush end plates. The structural behaviour of the new system in conjunction with application of post-installed friction-grip bolted shear connectors for developing deconstructable composite floors is investigated. The test results show that the proposed composite beam-to-column joints can provide the required strength and ductility according to EC3 and EC4 specifications, and that the system can be easily deconstructed at the end of the service life of the structure as a proof of concept.

INTRODUCTION

Among different construction materials, steel has a great potential to significantly improve the sustainability of construction industry; steel structures have high strength to weight ratios, they can be erected rapidly and their construction and demolition waste can be minimised by employing prefabricated and deconstructable systems. Moreover, using prefabrication and deconstruction in conjunction with steel frames can drastically facilitate the full recycling and reuse of the construction materials and structural components. Accordingly, over the past decade several attempts have been made to enhance the sustainability of steel structures by either using high-strength durable steels or developing prefabricated demountable steel framing systems (Gogue 2012); however, the application of HSS in conjunction with deconstructable frames remains unexplored and this is the main focus of the present study.

The use of HSS has recently gained popularity in the construction industry owing to its higher yield strength, greater corrosion resistance and higher toughness compared with mild steel. In HSS construction, design stresses can be increased and thickness of plates may be reduced that, in turn, can save on the costs of labour, welding, transportation, erection and fabrication. The cost of the foundation may be reduced owing to lower self-weight of HSS structures compared to mild steel structures and significant cost benefits and reduced construction time can be achieved by increasing design stresses and reducing the thickness of plates (Mursi and Uy 2004). However, the efficient use of HSS in structural members has been hampered by problems associated with its lower ductility, weldability, toughness and fatigue resistance. In particular, the lower ductility of the HSS can potentially affect the structural performance of beam-to-column connections where the steel plates can experience large strains well-beyond the yield strain (Giaro Coelho and Bijlaard 2007; Girao Coelho *et al*. 2010). Girao Coelho and Bijlaard (2007) carried out an experimental investigation of moment connections with end plates made from high strength steel of grades S460, S690 and S960 to provide insight into the nonlinear behaviour of these joints and it was concluded that the extrapolation of the design philosophy in the current EC3 provisions, based on the semi-continuous/partially-restrained concept, can provide accurate strength predictions. In addition, it was shown that the HSS end plate connections can provide the rotation demands required for beam-to-column connections of rigid/semi-rigid moment resisting frames.

Apart from its attributes of high-strength and high-performance, design for deconstruction in conjunction with the use of recycled steel can significantly enhance the sustainability of steel structures. In a fully deconstructable steel frame, the beam-to-column connections as well as the floor slab to steel beam connections should have the potential to be easily dismantled. Bolted beam-to-column connections with flush- or extended end plates can partly provide the ease required for dismantling steel frames, but existing composite steel-concrete floor systems typically take advantage of monolithic construction to ensure adequate performance (*i.e*. near full composite action) and hence they cannot be easily disassembled and reused at the end of the service life of the structure. Furthermore, the demolition of monolithic concrete-steel composite floors in which the shear studs have been permanently buried in cast *in situ* concrete (or pockets filled with grout), requires much energy and leads to large amounts of construction waste. Accordingly, there is a need to develop deconstructable steel-concrete composite floors that can be easily dismantled at the end of a structure's service life.

Post-installed Friction-grip Bolted Shear Connectors (PFBSCs) installed through bolt holes placed in precast slabs and pre-drilled in the top flange of the steel beams is a novel method for developing composite action between precast concrete slabs and steel girders. The composite floors employing PFBSCs can be easily dismantled at the end of their service life, and this in turn can minimise the construction waste associated with the demolition of composite floors and can maximise the possibility for future reuse of the structural components (Marshall *et al*. 1971; Dallam 1968; Dallam and Harpster 1968; Kwon *et al*. 2010, 2011; Bradford and Pi 2012a, 2012b; Rowe and Bradford 2013; Lee and Bradford 2013; Ataei and Bradford 2013; Ataei *et al*. 2014, 2015). Furthermore, demountable composite floors with precast slabs and prefabricated steel girders can increase the speed, accuracy and quality of construction and reduce the time and environmental impact (*viz*. noise, disruption to traffic and pollution) of the construction.

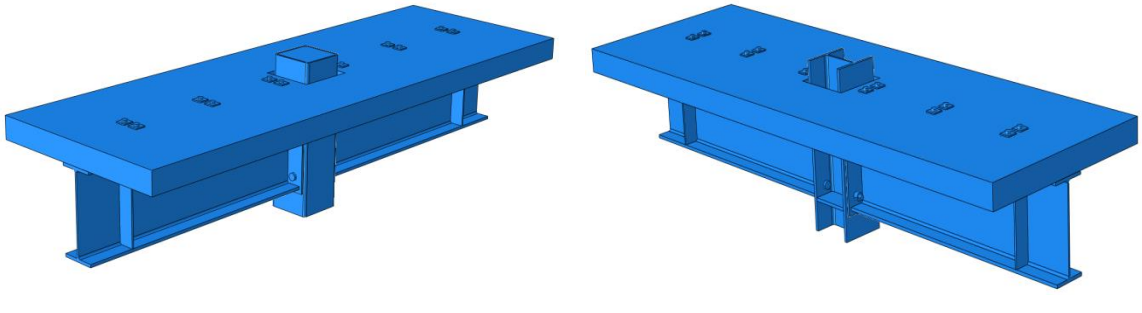
The first tests on bolted shear connectors date back to the late 60s (Dallam 1968; Dallam and Harpster 1968), but surprisingly limited studies have been conducted on the behaviour and application of bolted shear connectors since then (Marshall *et al*. 1971; Kwon *et al*. 2010, 2011; Bradford and Pi 2012a, 2012b; Row and Bradford 2013; Lee and Bradford 2013; Ataei and Bradford 2013; Ataei *et al*. 2014, 2015), and most of these studies are related to bolted shear connectors permanently buried in concrete or grout-filled pockets (Dallam 1968; Dallam and Harpster 1968; Kwon *et al*. 2010, 2011) with less attention being paid to the potential application of PFBSCs for developing deconstructable steel-concrete composite floors (Bradford and Pi 2012a, 2012b; Rowe and Bradford 2013; Lee and Bradford 2013; Ataei and Bradford 2013; Ataei *et al*. 2014, 2015). In general, the available test results show that bolted shear connectors exhibit higher load capacity and significantly higher fatigue strength than those of stud shear connectors (Dallam 1968; Dallam and Harpster 1968; Kwon *et al*. 2010, 2011). Moreover, limited experimental studies on bridge decks have demonstrated the adequacy of PFBSCs for strengthening non-composite bridge girders by increasing their stiffness, load carrying capacity and fatigue strength (Kwon *et al*. 2010, 2011).

This paper presents the results of static tests conducted on four full-scale Flush End Plate Semi Rigid (FEPSR) beam-to-column joints made up of grade S690 HSS in a steel-concrete composite frame that takes advantage of deconstructable PFBSCs and precast "Green Concrete" (GC) slabs associated with reduced cement content (Boral Australia 2013). The main objective is to determine the failure mode and characterise the moment and rotation capacity, moment-rotation relationship and ductility of this new sustainable composite system with high strength steel FEPSR beam-to-column joints. Moreover, the provisions of EC3 (2005) and EC4 (2006) are employed to assess the structural performance of the HSS FEPSR joints with deconstructable composite beams and the influence of the type of bolted shear connectors, degree of shear connection and type of columns (open sections and concrete filled steel tubes) on the structural behaviour of the proposed composite joints are investigated.

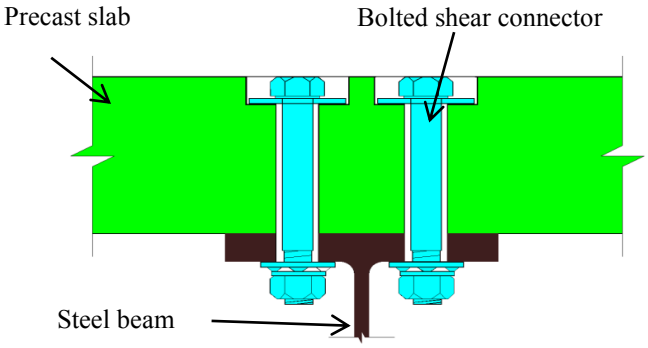
TEST SPECIMENS

Specimen design

Four full-scale cruciform beam-to-column joints with flush end plates were designed and constructed according to the provisions of EC3 (2005) and EC4 (2006) to evaluate the stiffness, ductility, bending moment and rotation capacity of the proposed deconstructable composite joints with HSS flush end plates. The beam-to-column assemblages were symmetric to simulate behaviour of an internal joint in a semi-rigid frame. The specimens were tested under a displacement-controlled vertical load applied at the tip of the beam. The geometry, dimensions and details of all specimens are illustrated in Figures 1 to 3 and the details of composite beams and post-tensioned PFBSCs are given in Table 1.



(a) (b)



(c)

Figure 1 Schematic outline of deconstructable composite beam-to-column joint with flush end plate connection: (a) pictorial view of CJ1 and CJ2; (b) pictorial view of CJ3 and CJ4; (c) friction-grip bolted shear connection.

Table 1 Test specimens.

Specimen	Column type	Steel beam	Shear connector	Degree of shear connection (%)	Hole diameter in slab (mm)	Hole diameter in steel beam (mm)	Applied bolt pretension (kN)
CJ1	250×250×12.5	460UB82.1	6M20	195	24	22	145
CJ2	250×250×12.5	460UB82.1	6M16	124	20	18	95
CJ3	250UC89.5	460UB82.1	4M16	82	20	18	95
CJ4	250UC89.5	460UB82.1	4M20	130	24	22	145

All four cruciform joints (*viz*. CJ1 to CJ4) consisted of 460UB82.1 steel beam sections. For specimens CJ1 and CJ2, the columns were a concrete-filled tubular steel 250×250×12.5 mm columns and for specimens CJ3 and CJ4, a 250UC89.5 I-section was used. Composite action between the precast concrete slabs and steel beams was provided by the bolted shear connectors installed in pairs as shown in Figure 1(c). Grade 8.8 M20 or M16 high strength bolts were used to attach the precast concrete slab to the top flange of the steel beam. In order to confirm the minimum post-tensioning forces of 95 kN and 145 kN respectively induced in the M16 and M20 bolts, an electric control torque wrench with Squirter Direct Tension Indicating washers were used. The outline and general configuration of the cruciform joints before installation of the precast concrete slabs is shown in Figure 4(a), and the precast concrete slabs after de-moulding are shown in Figure 4(b).

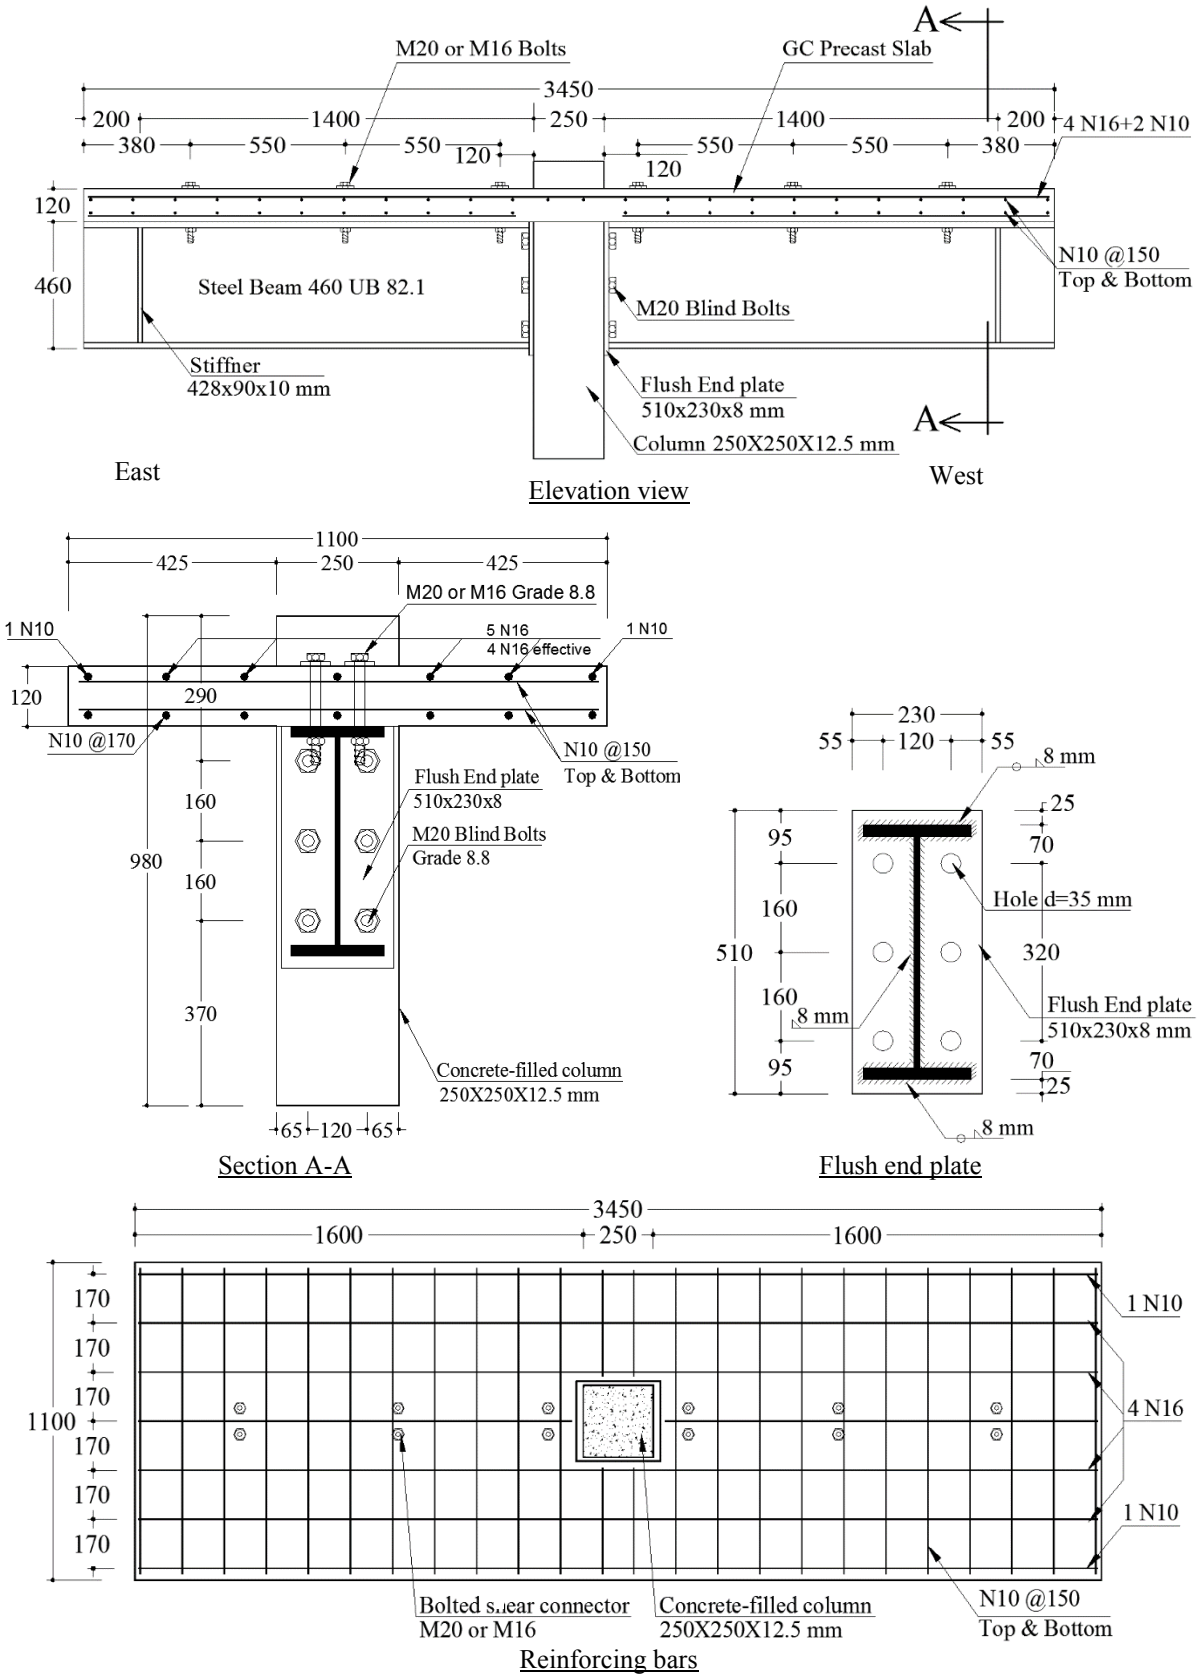


Figure 2 Geometry and details of joints CJ1 and CJ2 (unit: mm).

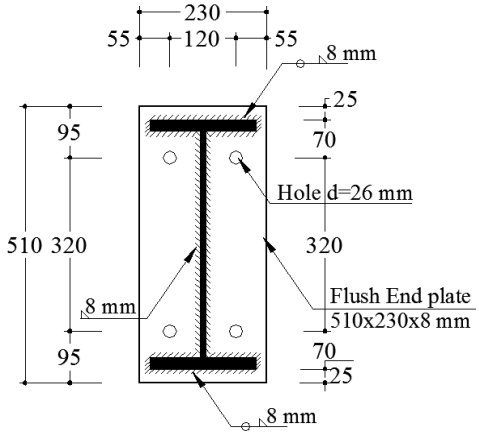
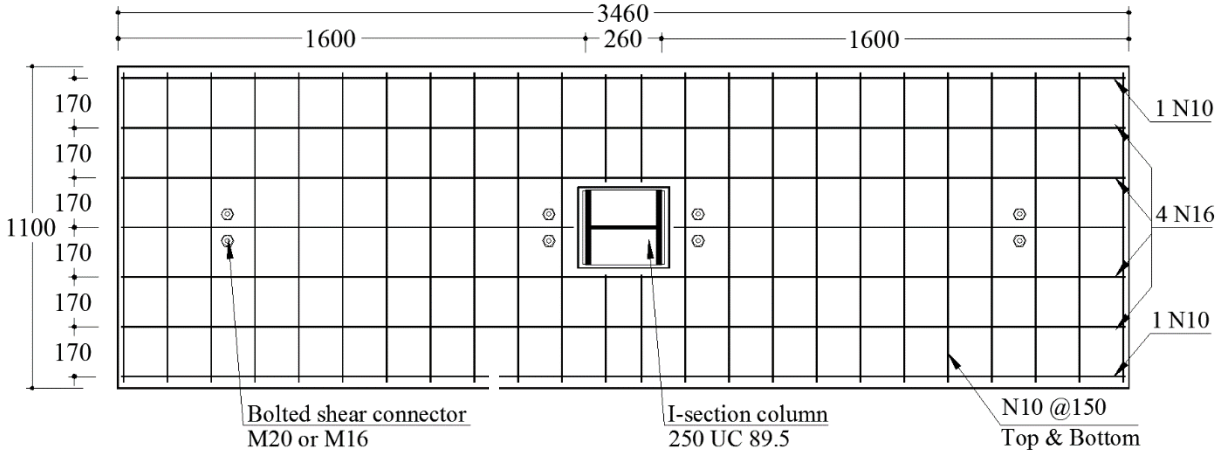
Section A-A



Flush end plate



Reinforcing bars

Figure 3 Geometry and details of joints CJ3 and CJ4 (unit: mm).

According to the provisions of EC3 and EC4, in order to prevent non-ductile failure of connections made up of mild steel grades, the thickness of the end plate should be limited to 60% of the bolt diameter (*e.g*. 12 mm thick plate for M20 bolts and 15 mm thick plate for M24 bolts). However, in a study conducted by Ataei *et al*. (2015), it was shown that the end plate thickness recommended in EC3/EC4 cannot sufficiently prevent the non-ductile mode of failure associated with rupture of bolts in FEPSR beam-to-column composite joints with deconstructable PFBSCs, mainly because of the stiffening effect of reinforced concrete slabs that has not been considered in the EC3/EC4 recommended end plate thickness. Accordingly, in this study, an 8 mm thick flush end plate (40% of the M20 bolt diameter for concrete-filled column and about 35% of the M24 bolt diameter for I-section column) made of S690 grade steel was welded to the end of steel girders to ensure ductile mode of failure. Six M20 grade 8.8 Hollow-bolt (blind bolts) (Lindapter International 2004; Standards Australia 1996; Loh *et al*. 2006) and four M24 grade 12.9 bolts were used for connecting the steel girders to CFST columns and I-section columns, respectively.

Figure 4 (a) Assembled cruciform steel joints before installation of precast concrete slabs; (b) precast concrete slabs after de-molding; (c) specimens CJ1 and CJ2 ready to be tested.

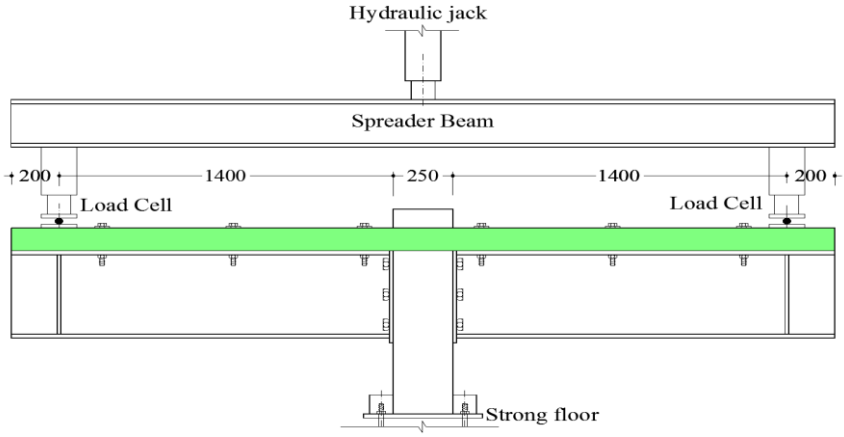

Figure 5 Test set up for the joint tests.

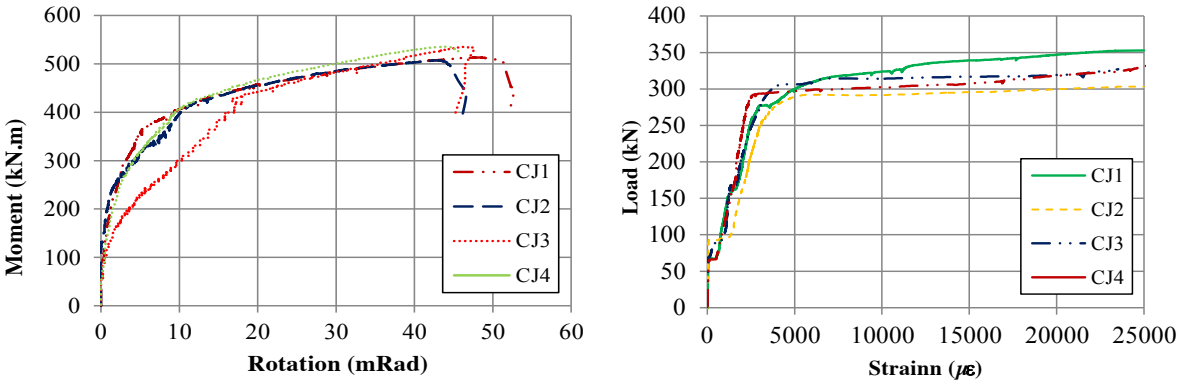
In all tested joints, the precast GC concrete slabs attached to the top flange of the steel girders were continuous over the column as shown in Figure 4(c). A longitudinal reinforcing ratio of 0.73% was provided for the slabs with the reinforcing bar configurations shown in Figures 2 and 3. It is noteworthy that the N10 bottom bars in the slabs were terminated near the column face to prevent their contributing to the bending moment resistance of the joints. Moreover, two layers of N10 bars were used in the transverse direction (see Figures 2 and 3) to prevent the longitudinal splitting of the precast slabs. The configuration of specimens CJ1 and CJ2 after assembling the continuous precast concrete slab are shown in Figure 4(c).

Experimental setup and loading procedure

The test setup and loading procedure for the composite beam-to-column joints are shown in Figure 5.Vertical displacement-controlled loading was applied to the both ends of the composite beams by a 5000 kN capacity actuator and a spreader beam. In order to verify the test set-up and performance of the components and instrumentation, before conducting each test, a small load about 10% of the predicted ultimate load carrying capacity of the specimens was applied to the specimens, and the specimens were then unloaded. The specimens

were reloaded until no further load could be sustained by the specimen. Three displacement rates of 0.3 mm/min for the linear elastic range and 0.6 mm/min and 1.2 mm/min for the nonlinear plastic parts were used sequentially.



(a) (b)

Figure 6 (a) Moment-rotation response of the specimens and (b) tensile strain in longitudinal reinforcing steel bars at the mid-span.

EXPERIMENTAL RESULTS

Moment-rotation response

To establish the moment-rotation response of the joints, the moment acting on the connection was obtained by multiplying the load applied at the end of the composite beam by the lever arm (*i.e*. distance between the centre of the loading on composite beam and the column face). Regarding the rotation of the joints, two different methods were adopted; in the first method, the difference between the rotation of the column and the steel beam measured by inclinometers was considered as the rotation of the connection, whereas in the second method, the rotation of the joint was obtained by subtracting the displacements measured by bottom LSCT from that measured by top LSCT and dividing the result by the distance between these two LSCTs. The moment-rotation responses of all four specimens are shown in Figure 6(a). Moment capacities of 513.0, 506.8, 534.8 and 535.4 kNm with rotation capacities of 48.6, 43.3, 46.8 and 44.1 mrad were recorded for specimens CJ1, CJ2, CJ3 and CJ4 respectively, and all specimens exhibited significant non-linearity with very satisfactory moment-rotation behaviour. Figures 7 (a) and (b) illustrate the state of specimens CJ2 and CJ4 after the test. The typical failure mode of the specimens is also shown in Figure 7(c).

(a) (b) (c)

Figure 7 (a) Specimen CJ2 after the test; (b) specimen CJ4 after the test; (c) typical failure mode of the specimens.

According to the EC3 and EC4 provisions, among three possible modes of failure, including yielding of the end plate or column flange, bolt failure combined with column flange or end plate yielding and bolt failure, only the first failure mode associated with complete yielding of the end plate or column flange can be considered as ductile and the third mode of failure in which only bolt rupture occurs should be considered as brittle (non-ductile). In the present experimental study, yielding and plastic deformation of the HSS grade S690 flush end plate in the beam-to-column joints with deconstructable PFBSCs took place with no fracture of the bolts located in the tension zone of the connection, which is characteristic of the ductile failure mode specified in EC3/EC4.

Moreover, in accordance with EC3 and EC4, in order to allow for plastic analysis and design, the rotation capacity of the joint must be greater than 30 mrad and as can be seen in Table 2, all specimens had a rotation capacity higher than that specified in the EC3/EC4 design codes. Accordingly, it can be concluded that despite using HSS flush end plates, the proposed deconstructable connections have sufficient rotation capacity and can be considered as ductile.

Table 2 Test result of composite and non-composite FEPSR beam-to-CFST column joints.

Specimen	Moment capacity (kNm)	Rotation capacity (mrad)	Mode of failure
CJ1	512.3	48.6	Bar fracture
CJ2	506.8	43.3	Bar fracture
CJ3	534.8	46.8	Bar fracture
CJ4	535.4	44.1	Bar fracture

Strain in longitudinal reinforcing bars

The load versus tensile strain in the longitudinal reinforcing bars at mid span of all specimens is shown in Figure 6(b). The sudden increase in tensile strain of steel bars at a load of about 80 kN can be attributed to the development of a transverse crack in the precast concrete slab and at sections adjacent to column. Moreover, it is observed that the average longitudinal strain in the reinforcing bar at the mid span for all composite specimens including the ones with weak partial shear interaction (*i.e*. specimen CJ3) exceeded the yield strain at the ultimate load.

CONCLUSIONS

In this paper, the behaviour of four full-scale sustainable high strength steel Grade S690 FEPSR beam-to-column composite joints with deconstructable PPBSCs was investigated. A novel steel-concrete composite floor with precast GC concrete slabs and deconstructable PFBSCs was adapted to improve the sustainability of the composite floor and enhance possibility for recycling and reuse of construction materials and subsequently reduce the carbon footprint of the construction industry. Type of bolted shear connectors, degree of shear connection and column type were the main variables in the experimental programme. Based on the experimental results, the structural behaviour of this novel composite system that take advantage of precast slabs and PFBSCs in conjunction with high-strength steel flush end plates were investigated. From the experimental results the following conclusions can be drawn.

- The test results show that a HSS FEPSR composite joint with PFBSCs can provide a higher rotation capacity (43 mrad and above) than that specified in the EC3/EC4 codes.
- A ductile mode of failure (as specified in the EC3/EC4 provisions) for beam-to-column joints with deconstructable PFBSCs and HSS flush end plates can be achieved, provided the end plat thickness is limited to 35-40% of the bolt size.
- The friction-grip mechanism mobilised by the pre-tensioning force in the bolted shear connectors, can effectively transmit shear between the precast concrete slabs and top flange of the steel beam at the initial stage of loading.
- Decreasing the degree of shear connection leads to a decrease in the initial strength of composite joint that in turn can increase the deflection of the composite beams under service-load condition.
- First slip with stronger bolted shear connectors occurs at higher levels of load as expected and partial shear connection leads to more ductile behaviour for the composite joint.
- Yielding and plastic deformation of the flush end plate made up of HSS S690 occur without fracture in blots located in the tension zone of the connection, provided the thickness of end plate is limited to 35-40% of the bolt size.

ABSTRACT

Presented in this paper is a method for seismic performance assessment of cold-formed steel buildings built with shear wall panels as the lateral load resisting system. In the proposed method, performance-based design philosophy is adopted to assess the seismic performance for the cold-formed steel framing system. The structural responses of cold-formed steel buildings are obtained from a simplified finite element based on pushover analysis developed in this study with accounting for the nonlinear behaviour of shear wall panels. A practical example is presented to illustrate the effectiveness of the proposed method. The results from the proposed method are compared to results obtained from the conventional analysis. Issues associated with performance-based design of cold-formed steel buildings are discussed.

INTRODUCTION

The application of cold-formed steel framing in residential building construction has increased significantly in past few decades. The global trend of applying cold-formed steel framing is advancing to mid-rise buildings. This includes hotels, multi-family housing, dormitories, and mixed-use buildings of 4-9 stories. Cold-formed steel framing provides an efficient and economical structural system which has numerous advantages and benefits with broad applications. Among them, the features of being lightweight and having good ductility have made cold-formed steel framing an attractive structural system in seismic regions where mid-rise buildings traditionally have relied on heavier construction materials.

Aimed to more reliable means of achieving life safety and property protection in seismic events, performance-based design principles have been adopted in new generation of building codes globally. In contrast with conventional design practice that focuses primarily on life-safety load levels, performance-based design also requires a structure to meet several performance objectives at lower load levels, within acceptable ranges of reliability. Such change in design philosophy and the consequent necessity for more complex analysis and design techniques to accurately evaluate structural performance at different load levels, creates a new challenge for structural engineers.

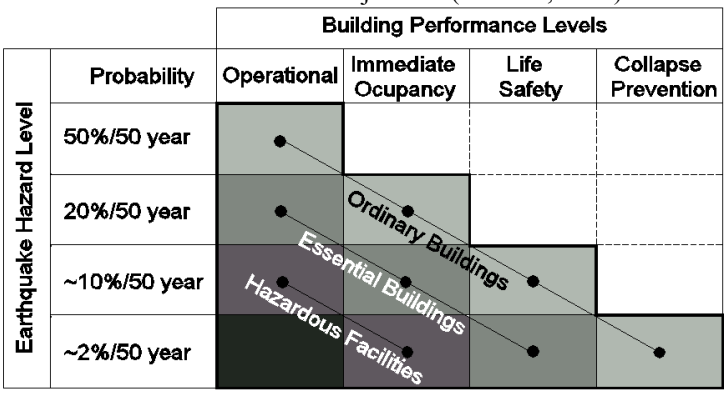
The application of performance-based design (PBD) assessment does not follow a prescribed procedure; however, nor is it the same procedure for all structural systems since it depends on the building characteristics and designer's preferences. For instance, several methods for carrying out the seismic assessment of buildings for PBD are available in current practice, such as linear, nonlinear, static, and dynamic methods, and combinations of those methods. The complexity of the application of each method is different and so are their capabilities; as a result, some of the methods might not be suitable for analyzing certain types of structures. Previous study has shown that results with reasonably accuracy can be expected from applying pushover analysis (nonlinear static method) of cold-formed steel (CFS) buildings with medium height (Martinez 2007, Martinez-Martinez and Xu, 2011). Therefore, the proposed method is limited to low- and mid-rise buildings that have a predominant fundamental mode of vibration in their response, so that single mode pushover analysis can be used. The inelastic behaviour of a building in a seismic event is a consequence of the geometric and material

nonlinear behaviour of its structural components. Where, the material nonlinearity is accounted for by incorporating the nonlinear load-to-displacement curve of the lateral-load resisting system of the building.

PBD assessment involves transforming each selected performance objective to be satisfied by the structure into a tangible parameter that can be measured in a seismic analysis. This study adopts a spectrum-based pushover analysis approach, also known as the force-based approach, in which the performance objectives are transformed into corresponding target base shears. When the lateral loads applied on the building reach to the target base shear associated with one of the governing performance objectives, the shear wall panels (SWP) are checked to determine if they comply with the acceptance criteria corresponding to the performance level.

In this study the acceptance criteria (limit damage state) for CFS buildings are established as a function of the lateral drift and lateral strength of the SWP. FEMA 273 (1997) provides limit drift ratios for several types of structures, including steel moment frames, concrete walls, masonry infill walls, and wood stud walls. The four performance levels shown in Table 1 are associated with limit drift ratios to determine if a structure design is adequate. It is common to use the drift ratios to compute target displacements for the displacement-based PBD assessment of buildings. FEMA 273 provides such limit drift ratios for wood framed panels only and no information is available for CFS shear wall panels. Therefore, in this study, the drift ratios for CFS buildings are determined from experimental test results.

Table 1 Performance objectives (SEAOC, 1995)



SPECTRUM-BASED PBD ASSESMENT OF CFS BUILDINGS

In this study, the spectrum-based approach is preferred over the displacement-based approach for the PBD assessment of CFS buildings. Typically, a building design is carried out using design spectra from pertained seismic design standards, which are used to compute the target base shears and the magnitude of the applied lateral loads of the building. Conversely, if the displacement-based approach is chosen for the PBD assessment of a building, lateral displacement is used as a target parameter. Arbitrary lateral load increments or lateral displacements are applied to the building until the target displacement is reached or until the structural collapse occurs. Then, with the total lateral load applied on the building in the analysis, the base shear can be computed and consequently the acceleration is then compared to the site design spectra to determine if the building satisfies the site requirements. Thus, in the displacement based approach, designers do not know if the building satisfies the site requirements until the analysis is complete. This may require more unnecessary displacement or load increments. The spectrum-based approach, however, is consistent with the seismic design standards. A discussion on the advantages and disadvantages of both approaches was presented by Grierson et al (2005).

For spectrum-based PBD assessment, each performance objective is associated with a particular earthquake hazard. The corresponding base shear is adopted as the damage target parameter, which represents the maximum base shear that a building can undergo during an earthquake. The target base shear for a building is computed as a function of the spectral acceleration (S_a), structural seismic weight (W), and gravity acceleration (g) for each selected performance objective as follows: for each of multiple performance objectives (PO) possible for a building (see Table 1), the base shear is computed as:

$$V_b^{PO} = S_a^{PO} \frac{W}{g} \tag{1}$$

Where S_a^{PO} is the spectral acceleration at the selected performance objective (PO), W is the seismic weight of the building and g is the gravity acceleration.

SPECTRUM-BASED PUSHOVER ANALYSIS FOR CFS BUILDINGS

In the spectrum-based pushover analysis adopted in this study, the building is subjected to incrementally applied lateral loads until the target base shear is reached or the structure collapses (the lateral force resisting elements have lost their strength and stiffness). Throughout this analysis process, the gravity loads are maintained constant on the building. Upon applying a lateral load increment on the structure, the structural analysis can be carried out by the finite element analysis. In this study, however, the analysis is carried out using a simplified finite element method discussed below with accounting for both geometric and material nonlinearities of the CFS shear wall panels (SWP) (Martinez-Martinez and Xu, 2011). From the structural analysis results at each incremental load level, the corresponding incremental displacements are obtained, and then the accumulated total displacements up to the current stage of the loading process are found.

In the PBD assessment of a CFS building, the acceptance criteria for the SWP are checked when the base shear of the building is equal to the target base shear for any selected performance objective, V_b^{PO}. Thus, if the structural elements satisfy both the deformation and strength requirements, the acceptance criteria for the specified performance objective are satisfied.

Simplified Finite Element Analysis

The simplified method can be used with any finite element analysis software with orthotropic shell elements. For that purpose, a SWP in a CFS building needs to be transformed into a flat shell with equivalent properties in both x and y directions as shown Figure 1.

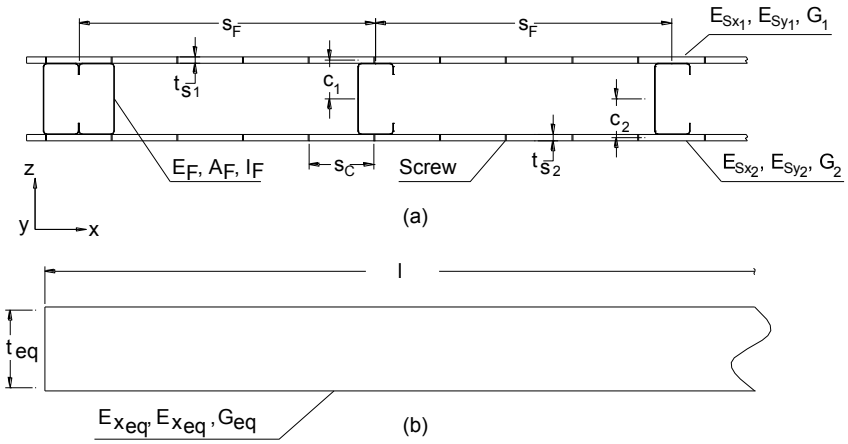


Figure 1 a) SWP cross section; b) equivalent shell

Figure 1 shows the cross section of a CFS SWP and its equivalent shell cross section, where: s_F is the spacing between CFS C-shape studs, s_C is the distance between screws on the edge of the panel, and c_1 and c_2 are the distances from the centre of the studs to the mid-plane of Oriented Structural Board (OSB) sheathing on side 1 and 2, respectively. The parameters E_F, A_F, and I_F denote the modulus of elasticity, cross sectional area, and moment of inertia about the strong bending axis of the studs, respectively; while l is the length of the panel and equivalent shell element; and t_{S1} and t_{S2} are thicknesses of the sheathing on side 1 and side 2, respectively. E_{sx}, and E_{sy} are the modulus of elastic of the sheathing for the x and y directions for each side, and the G_s is the sheathing shear modulus of elasticity.

Troitsky (1976) developed equations to determine the equivalent rigidity of orthotropic ribbed plates in bending. Martinez-Martinez and Xu (2011) extended Troitsky equations to account for the axial rigidity of the panel in the direction along the longitudinal axis of the studs (i.e., y direction). The equivalent thickness and modulus of elasticity in the y direction of a shell element are determined by equating and solving the axial and flexural rigidities of a panel and an orthotropic element. Afterwards, the equivalent modulus of elasticity in x direction is determined by equating and solving the bending rigidity of a panel and an orthotropic shell. The equations for computing the equivalent properties for the SWP are provided by Martinez-Martinez and Xu (2011).

Nonlinear finite element analysis

The shell element used in this study to model SWP in a CFS building is an isoparametric element, which typically has between four and sixteen nodes. It is recommended that sixteen-node shell element to be used because of its accuracy of modeling a typical 4' × 8' (1200mm × 2400mm) CFS SWB with one shell element. Each node of the sixteen-node shell element has five degrees of freedom (i.e., three translations along the x, y, and z axes, and two rotations about the x and y axes), which is adequate to simulate CFS panels used in construction practice.

An updated Lagrangian formulation is adopted to develop the element stiffness matrix of the sixteen-node shell element, where the values of all parameters, static and kinematic, are computed in accordance with the latest deformed configuration of the element. The procedure to achieve the elastic and geometric stiffness matrices for the sixteen-node shell element is presented in Bathe and Bolourchi (1982).

PERFORMANCE ACCEPTANCE CRITERIA FOR CFS BUILDINGS

The acceptance criteria determine if a building is properly designed to satisfy the performance levels (demands) imposed by the seismic hazards. In PBD assessment, the acceptance criteria are associated with the performance levels. If FEMA 273 (1997) criteria are adopted, as that in this study, the intensities of building damage increase from low to high for the Operational (OP), Immediate Occupancy (IO), Life Safety (LS) and Collapse Prevention (CP) performance levels. In CFS buildings, the SWP's are the primary structural elements in resisting lateral loads; consequently, acceptance criteria based on SWP lateral drift is established. In addition, the strength of each SWP also needs to be checked to prevent premature structural failure prior to reach the limit drift. In some cases, the lateral drift of a SWP might be less than the limit value but the applied lateral loads may exceed the strength of SWP, or vice versa. Therefore, both the lateral drift and strength of the SWP need to be checked to determine if the panel has been designed appropriately.

For CFS SWP, FEMA 273 (1997) does not provide any information about the limit drift ratios and acceptance criteria for estimating target displacements. Although wood and CFS shear wall panels are built in a similar manner, their force-displacement curves are not similar. Thus, the limit drift ratios for wood-framed SWP cannot be used for CFS-framed SWP. In this study, the limit drift ratios for CFS shear walls are estimated from experimental data by Branston *et al*. (2006). FEMA 273 (1997) provides the equations for determining the normalized deformation associated with the three performance levels CP, LS and IO. The equations are expressed as a function of the ductility d of the SWP, which is the normalized lateral deformation of the SWP at the CP performance level. The equation for the normalized deformation corresponding to the OP performance level is not provided by FEMA 273 (1997). For SWP, it has been reported that 40% of the yield displacement represents the service load level (Branston *et al*, 2006). The limit drift ratios for SWP at any performance level are given by the following equation:

$$LDR(\%) = \left(\Delta_{PL}/\Delta_y\right)\frac{\Delta_y}{h}\times 100 \qquad (2)$$

where LDR is the limit drift ratio for the selected performance level (PL); h is the height of the SWP; and ratio $\left(\Delta_{PL}/\Delta_y\right)$ is the normalized deformation.

The limit drifts for the performance objectives need to be computed before the pushover analysis is initiated. The limit drifts ($Drift^{PO}$) for a SWP are evaluated by multiplying the SWP height by the corresponding performance level LDR (i.e., 2.5%, 2.1%, 1.0% and 0.20% for the CP, LS, IO and OP performance levels, respectively). If the SWP lateral drifts obtained from the pushover analysis are less than the corresponding limit drifts, the displacement performance criterion is satisfied and otherwise the design must be improved.

In addition to checking the limit drifts of the SWP, the adequacy of lateral strength also needs to be satisfied to ensure the lateral strength of SWP, P_R, is greater than the applied lateral force, P_a. The lateral strength of the SWP, P_R, can be obtained from the published codified data (AISI, 2012) which is determined by testing. In the absence of applicable date, rational analysis such as the method proposed by Xu and Martinez (2006) can be considered to determine the corresponding strength. While design a CFS SWP, the following design considerations have significant impact on the lateral strength of the SWP: increasing the sheathing thickness, attaching sheathing on the both sides of the SWP (vs. sheathing being used only on one side), reducing the spacing of the screws for the sheathing-to-framing connections at the perimeter of the SWP, and increasing the diameter of the screws; while modifications below are considered to have minor influences on the lateral

strength of a SWP: increasing the thickness and depth of the CFS wall studs, reducing the spacing between the studs, and reducing the spacing of the screws for the sheathing-to-framing connections in the field of the SWP. The effects of the foregoing design considerations on the lateral strength of a SWP have been observed from experimental tests by Serrette et al. (2002) and Branston et al. (2006); and confirmed by the numerical analysis conducted by Xu and Martinez (2006).

STIFFNESS DEGRADATION MODEL FOR THE SWP

Experimental investigations, such as those reported by COLA-UCI (2001), Fulop and Dubina (2004), and Branston et al. (2006), have shown that the load-displacement relationship for a CFS SWP is nonlinear. In addition, it is observed in the aforementioned experimental investigations that the loss of stiffness and the failure of SWP are primarily due to the failure of sheathing-to-framing connections. Therefore, the nonlinear relationship between load and displacement of SWP needs to be accounted for in the finite element model of the building.

Shown in Figure 2 is the proposed nonlinear model to characterize the stiffness degradation of SWP subjected to lateral forces: K_i is the initial stiffness of the SWP as the tangent at $P_r = 0$; $K_a^{(q)}$ is the secant stiffness corresponding to the load increment, q; P_R is the lateral strength of the SWP; P_a is the magnitude of the total lateral force applied on the top of the panel at load increment q; $\lambda^{(q)}$ is the stiffness degradation coefficient that characterizes the nonlinear behaviour of the SWP under the applied lateral forces until failure and is defined by,

$$\lambda^{(q)} = 1 - \left(\frac{P_a^{(q)}}{P_R} \right)^{\beta} \tag{3}$$

where β=(38mm/s_C) is a stiffness degradation nonlinearity exponent, calibrated in accordance with experimental results from Branston et al. (2006) and COLA-UCI (2001). It is observed from the results of the experimental investigations that the nonlinear load-displacement relationship for a SWP is primarily influenced by the sheathing material and edge screw spacing. For reasons of simplicity, β was calibrated considering the screw spacing on the SWP perimeter (s_C) only in this study as described by Martinez (2007).

$\lambda^{(q)}$ shown in Eq. (3) is equal to unity at the initial load increment, indicating that the SWP lateral stiffness has not yet been affected. When the applied load P_a is equal or greater than the maximum strength P_R, $\lambda^{(q)}$ becomes zero, which indicates that the SWP has completely lost its stiffness to resist lateral deformation. However, the modulus of elasticity of the CFS studs remains unchanged in the y direction of the shell element, which means the equivalent shell may still have sufficient stiffness contributed by the studs to allow the SWP to continue carrying gravity loads.

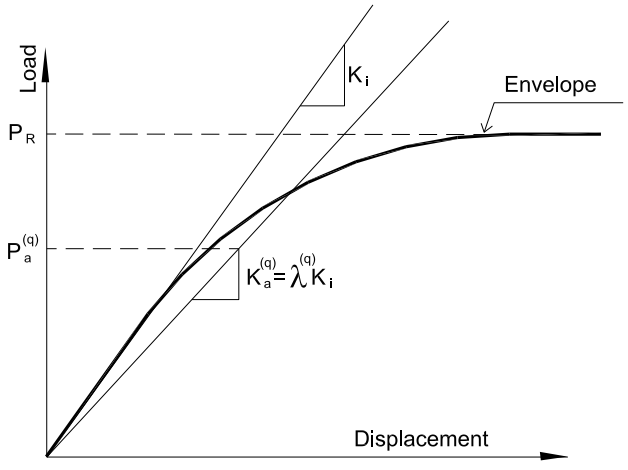

Figure 2. Characterization of the SWP loss in strength

PROCEDURE OF PBD ASSESSMENT FOR CFS BUILDINGS

A flowchart shown Figure 3 summarizes the procedure of the proposed method for PBD assessment of CFS buildings.

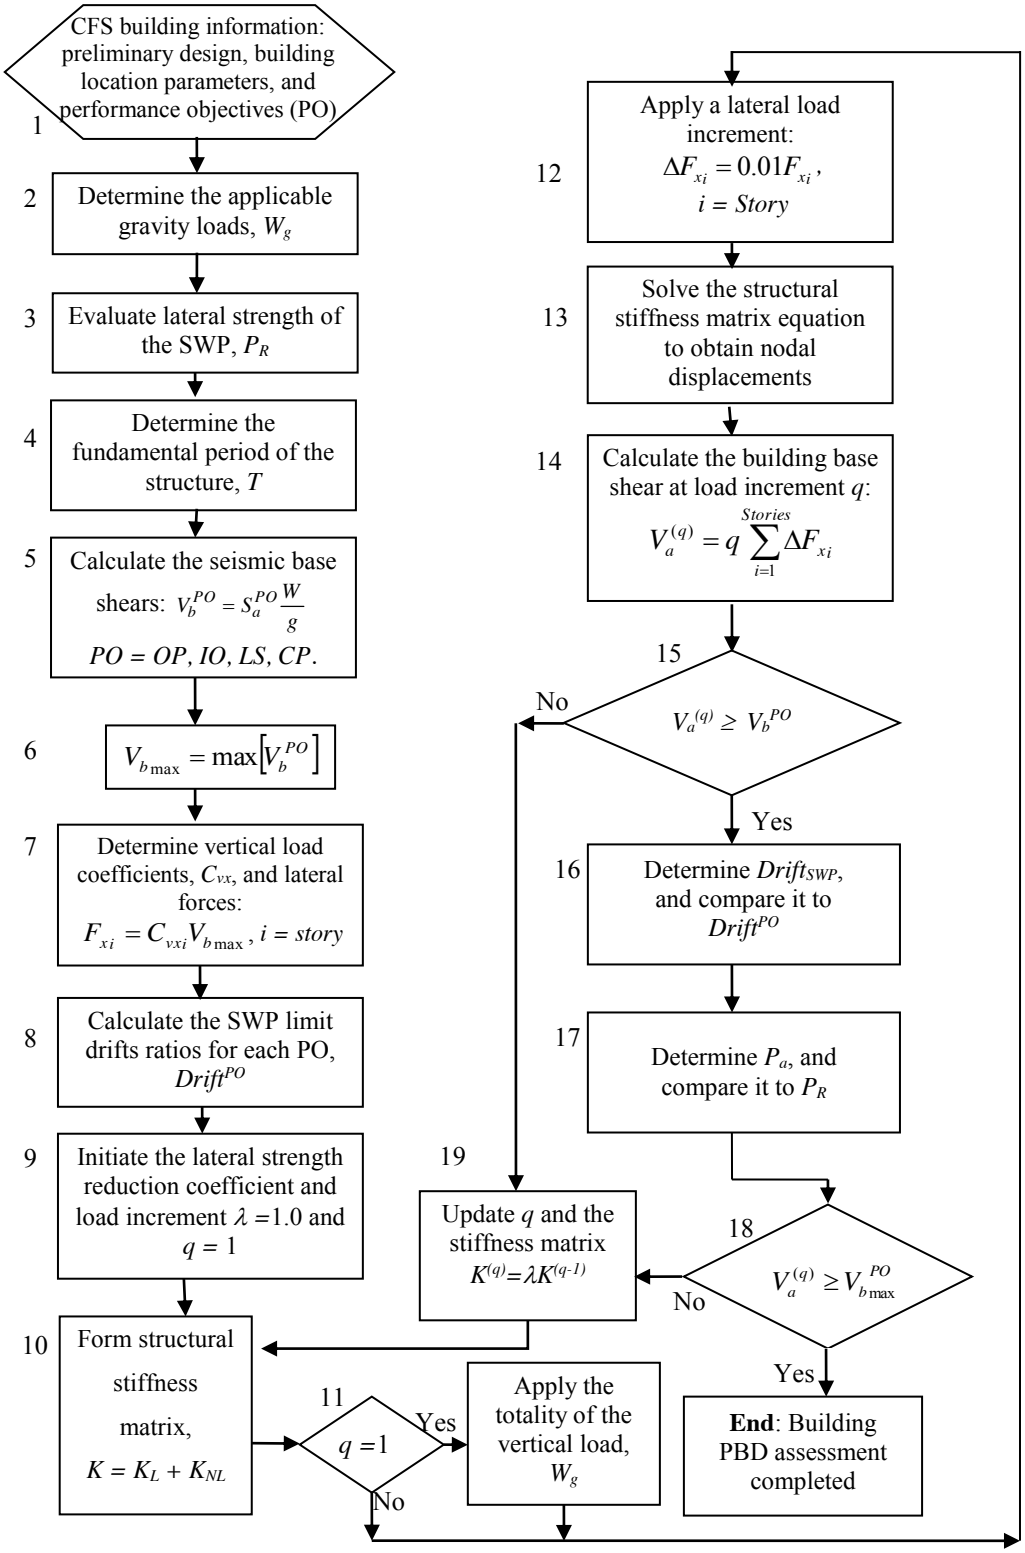

Figure 3 Proposed PBD assessment procedure

EXAMPLE

Shown in Figure 4 is a three-storey CFS building, for which the lateral displacements are to be computed for four performance levels using the pushover analysis, and the results obtained from the pushover analysis will also be compared to that of conventional linear elastic analysis. The typical floor plan of the building is shown in Figure 5. All the SWP in the building are built with cold-formed steel C-shape studs 152S51–1.73 mm (600S200-68 mils), sheathed on both sides with 12.5 mm (1/2 in) Douglas Fir Plywood (DFP). The studs in

SWP 2 are spaced 610 mm on centre. In all the SWPs, a single end-stud is used. No. 8 screws are used to attach the sheathing to the framing at 102 mm and 305 mm spacing on the edge and in the field of the SWP, respectively. The size and spacing of the screws are included to evaluate the lateral strength of the SWP in accordance with the procedure described in Xu and Martinez (2006). All the SWP on the first storey have pin supports. The floor panels consist of a concrete slab of 127 mm thickness, supported by 254 mm (10 in) deep CFS joist, designated 254S64-1.37 mm (1000S250-54 mils). The height for all the storeys is 2850 mm, and the pitched roof has 17% slope. For this example, for the reason of simplicity, the roof panels are assumed to be identical to the floor panels.

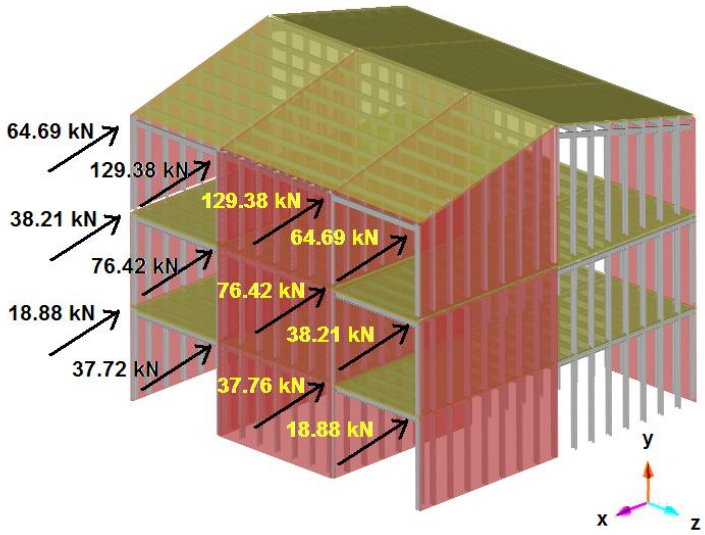

Figure 4 Example: three-storey CFS building

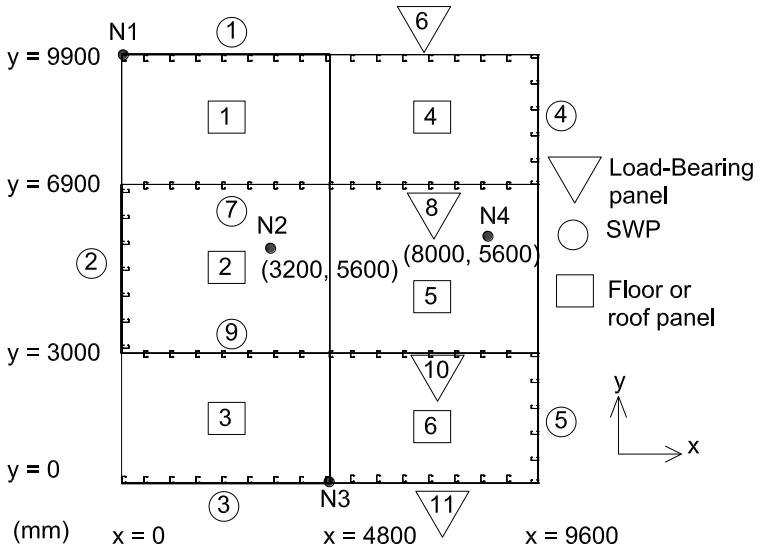

Figure 5 Typical floor plan and element illustration of the three-storey CFS building

The three-storey building is considered to be ordinary according to the categories established by SEAOC (1995), so that the building must satisfy the four performance objectives described in Table 1. The building is assumed to be located in California at latitude 41.0° N and longitude 115.2°W on a site class B. The four performance objectives are the following: OP for a 50%/50 year earthquake, IO for a 25%/50 year earthquake, LS for a 10%/50 year earthquake, and CP for a 2%/50 year earthquake.

The seismic weight of the building is W=405 kN. The natural period of the building is T=0.324 second in the x direction, which is computed according to the procedure adapted by Martinez (2007) for CFS buildings.

Shown in Table 2 are the target base shears corresponding to the specified four performance objectives, which are computed as functions of the zone seismic parameters and natural period of the building. After the base shears are computed, the lateral load for the pushover analysis is defined by the maximum target base shear $V_{b\,max}$=730.70 kN. The lateral loads are applied on the building in 1% increments of 7.307 kN, until the maximum target base shear is reached or the structural collapse occurs.

Table 2 Target base shears (kN)

PO	S_S	S_1	S_{MS}	S_{M1}	S_{DS}	S_{D1}	T_o	T_s	S_a	V_b
	(g)						(sec)		(g)	(kN)
OP	0.109	0.035	0.109	0.035	0.073	0.023	0.064	0.321	0.073	**71.75**
IO	0.180	0.058	0.180	0.058	0.120	0.039	0.064	0.322	0.120	**118.91**
LS	0.250	0.080	0.250	0.080	0.167	0.053	0.064	0.320	0.167	**164.01**
CP	1.100	0.410	1.100	0.410	0.733	0.273	0.075	0.373	0.733	**730.70**

Presented in Table 3 are the inter-storey drifts and limit drifts for the SWP related to each performance objective, which are computed by the limit drift ratios 0.2%, 1.0%, 2.1% and 2.5% for the OP, IO, LS and CP performance level, respectively. The limit inter-storey drifts are obtained by multiplying the lateral drift ratios to the height of the SWP. SWP 1 and 3 exhibit the largest lateral drifts, because the seismic loads are applied on these panels. It is found that both the lateral drifts and the lateral strengths of SWP 1 and 3 satisfy the specified performance objectives.

Table 3 SWP inter-storey drift (mm)

SWP	Performance objective											
	OP (limit=4.8)			IO (limit=24.0)			LS (limit=50.4)			CP (limit=60.0)		
	Storey			Storey			Storey			Storey		
	1	2	3	1	2	3	1	2	3	1	2	3
1	0.34	0.39	0.43	0.76	0.77	0.76	1.22	1.19	1.10	21.40	14.84	9.44
3	0.36	0.40	0.43	0.78	0.78	0.76	1.25	1.20	1.11	21.50	14.89	9.46
6	0.34	0.39	0.43	0.75	0.76	0.76	1.22	1.18	1.11	21.38	14.81	9.48
7	0.35	0.39	0.43	0.76	0.77	0.75	1.23	1.19	1.10	21.43	14.85	9.41
9	0.35	0.39	0.43	0.77	0.77	0.75	1.24	1.19	1.10	21.47	14.87	9.41

Indicated in Table 4 are the lateral strengths P_R and lateral forces P_a for the SWP at different performance objectives. The lateral strengths are computed in accordance with method proposed by Xu and Martinez (2006), and the lateral forces are obtained from the pushover analysis. Since the lateral forces in the SWP are less than the corresponding strengths, the performance objectives are deemed to be satisfied. The largest forces are obtained for the CP performance objective, since it is associated with the maximum target base shear. It is observed from the table that the summation of lateral forces in the SWP is different from the lateral loads applied on the building, i.e., for the CP performance objective the summation of forces is 677 kN while the lateral force applied on the building is 730 kN. The reason for the difference is that the panels in the *y* direction (i.e., perpendicular to the SWP 1, 3, 7 and 9) are resisting a small proportion of the lateral loads. The loads that are resisting by SWP 2, SWP4 and SWP5 are 23.79 kN, 14.85 kN and 14.77 kN, respectively.

Listed in Table 5 is the stiffness degradation coefficient, represented by λ, for each SWP. It can be observed that none of the panels has failed, although several panels on the first storey are very close to failure for the CP performance objective due to the loss of lateral load resisting capability ($\lambda \leq 0.1$).

From the results of the spectrum-based pushover analysis, it is observed that the building satisfies all seismic requirements. The four performance objectives are deemed to be satisfied since the inter-storey drifts and lateral strengths for the SWP are less than the limit values. Therefore, the PBD assessment for seismic forces is completed, and the lateral design of the building does not require modification.

Table 4 SWP lateral strength P_R and lateral force P_a (kN)

SWP	P_R	Lateral force, P_a

Illustrated in Figure 6 is a comparison of the inter-storey drifts and lateral displacements for SWP 1, obtained from the pushover analysis and the linear elastic analysis at the level of CP performance objective.

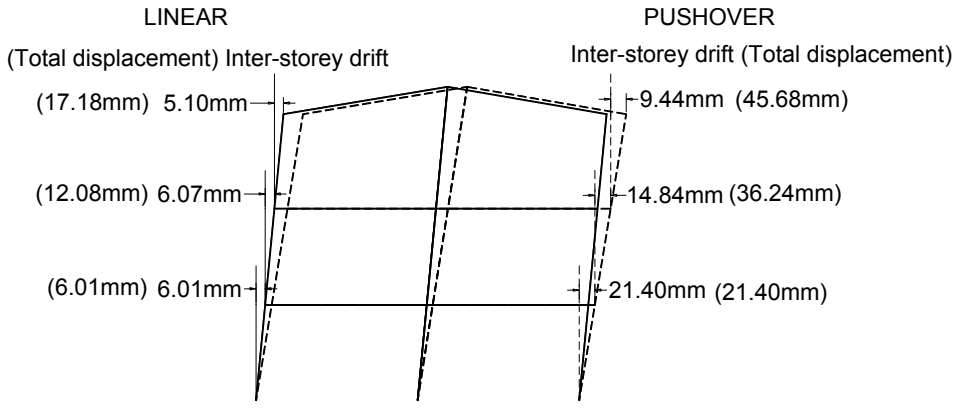

Figure 6 Inter-storey drifts and displacements of SWP 1: pushover vs. linear analysis

CONCLUSIONS

One of the primary difficulties to conduct the PBD assessment of a structural system is to establish the acceptance criteria and levels of damage associated with the performance levels of the lateral load resisting components. In this study, the acceptance criteria of CFS buildings for different performance levels are established according to the lateral drift and strength of the SWP. To account for the nonlinear behaviour of the

SWP, a stiffness degradation model was introduced in proposed push-over analysis which captures very well the nonlinear behaviour of the SWP. In addition, the model monitors the stress in the SWP during the analysis and predicts the failure of the SWP.

The results obtained from the proposed PBD assessment method of the presented example were compared to that of the conventional linear analysis. At the CP performance level, the building was subjected to the same loading condition for both types of analysis. The maximum lateral displacement of the building obtained from the pushover analysis was 2.65 times larger than that of the linear analysis which greatly underestimated the lateral drifts of the building. Therefore, considering the fact there is no appropriate method for assessing the seismic performance of CFS buildings in current practice, the proposed PBD assessment method is recommended for the seismic assessment of low- and mid-rise CFS buildings.

ABSTRACT

This study aims to propose an improved fabricated high-rise steel frame system with buckling restrained braces (BRBs) and pin beam-column connections, which is applicable to seismic areas. In this system, damages to the main structural members resulted from earthquake ground motions can be prevented by BRBs which are capable of resisting all the lateral seismic loads, whilst the other structural members are mainly responsible to carry the gravity loads. Having explicit load-carrying characteristics, this system is thought to have a competitive advantage of rapid construction. In this study, a 3D finite element model of a specific fin-plate connection, a typical type of pin beam-column connections, is built and its rotational stiffness is evaluated. Subsequently, a high-rise steel frame model with both BRBs and the fin-plate connections are established. The earthquake-resistant performances of the model under different levels of seismic excitation are analyzed using the nonlinear dynamic time-history method. Numerical results indicate that the proposed system performs elastically under frequent earthquakes, whereas under severe earthquakes the main structural components are well within their capacities. Furthermore, the BRBs show significant energy dissipation capacity under severe earthquakes.

Pin-connected steel frame system with BRBs; Fabricated pin connections; Earthquake resistance; Finite element analysis.

INTRODUCTION

In recent years, an increasing number of high-rise buildings are being constructed in developing nations such as China and other Asia-Pacific countries. For buildings constructed in the seismic areas, the expense of repairing or replacing the earthquake-induced damages is significant. For steel frame structures, in particular, the conventional rigid connections usually require on-field welding which lacks construction quality assurance and is prone to industrial accidents. In this proposition, it is obvious that the construction speed, precision and labor cost, are primary factors influencing the construction quality. Specifically, the developmental strategy advocated by the Chinese government indicates that a fabricated construction procedure, which emphasizes construction speed, safety, and cost effectiveness, should be highlighted to promote a new building revolution.

In the seismic design procedure of conventional high-rise steel frames, the rigid beam-column connections are considered to have relatively high ductility and energy dissipation properties, which are able to provide a certain level of lateral stiffness. However, extensive plastic deformations are likely to occur in individual structural members under a severe earthquake. In view of this drawback, rigid connections can be replaced by pin connections which only require on-site bolted assembly. The potential damage to the main structural members caused by earthquake ground motions can be effectively reduced by employing braces to withstand all the lateral seismic loads. Meanwhile, the pin-connected beams and columns are designed to carry gravity loads only. For a design-level earthquake, structural damages are reduced by the lateral-load-resisting members only when other structural members remain elastic (Kim and Seo 2004). As pin connections are normally assembled by bolts on site, the risks of low construction quality and industrial accidents would be decreased substantially. Given that the construction of the connections constitutes up to 50% of the overall cost of a steel frame structure, the application of pin connections will bring significant economic benefits (Bijlaard 2006).

It is well recognised that under earthquake loads, the energy dissipation capacity of a conventional braced frame is highly limited due to buckling of the braces. This issue has been rectified by using a novel buckling restrained braces (BRBs) which have become popular in high-rise steel building constructions in Asian countries in the past few years (Xie 2005). It has been demonstrated in many recent publications (Sabelli et al.2003, Kiggins and Uang 2006) that the BRB has similar strength and ductility behavior in both compression and tension, thereby

being able to absorb significant amount of energy during cyclic loading. As such, BRBs can be used as a replacement for conventional braces in a steel framed structure. As energy dissipation in steel braced frames mainly relies on the inelastic deformation of the diagonal members, the application of BRBs can significantly increase the energy dissipation capacity of the overall structural system. Consequently, demands for inelastic deformation of other structural members can be dramatically reduced.

In previous studies of pin-connected steel frames with BRBs, the connections have often been assumed to be ideal pins. However, in real situation, the "so-called" pin connections not only transfer end shear but also offer a limited level of rotational resistance. Indeed such idealised connections exhibit semi-rigid behaviors to some extent. As described above, this study aims to examine the performance of a pin beam-column connected structural system with BRBs, with a particular emphasise on the Chinese construction practice. In this system, the beam-column connections are considered to have certain rotational stiffness. Specifically, numerical study of a typical fin-plate beam-column connection (as shown in Figure 4) designed based on the existing code is performed using commercial finite element package ABAQUS. The resulting rotational stiffness of the connection is subsequently adopted for the analysis of a high-rise BRB steel frame (BRBF) with fin-plate connections. This is achieved by using open-source software OpenSees, through which the structural responses under earthquakes can be evaluated.

EXISTING DESIGN CODES FOR PIN BEAM-COLUMN CONNECTIONS

To date, the application scope of pin connections in high-rise buildings in earthquake-prone regions in China is still limited. As a result, the provisions of the design procedure for this type of buildings are also seldom found in the Chinese seismic design code (MOC, 2010).

In 1990, a categorisation system was proposed by Bjorhovde, et al. (1990) to classify steel beam-column connections according to their stiffness, ultimate strength, and ductility requirements. Based on their study, *Eurocode3 Part1.8 (EC3)* (CEN 2005) classified joints as rigid, nominally pinned or semi-rigid by their stiffness and strength. The classification boundaries in terms of the initial rotational stiffness and strength are shown in Figure 1, where M=actual connection moment; M_p=plastic moment capacity of the beam; θ_r=actual connection rotation; θ_p=plastic rotation. EC3 also recommends several common forms of simple connections such as single web-angle, double web-angle, flexible end plates and fin-plates.

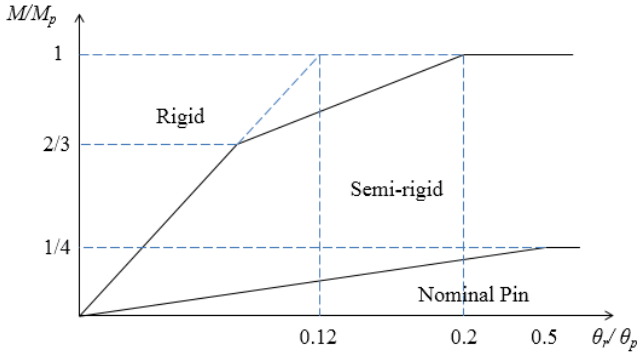

Figure 1 *EC3* classification system

On the other hand, studies related to *EC3* steel connections (Kishi et al. 1997, Jaspart and Demonceau 2008) revealed that *EC3* does not provide sufficient guidance on structural design of pin connections, especially on the behavior of joints. Therefore, it is necessary to verify the actual behavior of the connection designed following *EC3* by means of finite element simulation, to facilitate safe and accurate structural designs.

NUMERICAL MODELLING AND ANALYSIS

ABAQUS, as a finite element modelling program with visualized pre- and post-processing, is very effective in conducting detailed analyses for complex assembled structural components, such as the fin-plate beam-column connection investigated in this work. It can also be used for an accurate nonlinear analysis of the seismic responses of a building. Another finite element software, the Open System for Earthquake Engineering Simulation (OpenSees), has increasingly become one of the most influential open platforms for earthquake engineering research (Lu et al. 2015). For these reasons, both ABAQUS and Opensees are adopted in this study to perform the required analyses.

In this study, a typical fin-plate beam-column connection, and a BRBF encompassing this type of connections, are designed following *EC3* (CEN 2005) and Chinese design code (MOC, 2010) respectively. The outcome of the design is shown in Figure 4. Subsequently, ABAQUS is used to obtain the moment-rotation behavior of the connection, which is then used to simulate the seismic resopnses of the BRBF by OpenSees.

Structral details

A 3D model of a 9-story steel frame is considered herein. In accordance with the current Chinese seismic design provision (MOC, 2010), the model is designed for a highly seismic location where the seismic fortification intensity is 8°, and the design basis earthquake acceleration value is 0.3g (g presents the gravity acceleration). The design earthquake group is 2 and the construction field belongs to Site-class Ⅱ. The structural safety is specified as the second class, and the design working life is 50 years. The plan and elevation of the model are shown in Figures 2-3. The total height of the frame is 27m with a typical 3m story height. Its plan dimension is 21.6m×21.6m comprising of 3 bays in each direction. All columns are fixed to the ground. The yield strength of the steel beams and columns is 235MPa. The cross-sectional area of the BRB is 4900mm^2, and its yield strength is 160MPa. Detailed dimensions of the model are listed in Table 1.

In this study, it is assumed that the BRBs are arranged symmetrically in the exterior corner bays along the X-axis and at odd stories only (Figure 3). Such an arrangement is to examine the overall structural performance under seismic load in the X-axis. The columns are continuous and connected with beams by pin connections which are in the form of a specific fin-plate connections (which will be discussed under "Rotational stiffness of fin-plate connection").

Rotational stiffness of fin-plate connection

The fin-plate connection (shown in Figures 4-5) considered in this study is designed following *EC3* (CEN 2005). As shown in Figure 4, the configurations of the fin-plate connection consist of a rectangular fin-plate welded to the column, and bolted to the web of the beam by six bolts. The bolts are Grade 5.4 and the diameter of each bolt is 20mm. The lengths of the column and the beam are set as 1000mm and 500mm, respectively. To evaluate the rotational stiffness of this connection, a 3D model is built in ABAQUS. Solid elements are used to model the entire connection while contact pairs are created to simulate the geometrical discontinuities at the contact surfaces. The stress-strain relationship for all the components are taken as elastic-perfect plastic with a Poisson's ratio of 0.3, and the von Mises yield criterion is used to predict the onset of yielding. The coefficient of friction for the contact surface between the fin-plate and beam web is taken as 0.44. Note that the connection behaviour is significantly influenced by the boundary conditions. In this study, a pin support is assumed to restrain the top and bottom of the column, while the beam is restrained by a vertical roller (see Figure 4). A 15mm downward prescribed displacement is applied to the restrained boundary of the beam, in order to generate a bending moment to the connection.

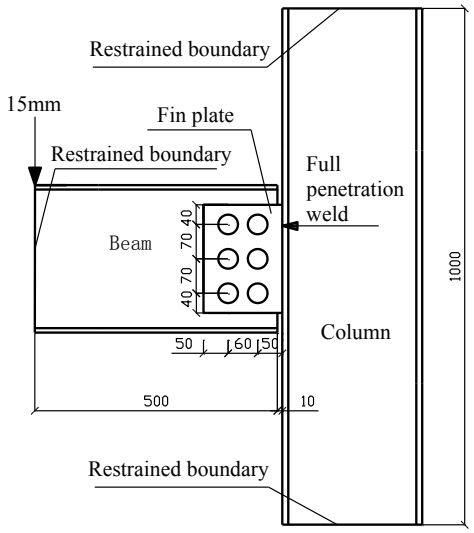

Figure 4 Configuration of the designed fin-plate connection/mm

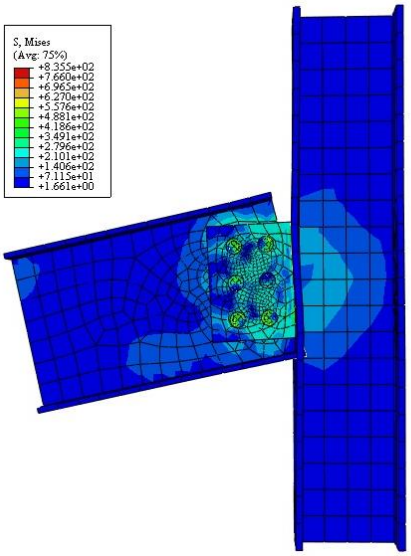

Figure 5 von Mises stress distribution/MPa

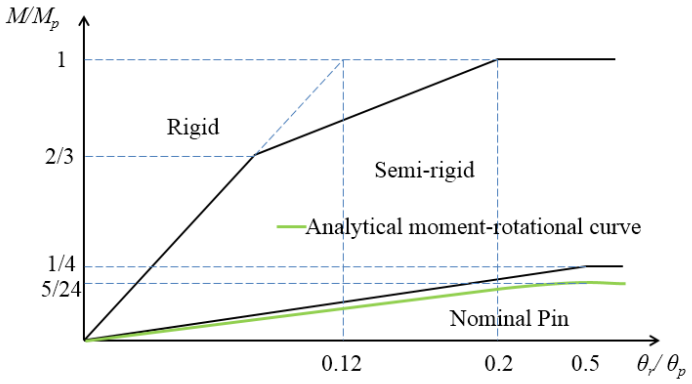

Figure 6 Moment-rotational behaviour

Figure 5 shows the von-Mises stress distribution and the deformed shape of the connection under the action of the prescribed displacement. The stresses within the connection are generally low except at the region around the

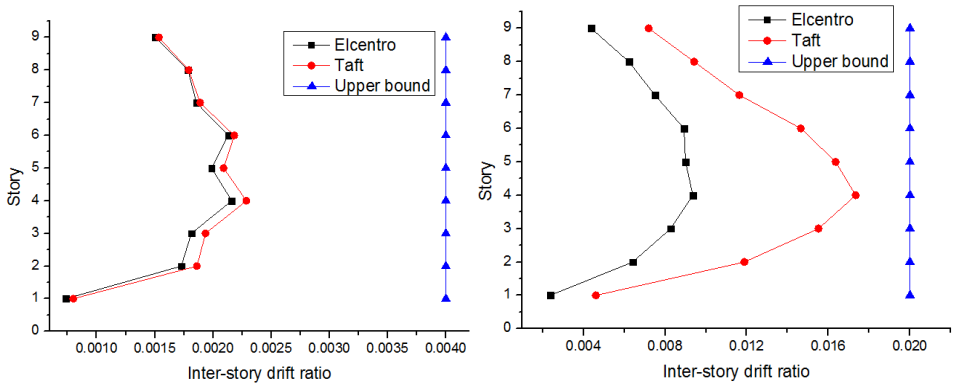
top two bolts, which indicates a relatively weak moment-transfer capability of the connection. As shown in Figure 6, the analytical moment-rotation behaviour of the fin-plate connection obtained from ABAQUS is superimposed on the *EC3* classification system (Figure 1). It is evident that the numerically predicted behaviour of the fin-plate connection falls within the semi-rigid area, thereby can be categorised as a pin connection in the structure design procedure.

OpenSees models

In the OpenSees model of the 9-story steel frame with BRBs (Figures 2-3), the displacement-based beam column elements with fiber sections are used to simulate the beams and columns. To take into account material nonlinearity, "steel 01" material with bilinear behaviour is applied. For geometry nonlinearity, P-δ effects are considered for the columns and BRBs. Truss elements are used to model BRBs, and "steel 02" material with hysteretic behaviour in both tension and compression (Uriz and Mahin 2008) is employed to simulate the BRBs. For the pin connections exhibiting a certain level of rotational stiffness, a pair of slave and master nodes must be defined at each beam-column connection. Specifically, these nodes are connected with a Zerolength element and share the same translational degrees of freedom. To simulate the in-plane (i.e., X-Z plane) rotation of each connection under seismic load, a multilinear material with the rotational stiffness predicted by ABAQUS (Figure 6) is assigned to the Zerolength element around the Y-axis. The out-of-plane rotations of the connections around the X- and Z- axes are replicated by assigning an elastic material property with a relatively low stiffness.

Dynamic time-history analysis method has the advantages of providing informative and accurate solutions for seismic resistance study. Therefore, this method is used herein to obtain the seismic behaviour of the structure under frequent and severe earthquakes. Two recorded earthquake ground motions, from the 1940 El-Centro Earthquake and the 1952 Taft Earthquake, are considered. The ground motions, which are scaled to a value of peak ground acceleration (PGA) of 110gal (representing frequent earthquake) and 510gal (severe earthquake), are initially used as the seismic input to the structure along the X-axis, after the static and modal analysis are conducted. Additionally, a 2% damping ratio is taken into account during the nonlinear dynamic time-history analysis.

Figure 7 shows the envelope of the inter-story drift ratios of the structure under the action of two seismic ground motions with different earthquake intensities. It can be seen that the maximum drifts occur at the 4th story when the structure suffers both frequent and severe earthquakes. Due to the various hysteretic behaviors of the seismic wave input, the response of the entire structure, especially when PGA is 510gal, is more pronounced under Taft ground motion. It can be further noticed that the predicted inter-story drifts of the structure are less than the specified upper bound values, i.e., 1/250 under frequent earthquakes and 1/50 under severe earthquakes, as specified by the Chinese code (MOC, 2010), indicating a reasonable level of lateral stiffness of the structure.



a. PGA=110gal b. PGA=510gal

Figure 7 Inter-story drift ratio

Identical behaviour of BRBs are observed on both exterior spans due to their symmetrical arrangement (see Figure 3). The axial force-displacement relationships of the typical BRBs on the left exterior span of the 1st, 3rd, 5th and 7th stories are plotted in Figure 8. Although the seismic response of the structure is stronger under Taft ground motion, yielding of the BRBs are found under both earthquake actions for PGA=510gal. It can be seen from the figure that the BRBs on the 3rd and 5th stories exhibit excellent hysteretic and ductile behaviour, thus they play the most effective roles in dissipating seismic energy. On the contrary, the BRBs on the 1st and 7th stories demonstrate relatively smaller hysteretic energy capacity. Although not showing in the figure, the BRBs on the 9th story are found not to completely enter the plastic state. To achieve more economic design, the BRBs

on the top and bottom stories can be designed to have smaller cross section, leading to more uniform contribution from all BRBs to the overall structural performance.

CONCLUSION AND FUTURE DIRECTION

Pin connected steel frames with BRBs are able to take advantages of the BRBs in resisting earthquake loads without undergoing large plastic deformations. The finite element models are established using two software packages ABAQUS and OpenSees to study the seismic performance of such structures. The rotational property of a specific fin-plate connection and the seismic responses of the whole structure are evaluated. Simulation of the fin-plate connection demonstrates that it performs as a pin connection for the design purpose. Analysis results of the high-rise BRB steel frame (BRBF) employing this type of connections reveals that the structure performs well in energy dissipation. Most BRBs are developed into the plastic stage and exhibit excellent hysteretic and ductile behaviour in resisting the lateral forces. In other words, the BRBs play important roles in absorbing energies against seismic activities. Based on these observations, it can be initially concluded that the BRBFs can be used in the areas with a fortification intensity of 8°.

Although the seismic response of the BRBF with a typical pin connection has been preliminarily studied, more analytical data are still required to further examine this structural system. As the behaviour of connections can be significantly affected by various connection types and the number of bolts, more finite element studies will be conducted to investigate the behaviour patterns of different connections. This will facilitate further evaluation of the rotational stiffness of beam-column connections and their influences on the seismic performance of BRBF. Furthermore, different BRB arrangements and sections will be studied to optimize the performance of this type of structural system.

ABSTRACT

Structural bolts have been manufactured for building construction for hundreds of years. In practice, failure of high strength structural bolts might be caused by their tolerance classes or coating procedures, which may weaken their internal or external threads. However, this research work is dedicated to understanding a bit more on bolt performance in tension, accounting for effects of tolerance classes in the applied numerical simulation for assessment of performance of structural bolts subjected to tensile loading. In addition, different constitutive relationships has also been taken into account in the numerical analysis in use of both implicit and explicit methods. The observed simulation results demonstrated two failure mechanisms for structural bolts, threads stripping and bolt shank failure, which has proved to be associated with their tolerance classes and coating procedures applied. As a result of this, carefully selecting bolts and nuts is a deliberate solution in preventing the premature failure (threads stripping) in bolted connections for performance-based steel construction.

High strength bolts, tension, numerical simulation, threads stripping.

INTRODUCTION

In modern steel construction, bolted connections are commonly in use for assembling steel beams and columns for a steel-framed building, transmitting the loads applied from one steel member to another. Based on their stiffness, strength and rotational capacity, a classification system has been proposed in the research work of Nethercot et al. (1998) and four categories, including fully connected, partially connected and pin connected and non-structural connections, are specified for both serviceability and ultimate limit states in the classification. It ought to be worthy of understanding that the rotational capacity of a bolted connection is rooted from the deformation of its components and the interactive mechanism between them (Kuhlmann and Furch 1997). In fire, mechanical performance of steel connections may be variable due to deterioration of material properties, i.e. strength and Young's modulus. Certainly, the interactive mechanism may be another interesting point for these connections, which, however, will not be discussed in this paper.

In addition, failure in structural bolts might be a critical phenomenon in a fire situation, which has been found for bolted connections in a series of experimental tests (Wang et al. 2010), also discovering two primary failure mechanisms: thread stripping and bolt shank necking. For engineers and designers, failure in threads means reduction of tensile resistance of structural bolts in a fire or non-fire situation, which has been proved in the experimental tests of Kirby (1995) and Hu et al. (2007). They also indicated that fire performance of assembled bolts and nuts would be affected by these failure modes plus factors related to the manufacturing process and variation in tolerance classes. As a result, tensile performance of high strength structural bolts in fire needs to be carefully examined through application of finite element simulation in this research work.

FINITE ELEMENT SIMULATION

Helical Thread Model for Structural Bolts

In simulation of bolt performance in tension, the simplified approach was applying a two-dimensional FE model to represent a three-dimensional problem (Chen and Shih 1999). However, this simplification would result in stacking an appropriate number of threads in the threaded portion for the FE models, unable to catch helical effects in external and internal threads, e.g. loosening phenomena of bolted joints. Therefore, Fukuoka and Nomura (2008) highlight that, when analyzing the mechanical behavior of bolted connections with three-dimensional analysis, it has been a common practice that using helical thread models for the threaded portion of bolts has asymmetrical geometry. The general details on geometrical dimension for a single fastener are

illustrated in Figure 1. In addition, as presented in the research work of Kirby (1995) and Hu et al. (2011), the tolerance class (the degree of fit) and over-tapping process (for accommodating the extra zinc coating layer) may have an influence on bolt performance in tensile failure. So internal and external threads have been set up for producing thread difference of tolerance classes in the numerical analysis. General details on tolerance classes for high strength hexagonal bolts are determined in accordance with specification of BS 4190 (BSI 2001), BS 3692 (BSI 1967) and BS EN ISO 4014 (CEN 2001) for the proposed helical thread model. Thread profile details are available in the specification of BS 3643-1 (BSI 1981) and ISO 965-5 (ISO 1998).

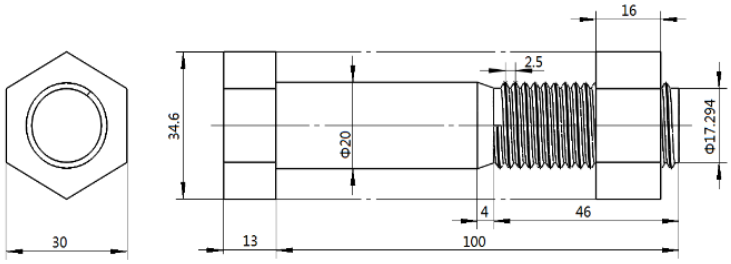

Figure 1 Geometrical details for a single fastener

Tolerance Class

Tolerance class is defined as a number and letter combination for indicating the degree of fit between internal and external threads: the figure representing the tolerance grade and the letter indicating the tolerance position, as illustrated in Figure 2. The previous standards (BS 3643-1, ISO965-4 and ISO 965-5) present the specified tolerance classes for internal threads to mate with external threads. The British standards (BS 4190, 2001) accept the tolerance class 7H/8g as the specification, while a closer fit (6H/6g) for internal and external threads has been adopted in the European standards (BS EN ISO 4014, 2001). The British standard also states that, when a thick protective coating is applied to a structural bolt of grade 8.8 or 10.9, internal threads are required to be over-tapped for protection of bolt threads. Normally, a zinc-based metallic layer has been applied to these threads based on the ISO standard (ISO 965-5, 1998) through calculating fundamental deviations, EI_{AX} or EI_{AZ}, where the over-tapped thickness for the coating is about 0.4 mm. This process may result in a problem on weakening the internal (nut) threads for structural bolts. The thread profiles for internal and external threads, including the major, pitch and minor diameters, are already available in the standard BS 3643-1 (1981), where their tolerance positions and thread profiles are also demonstrated in Figure 2.

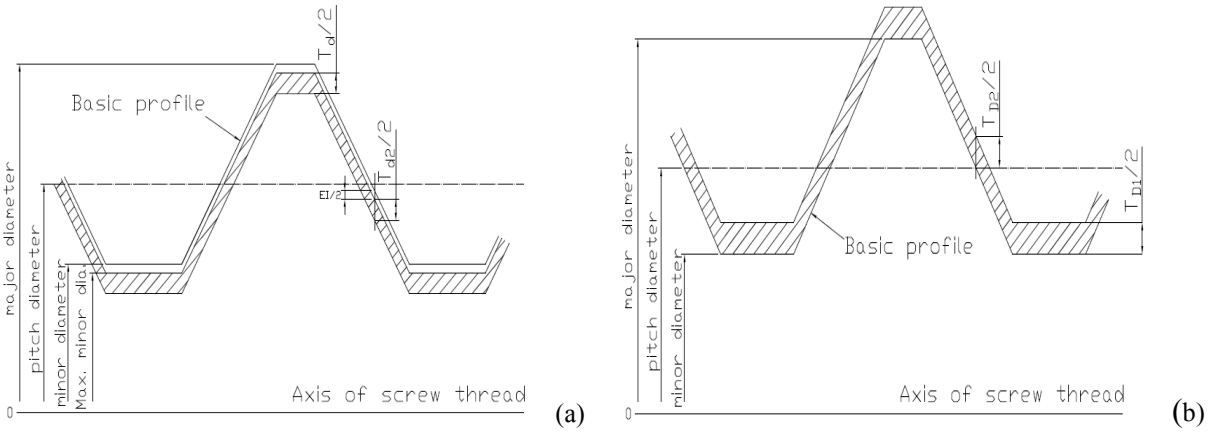

Figure 2 thread profiles for external and internal threads: a) tolerance position g for external threads; b) tolerance position H for internal threads

Mesh Generation and Contact

Fukuoka and Nomura (2008) advised researchers to use some sophisticated functions of commercial software for an effective modeling. So the mesh generation scheme proposed here may be executed with the help of commercial software e.g. ABAQUS. The finite element mesh for a single bolt with its boundary conditions is illustrated in Figure 3, with applying 3D continuum hexahedral elements in numerical analysis, recommended by Sherbourne and Bahaari (1994 and 1997). Regarding the FE model shown in Figure 3, for the bolt cylinder, axial displacements are fully restrained at the bottom surface of a bolt, and the axial force is applied as a

uniform displacement to a nut surface. For contact simulation, there are two formulations (small sliding and finite sliding) available for modeling the interaction between two contacting surfaces. Comparison has been performed for small sliding and finite sliding, and it has been realized that the small sliding formulation is less expensive in computation than the finite element sliding approach (Abaqus 2014). Regarding the contact friction, Fukuoka and Nomura (2008) present that coefficients of friction μ are varied from 0.05 to 0.20, with coefficient of friction = 0.15 employed within this study. Master surfaces and slave surfaces are specified for internal and external threads, as illustrated in Figure 3. In addition, general details for integration methods, element types, contact formulations and applied displacements are collected for the simulation in Table 1.

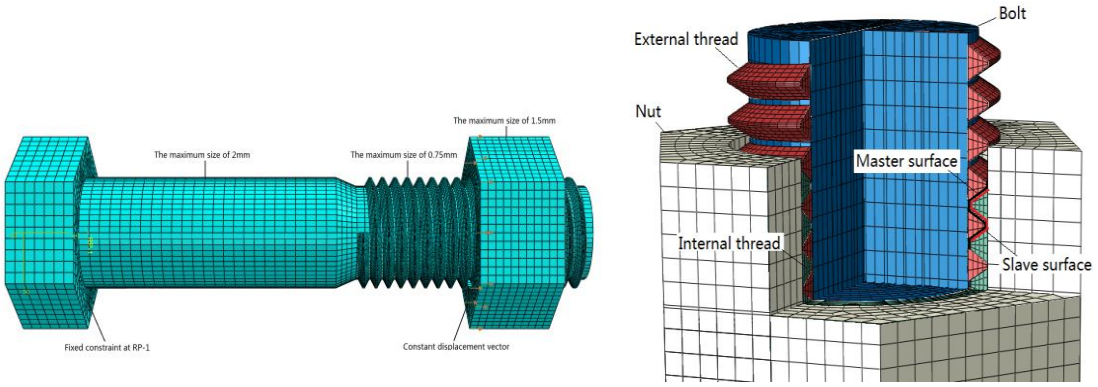

Figure 3 Finite element mesh with boundary conditions

Table 1 Detailed information of the numerical model

Bolt group	Bolt standards	Nut standards	Tolerance class	Integration method	Element type	Contact simulation	Failure mode
Bolt group B	Grade 8.8 (BS EN ISO 4014)	Grade 10 (BS EN ISO 4032)	6H/6g	Explicit	C3D8R	Small sliding	Ductile necking

Bolt group C				Implicit	C3D8I	Small sliding	Threads stripping

Material Laws

It has been a common practice that structural bolts and nuts are made from low alloy metals or carbon steels, whose Young's modulus and Possion's ratio are 200 GPa and 0.3, respectively. Four different constitutive relationships, demonstrated in Figure 3, are represented with engineering stresses and engineering strains for bolt materials, proposed in the research work of Hu et al. (2010), Bahaari & Sherbourne (1997) and Dessouki et al.(2013). The von Mises yield criterion is commonly applicable to the metal-based materials for prediction of the onset of yielding, and the behavior on further yielding is predicted by the associative 'flow rule' and hardening law. The bi-linear material model, shown in Figure 4 (a), assumed the onset of yielding at the strain ε_p corresponding to the proof stress, and simply determining the value of 5% as the ultimate strain for the bolt material. Bahaari and Sherbourne (1997) presented a trilinear stress-strain model displayed in Figure 4 (b), the yield stress was considered to take place at a strain of 0.006 and the ultimate strength presumed at a train of $8\varepsilon_p$, where ε_p is the proof strain. Dessouki et al. (2013) modified the previous trilinear stress-strain relationship for the bolt material, as illustrated in Figure 4 (c), where the yielding strain was assumed as $3.5\varepsilon_p$, corresponding to the 'yielding' strength ($0.67f_u + 0.33f_{0.2p}$). The ultimate strength and strain adopted are the same as previously described. The final trilinear material model, as displayed in Figure 4 (d), assumed a yielding plateau between ε_p and $3\varepsilon_p$, and the ultimate strength is specified at a strain of 5% for the numerical analysis.

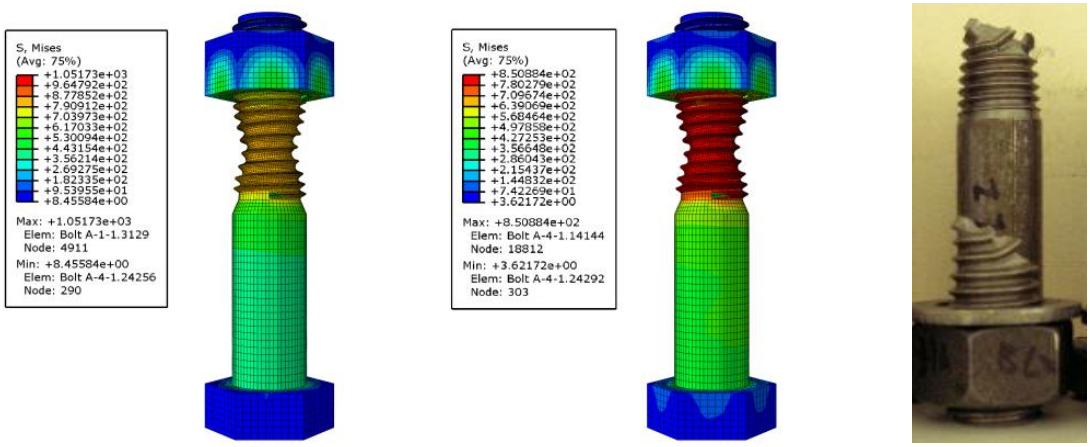
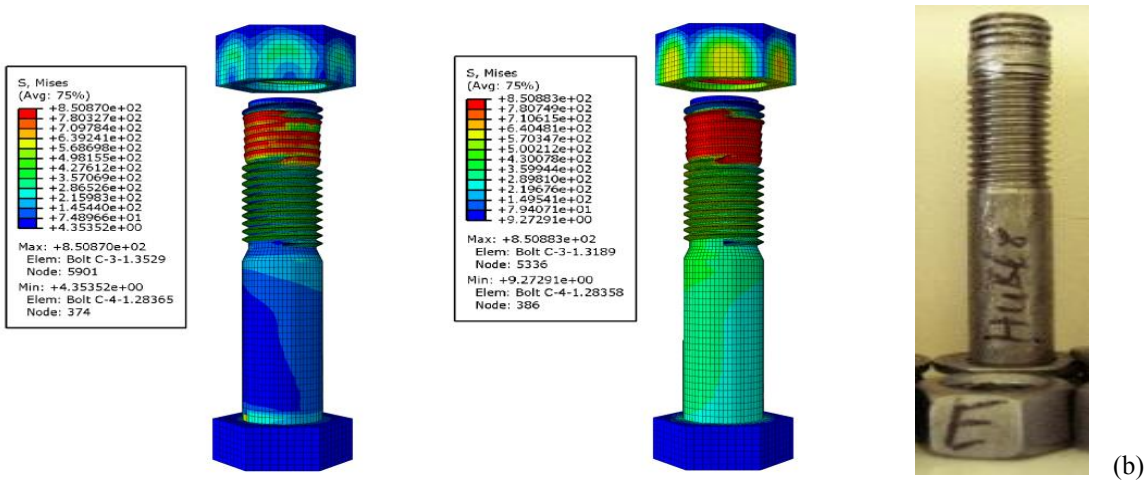
NUMERICAL RESULTS AND DISCUSSION

Failure Mechanisms

Failure of structural bolts in the numerical simulation has been illustrated in Figure 5, in comparison with bolt failure mechanisms in experimental testing. It has been observed that the failure mechanisms produced from the numerical analysis are consistent with experimental tests, including ductile necking and threads stripping for structural bolts. However, the numerical analysis is not capable of addressing the fracture behavior for these components, owing to no failure criteria introduced into the numerical simulation.





(b)

Figure 5 Failure mechanisms: a) bolt shank failure; b) threads stripping

Force-Displacement Curves

Previous discussion tends to be focused on producing the failure of structural bolts in the numerical analysis. Nevertheless, influence of various constitutive models on bolt performance may be worthy of further investigation. As a result, the force-displacement curves produced from the numerical simulations considered different constitutive material laws, as illustrated in Figure 4. In accordance with the European Standards (CEN 4014/4017), the yielding and ultimate loads (161 kN and 203 kN) are derived analytically for structural bolts, displayed in Figure 6. Then the numerical analysis has been performed through implicit and explicit integration procedures. From these numerical simulations, it should be very clear that before the yielding limit (161 kN), forces and displacements recorded are almost identical for all the plotted curves in Figure 6. After the material yielding, the load-deformation relationships for Bilinear model and Trilinear model 3 are almost consistent in the numerical analysis. In a similar way, the plotted curves for Trilinear model 1 and Trilinear model 2 are in good agreement with each other in the displayed figure below. In addition to this, the numerical simulation discovered that the bearing capacity of a single bolt was highly dependent on its failure mechanism. The numerical models with bolt shank failure overestimated their bearing capacities in comparison with the theoretical value calculated from the standards. For bolts failed with threads stripping, the numerical models might underestimate the peak values in the analysis.

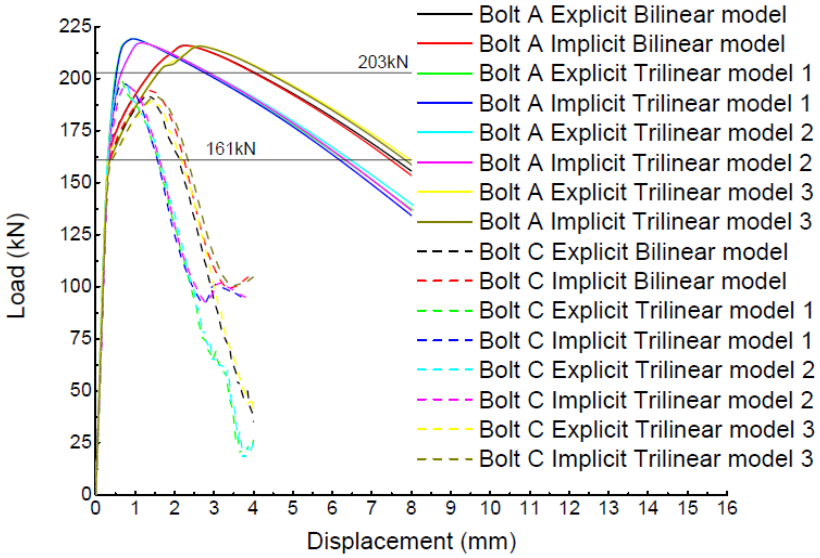


Figure 6 Numerical simulation results for constitutive laws

CONCLUSIONS

This research work investigated tensile performance of high strength structural bolts with determined tolerance classes in their threads in use of the numerical analysis. It also considered the influence of different material

laws and numerical integration procedures on numerical results. After compared with experimental and analytical results, it should be clear that the numerical simulation is capable of predicting the failure modes of structural bolts. Secondly, the bearing capacities of bolts are closely dependent on their failure mechanisms achieved in pure tension, confirmed by experimental testing and numerical analysis. Thirdly, the numerical prediction on the bearing capacity for a single bolt is generally in the acceptable region compared with the theoretical value (203 kN). Overestimation or underestimation to failure loads of bolts might be observed in the simulation relying on their failure modes produced.

ABSTRACT

Accidental events, such as impact loading, are rare events with a very low probability of occurrence but their effects often leads to very high human losses and economical consequences. An adequate design should not only reduce the risk for the life of the occupancy, but should also minimize the disastrous results and enable a quick rebuilding and reuse. A robust design prevents the complete collapse of the structure when only a limited part is damaged or destroyed. Design against disproportionate collapse is usually based on the residual strength or the alternate load path methods. Identification of an alternate path may lead to an effective and cost efficient design for progressive collapse mitigation by redistributing the loads within the structure. The continuity of the frame and of the floor represent essential factors contributing to a robust structural response. They in fact enable development of 3D membrane action. A European project focusing on robustness of steel and steel and concrete composite structures subjected to accidental loads is still ongoing. In the framework of the project the authors concentrated their studies on the redundancy of the structure through slab-beam floor systems as well as through ductile joint design. At this aim, two 3D full scale substructures were extracted from a reference building and experimentally investigated with the purpose to get an insight into the mechanisms allowing the activation of the alternate load paths resources, when a column collapse. The paper illustrates the main features of both the specimens tested and the experimental campaign. The preliminary results of the tests are presented and discussed.

KEYWORDS

Robustness, alternate path strategy, collapse of a column, steel and concrete composite structures, membrane action, full-scale tests.

INTRODUCTION

Accidental events, such as impact loads, extreme fires or blasts, are rare events with a very low probability of occurrence but their effects often leads to very high human losses and economical consequences. An effective design strategy should pursue the twofold objective of reducing the risk for the life of the occupancy and of minimizing the disastrous results enabling a quick rebuilding and reuse. Difficulties in identifying all the possible damage scenarios and sources of damage activation, associated with the need to adopt design strategies economically sustainable, lead to the set up of design strategies able to limit the spreading of the damage rather than avoid it. This concept is associated to the term 'structural robustness'.

A definition of robustness has been attempted aiming at provide the background to its implementation in design practice. The Eurocode 0 (CEN 2002) defines robustness as *"the ability of a structure to withstand events like fire, explosions, impact or the consequences of human error, without being damaged to an extent disproportionate to the original cause"*. Design a structure so that this requirement is met means to adopt structural measures economically justifiable to limit failure to an acceptable extent. A more recent definition (Sørensen 2011) describes robustness as *"the attitude of a system to survive to damage"*. In accordance with this definition, robustness is a combination of vulnerability, i.e. the attitude of an element to be damaged, and damage tolerance, i.e., the attitude of a system to survive to damage. Damage tolerance, vulnerability and robustness are properties of the structure and do not depend on the actions/events.

As to design practice, the Eurocode 1-7 (CEN 2006), which covers accidental actions, recognizes several design strategies to be adopted in design diversified on the basis of the impact that the collapse would produce on the society. Such an impact is evaluated by considering the consequences on people, on the economy and on the environment. Depending on the building type and occupancy, structures are categorized in 3 classes of consequences. For each of these classes, various strategies of prevention are identified. For low consequence of failure the adoption of minimum structural requirements are prescribed, while a risk analysis and the use of

refined methods based on dynamic analyses, non-linear models and incorporation of the interaction between the load and the structure are suggested for the highest consequence class. The choice of the strategy of prevention is also influenced by the peculiar features of the accidental actions. By considering the unforeseen probability of the events and the practical impossibility to define "a priori" all the possible scenarios, the Eurocode (CEN 2006) distinguishes between 'identified' and 'unidentified' accidental actions. Different design strategies are hence associated with each of the two categories of action (Figure 1).

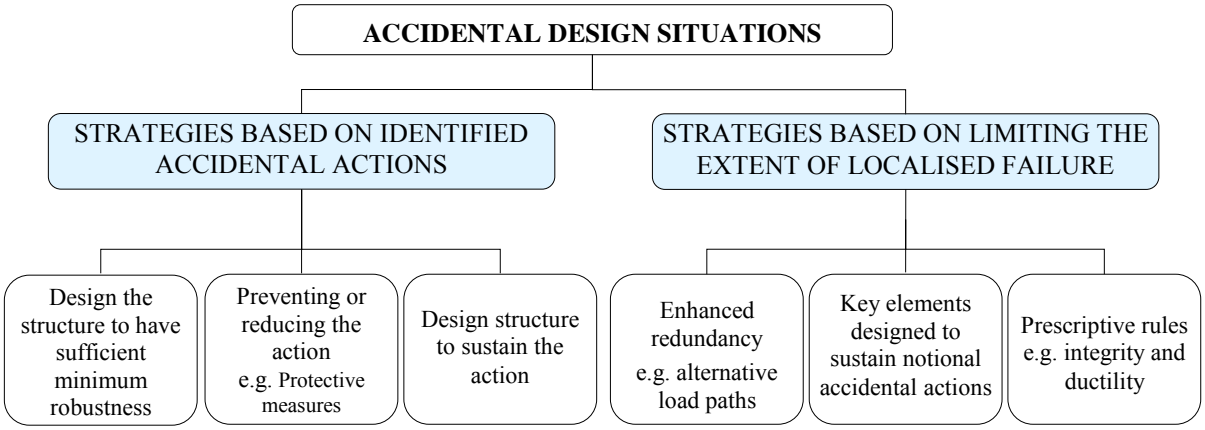

Figure 1 Strategies for accidental design situations as in EN 1991-1-7

The most recent structural Codes recognize robustness as a key structural requirement to be considered in design together with resistance, durability and serviceability. Studies and researches performed in recent years greatly contributed to the enhancement of the knowledge of the structural response under accidental actions and to the development of general design strategies to achieve robustness. The peculiar characteristics of the accidental actions oriented the studies first on the response of reinforced concrete structures subjected to extreme loads such as impact or blast, while only little research has been carried out on structures built up in different materials. Steel and steel concrete composite structures for their peculiar nature possess excellent reserve of resistance to extreme loading due to their high bearing capacity and high ductility, which lead to high energy dissipation capacity. The limited specific knowledge of their behaviour under exceptional load has a substantial impact in design practice. Aiming to fill such a gap, a number of research studies of composite steel-concrete systems were worldwide activated with the aim to develop Standards recommendations and practical tools enabling a reliable and effective robust design approach.

Residual strength and alternate load path methods are two effective and cost efficient design strategies for progressive collapse mitigation in case of framed structures. The general principle pursued is to allow the structure to reach new and stable equilibrium configurations by redistributing the loads to the undamaged parts through the continuity of the frame and of the floors enabling the development of a membrane action. In this context, the redundancy offered by the joints, including the column bases and the 3-D performance capabilities of the floor system are essential factors to achieve a robust structural response.

A European project, whose acronym is RobustImpact, focusing on robustness of steel and steel and concrete composite structures affected by accidental loads is ongoing (Hoffmann *et al*. 2015). The main aim of the research is the development of a robust design approach in case of impact loading based on the residual strength and alternate load path methods. Design guidelines for advanced impact design of steel and steel and concrete composite structures will also be an outcome. At this aim, the residual strength of impacted vertical members with different support conditions subjected to high dynamic lateral loads is numerically and experimentally investigated. Particular attention is paid to the interaction between the member and the surrounding structure and to the ductility demand to the joints for partially damaged elements. The residual strength of multi degree of freedom systems (MDOF) is a further issue for which numerical investigations are planned. Studies of the activation of alternate load paths on 2D and 3D systems are also parts of the project. To this purpose, quasi-static tests on 3D sub-structures and tests under high speed loading and impact loading on composite joints, beam-to-column joints, column bases and T-stubs are included.

In the framework of this project, the authors concentrated their studies on the redundancy of the structure through slab-beam systems as well as through ductile joints. At this aim, analytical, numerical and experimental activities were planned and executed. For a better insight into the mechanisms allowing the activation of the alternate load paths resources, two 3D full-substructures were extracted from reference buildings and

experimentally investigated simulating the collapse of a column. This paper focuses on the experimental part of the study. The main features of both the specimens tested and the experimental campaign are highlighted. The preliminary results of the tests are presented and discussed.

REFERENCE STRUCTURES

All the activities of the RobustImpact project are made consistent by the reference to two cases representative of typical European office buildings. The two buildings are 5 storeys and 6 bays x 2 bays steel and concrete composite framed structures characterised by the same plan overall dimensions of 34,2m x 11,4m. One configuration is symmetric with respect to both the plan directions while the other one is symmetric only with respect to one plan direction. The two case study structures, which will be referred to hereinafter as Symmetric and Asymmetric configurations, are shown in Figure 2 and 3 respectively. The location of steel braces designed to resist the horizontal actions in Y direction is asymmetric in both the frames. This solution, despite less effective with respect to the seismic performance, was adopted in order to have no steel brace in the sub-structures to be experimentally investigated. This makes the sub-structures more representative of a general case.

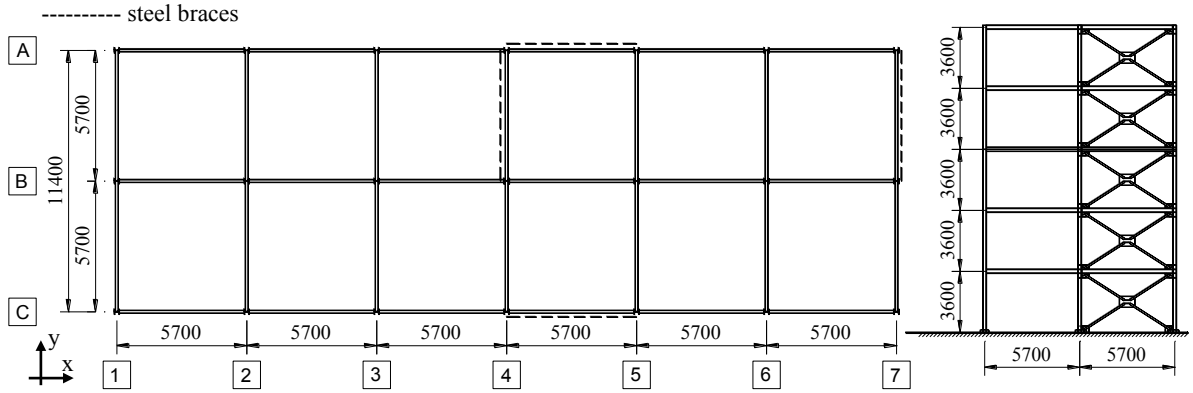

Figure 2 The reference building (Symmetric configuration - measures in mm)

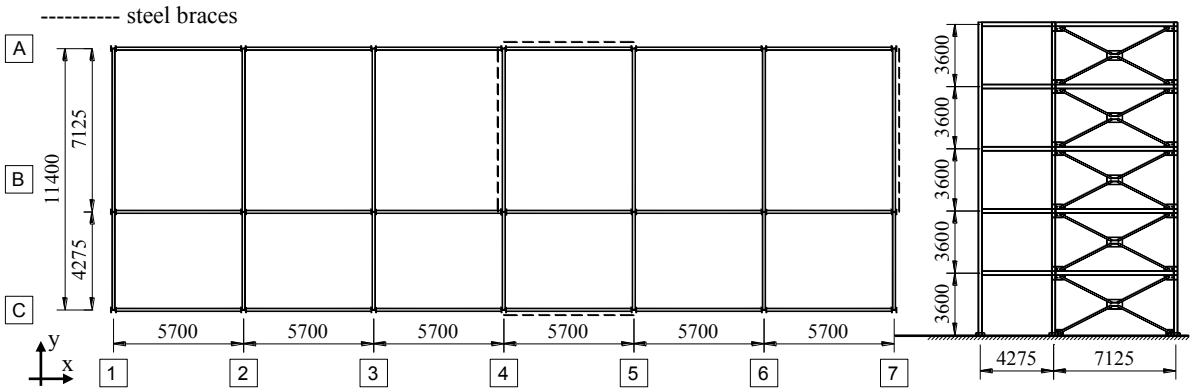

Figure 3 The reference building (Asymmetric configuration - measures in mm)

The design of both structures was based on the relevant Eurocodes (CEN 2004a, CEN 2010, CEN 2005, CEN 2004b), and in order to decouple issues of seismic and of robust design, no seismic considerations were made. As to the materials properties the following assumptions were made: concrete C30/37, structural steel grade S355, rebars grade B450C, bolts class 10.9 and shear studs Nelson SD 3/4"x4.". In order to reduce the number of variables to be accounted for when comparing the responses of the two structures, the same steel sections for the beams (IPE 240), the columns (HEB 220) and the diagonal braces, and the same thickness of the concrete slab (150mm) and the same steel connections were adopted. The rebars size and layout in the solid slab were obviously different. Beam-column steel connections are bolted flush end-plate connections (Figure 4), and full shear connection between steel beams and concrete slab were assumed in design.

3D SPECIMENS

The removal of a structural element is a typical design scenario, simulated in various studies and also prescribed by Codes in order to identify the structural resources to survive to accidental actions. The collapse of a column is

normally considered for framed structures. Within such a scenario, the floor system is expected to undergo large deformations in order to provide an alternative load path, so allowing the redistribution of the loads to the "undamaged" part of the structure to occur. This is an evolutionary phenomenon which is associated with the development of large displacements. In the case of framed steel and steel and concrete composite structures, the collapse of a column requires the joints do possess a large rotation capacity, sufficient to make catenary forces in the members and membrane forces in the floor slabs to activate. Aiming at investigating such phenomena the experimental study performed in Trento concentrated on the response of a portion of the first floor of the reference structures presented in the previous section. In order to identify the structural resources against accidental actions the collapse of a column was simulated.

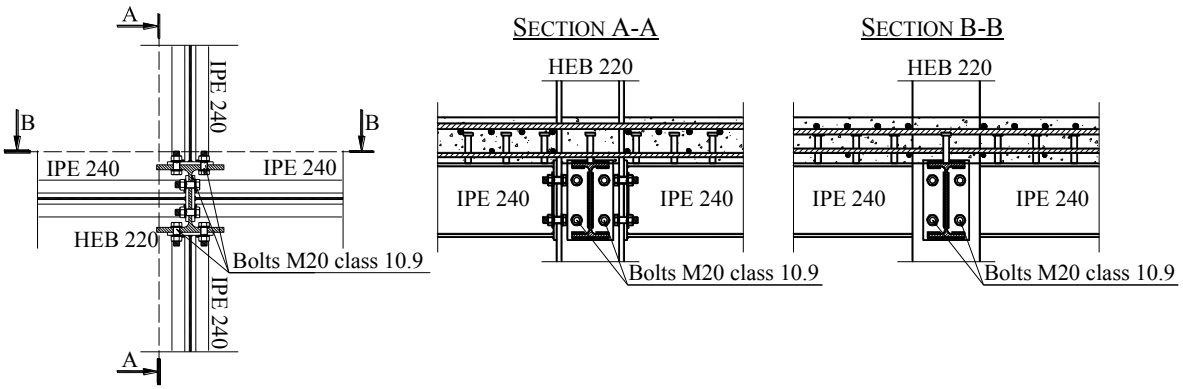

Figure 4 Beam-column interior joint with flush end-plate connection

The floor framing plan of the two specimens for the Symmetric and Asymmetric configurations are represented by the dotted area in Figure 5. In both the tests the collapse of the central column, the one indicated with a circle, was simulated.

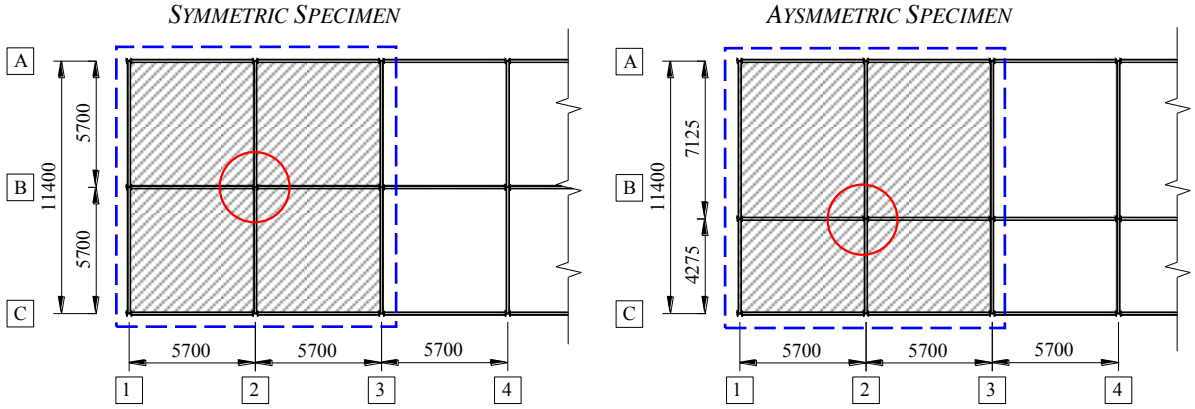

Figure 5 The full-scale specimens (plan view - measures in mm)

A critical point of the test design was the design of the restraints of the specimens. The sub-frames should be representative of the full-frames and hence the restraints have to approximate effectively the remaining part of the structure. Numerical studies were hence performed focusing on this subject. FE models of the full-frames (i.e., the reference buildings) and sub-frames (i.e., the specimens) were developed by using the Abaqus program (Abaqus 2010). In the models beams and columns were modeled as "Frame" elements while the slab was modeled by means of "Shell" elements. The rebars were embedded within the slab, the slab was rigidly connected to the beams and, in this preliminary study, a rigid connection was considered between the beams and the columns. The structural steel and the rebars were modeled by an elastic-perfectly plastic material model, and the Popovics law was assumed for the stress-strain relationship of the concrete.

Three facets of the problem were investigated: the restraints at the columns base, the possible need of connecting the columns at a certain height above the floor and the restraints at the floor level. Various solutions were considered and their adequacy was checked by comparing the results, in terms of deformations and internal forces, for the sub-frames and the corresponding full-frame. The analyses led to the restraining system showed in Figure 6 where:

- the columns are rigidly connected to the lab floor and interconnected by truss members at mid-height of the 'second storey';
- at B the X d.o.f. is left free (central beam in Figure 6), while the vertical and lateral displacements (along Y and Z) are prevented;
- at A and C the relevant d.o.f. along X is fully restrained;
- at L, to ensure stability to the specimen, the Y d.o.f. is prevented. FE analyses proved that the influence of this restraint on the specimen response is modest.

All the restraints are made up by truss elements connected to the steel frame.A more detailed coverage of this point can be found in (Zandonini *et al*. 2014).

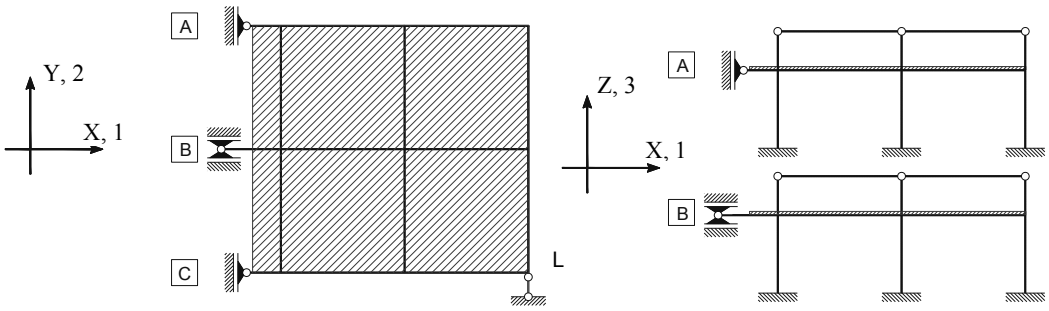

Figure 6 The restraining system (symmetric specimen)

TESTS

The specimens were built inside the Laboratory of Materials and Structures Testing of the University of Trento. Figure 7 shows the main phases of the construction of the symmetric specimen. The steel skeleton was first erected (Figure 7a) and connected to the strong floor and to the counter-walls by means of the restraining system described in the previous section. The slab was then cast (Figure 7b-c).

a) b) c)

Figure 7 The constructional phases

The column whose collapse is simulated in the tests was 'replaced' by a hydraulic jack (Figure 8a). During the constructional phases the hydraulic jack was held in place in a non operating state. The central beams were hence held in position by means of props which were removed just before the beginning of the test (Figure 8b). After formwork's removal the specimen measuring instruments were installed.

a) b)

Figure 8 The central column

The considerable amount of parameters affecting the response required an accurate selection of the quantities to be measured during the test. The attention was mainly focused on the response of columns, beams and beam-to-column joints.

Displacement transducers and clinometers allowed measuring the rotations of the columns at the beam level and of the beam-to-column joints. The central joints (position E in Figure 9) and of the joints between the internal beams EH, BE, EF, DE and columns H, B, F and D were instrumented. The instruments were positioned so as to decouple the joint and steel connection response. Additional transducers were employed to measure the torsional rotations of the external beams, the rotation of the corner column C, and the horizontal displacement of the column H at the beam level. Furthermore, the vertical displacements at the central joint and at the centre of the four slab panels were monitored.

Acquisition of all the instruments' signals, including the load cell connected to the hydraulic jack, was done at a frequency of 2Hz.

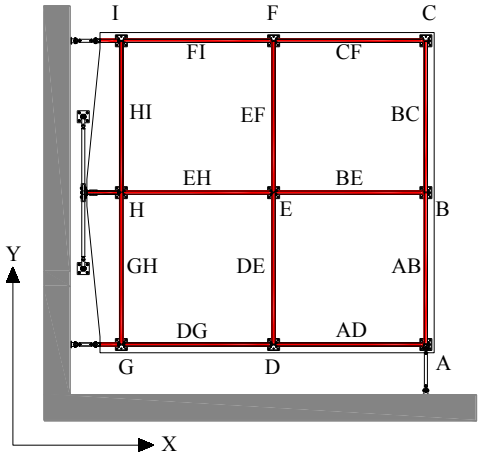

Figure 9 Layout of the steel frames (Symmetric configuration)

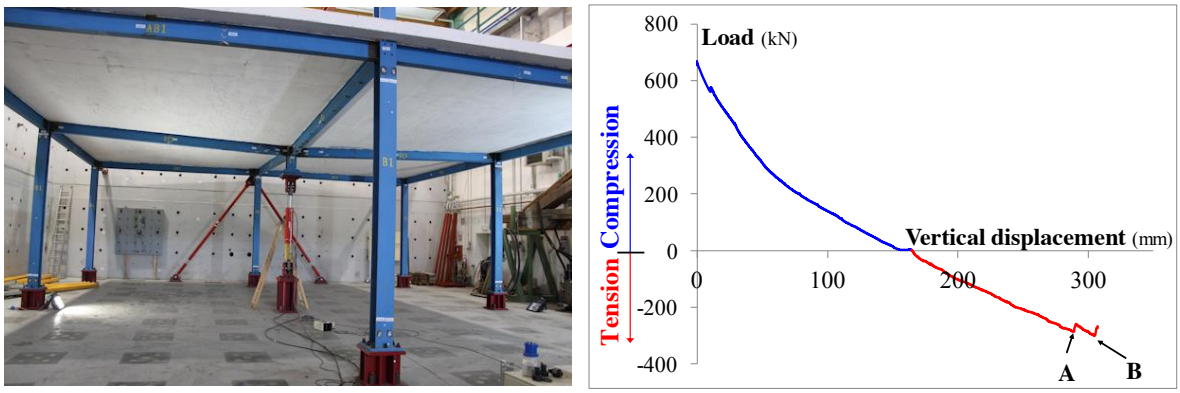
The tests comprise the following phases:

- activation" of the hydraulic jack, and removal of the props. The load measured by the loading cell allowed evaluating the self-weight portion of the specimen sustained by the central column;
- application of the vertical load to the slab. At this aim, bags filled with sand were placed on the slab surface reproducing a uniform distributed load of 8,8kN/m2 so as to approximate the factored design load including finishes, partitions and variable loads;
- gradual removal of the column simulated by reducing the pressure of the hydraulic jack down to zero;
- stabilization of the specimen;
- application by means of the hydraulic jack of a tensile force increasing up to the end of the test, with the aim of appraising the extent of the safety margin.

Figures 10 and 11 illustrate the deformation of the two specimens at the end of the test (Figures 10a-11a) and the load-central joint vertical displacement relation (Figures 10b-11b).

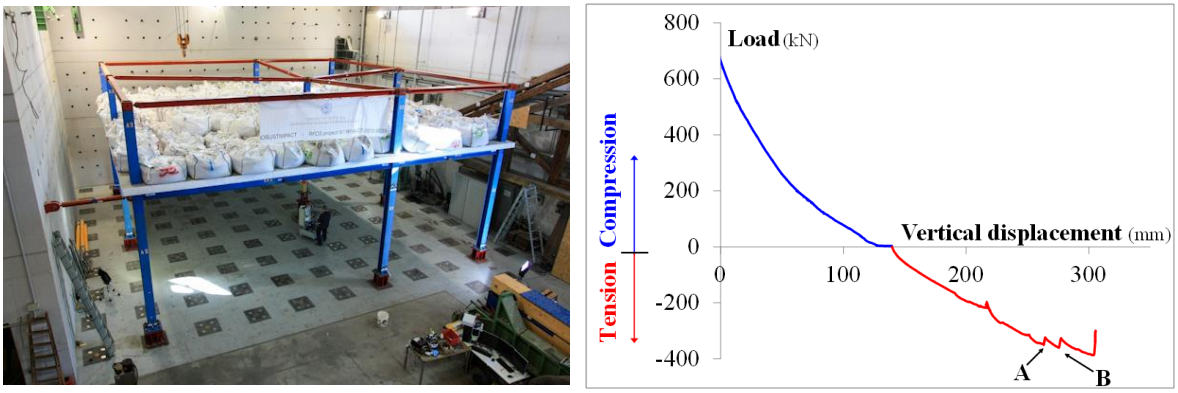


a) b)

Figure 10 Symmetric configuration: a) Specimen at the end of the test; b) Load-displacement curve of the central column

TESTS RESULTS

In both the tests, the beam to column connection at the central joint revealed themselves as the critical components. In both the tests, the collapse of a bolt of the bottom row of the connection between the central column and the beam EH took place first (point A in Figures 10b and 11b). The tests were continued up to the second bolt in the same row fractured (point B in Figures 10b and 11b). The tests were then stopped for safety reason due to the remarkable plastic deformation of the connections (Figure 12a) and the state of 'distress' of the concrete at the central joint (Figure 12b). For the asymmetric configuration, a tensile force was again applied, with the goal to further check the residual strength capacity. The collapse of a third bolt (bottom row of the connections with beams EF and DE) took place almost immediately (Figure 12c).



a) b)

Figure 11 Asymmetric configuration: a) Specimen at the end of the test; b) Load-displacement curve of the central column

The visual inspection of the specimens allowed also identification of significant deformations of the external columns H, F, B and D, mainly in the vicinity of the beam-to-column joints. Deformations were very similar in both tests: Figure 13 relates to the asymmetric specimen. A concentrated 'rotation' of the column reveals the significant plastic shear deformation of column B web panel (see Figure 13a). Furthermore, the mechanism of force transmission between column and beam induces compression at the beam lower flange with associated instability phenomena (Figure 13b). Horizontal cracks developed in the slab thickness on the outer side of the slab at columns F and D associated with the transmission of shear forces between concrete slab and column (Figure 13c).

a) b) c)

Figure 12 Deformation at column's collapse: the central joint (Asymmetric configuration)

a) b) c)

Figure 13 Deformation at the end of the test: joint (Asymmetric configuration)

The slab crack pattern at the end of the test, showed in Figure 14 for the asymmetric specimen, indicates the activation of a mechanism of force transmission between the central column, i.e., the collapsed column, and the external ones.

The measured data allow describing the evolution of key parameters such as the rotation of the beam-to-column joints and the axial and bending deformations of columns and beams. This outcome provides the base for a first appraisal of the demand of beam-to-column joints' ductility and of the redistribution of the internal forces between the main structural elements. As an example of the tests results, Figure 15 shows the load-rotation curves associated to the joints at the central column for the symmetric configuration.

Bottom side Top side

Figure 14 Experimental crack pattern (Asymmetric configuration)

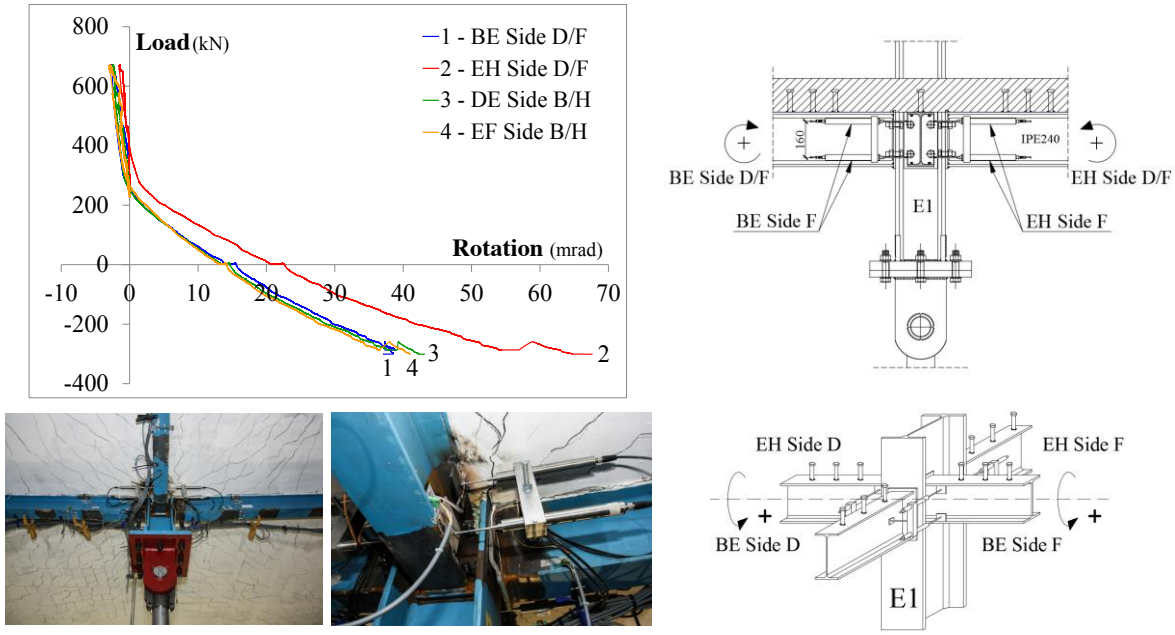


Figure 15 Deformation of the beam-to-column central joint (Symmetric configuration)

The collected data are currently accurately evaluated. As a general comment, based on the present results, it can be said that the importance of the 3D action associated with the continuity offered by the joints and by the flooring system is clearly pointed out. The need of a 'adequate' design of these components is also stressed.

CONCLUDING REMARKS AND CURRENT DEVELOPMENTS

A number of dramatic events leading to building collapses pointed clearly out the potential 'fragility' of structural systems, when solely designed to meet the traditional requirements of stiffness in service, strength at

ultimate and durability. A new term entered recently in the design and Code dictionary: robustness. A robust design prevents the complete collapse of the structure when only parts are damaged or destroyed. Design against accidental actions is usually based on the residual strength or the alternate load path methods, and a combination of these strategies may lead to an especially effective and cost efficient design for progressive collapse mitigation by redistributing the loads within the structure. To this aim, the continuity of the frame and of the floor enables development of membrane action. They hence represent essential factors contributing to a robust structural response.

A European project focusing on robustness of steel and steel and concrete composite structures affected by accidental loads is still ongoing. In the framework of the project the authors concentrated their studies on the redundancy of the structure through slab-beam-systems as well as by ductile joint design. At this aim two 3D full-substructures were extracted from a reference building and experimentally investigated with the purpose to get an insight into the mechanisms allowing the activation of the alternate load paths resources. In both tests the collapse of an internal column was simulated.

The paper illustrates the main features of the specimens and how the tests were carried out. Some of the important behavioural parameters, such as: the vertical displacement of the central node, the rotation of the joints at that node, the collapse mode, the deformed shape at ultimate and the crack pattern, are briefly presented. The extensive set of measured data is still under detailed evaluation. Preliminary results confirm the joints and the concrete slab as the critical actors against progressive collapse.

Aiming at a deeper understanding of the mechanisms of force transfer, numerical FE models were developed with the software ABAQUS (ABAQUS 2010). Their calibration against experimental results is in progress. The key role played by the beam-to-column joints suggested devoting particular attention to their modeling. At this aim different levels of complexity were adopted: the 'ideal' cases of hinged and fixed connections were considered first, the semi rigidity of the beam-to-column joints was then taken into account by the component method. As an example of the output of the analysis Figures 16 and 17 compare the experimental slab crack pattern at collapse and the principal tensile stresses, for the top and bottom side of the slab, respectively. The results are related to the symmetric configuration for the case of fixed beam-to-column joints modeling. The agreement is more than satisfactory.

The evaluation of the experimental data and the validation of the numerical models will provide a deeper understanding of the different facets of the frame response. The Authors count to highlight them at the Conference.

ABSTRACT

Origami-inspired foldable structures have seen much recent interest for applications in which transportability or rapid construction are primary design drivers, for example emergency shelters and temporary staging structures. This paper proposes a new type of a structural module that can be manually folded from flat steel sheet into a novel self-braced triangular structural section. Simple geometric relations are presented for the unit module, which can then be tessellated for the design of larger elements and frame assemblies. It thus avoids many of the geometric complexities typically encountered in origami-inspired folded structure designs. A set of integral connection details are then developed for computer-numerically controlled (CNC) manufacture of a foldable proof-of-concept prototype to validate geometric and folded fabrication processes. Finally, preliminary numerical analyses are conducted comparing typical hollow and folded self-braced triangular sections.

Folded frame structures; origami-inspired structures; folded fabrication; thin-walled structures.

INTRODUCTION

Origami Inspired Structures

Origami-inspired design techniques have been utilized in many industry applications such as appliance manufacturing, packaging design, and space exploration. Such designs utilise origami folding to deliver a compact package that contains a relatively large structure, which is favourable when transportation capacity is a driving design concern. Famous examples include the Miura Origami based solar power array deployed in a research vessel launched by Japan in 1995 (Miura, 2009), the foldable space telescope 'Eyeglass' designed in 2002 (Lang, 2004), and the 'Origami Stent' developed in 2003, which can be implanted into a patient's vein in a collapsed state and then manoeuvred to and expanded in a blocked artery to enable a better blood flow (Kuribayashi et al., 2006).

Other applications use origami folding to achieve a significant increase of stiffness at minimal expense of weight. One example is foldable military shelters, in which the folds can provide structural stiffness when deployed and can easily pack into a smaller volume for transportation or storage (Thrall and Quaglia, 2014). An optimised design for this been proposed in Martinez-Martin and Thrall (2014). Another example is folded sandwich structures, or foldcores, which consist of two outer faces and an origami geometry core. The proposed applications for foldcores include impact-resistant or isotropic sandwich panels (Heimbs, 2013; Miura, 1972) and lightweight or morphing building components (Schenk and Guest, 2011; Gattas and You, 2014). The above structural applications mainly utilise shell forms developed from a known origami pattern. This requires advanced geometric design methods (Tachi, 2010; Gattas et al., 2013) and thus widespread application had been hindered.

Folded Sheet Metal Fabrication

Folded sheet metal is widely used in manufacturing. The most common method is using a bending brake and press bend to form the bend line along the sheet metal (Gupta et al., 1998). Two problems are commonly encountered in folded sheet material fabrication. First, the metal sheet needs considerable force for bending and so heavy machinery is required for the manufacture of most items. Second, precise location of the bends can be difficult to control because of bending tolerance and the accumulation of tolerance errors. For origami-inspired designs, the crease lines often must be precisely controlled as kinematic or mechanical behaviours can be highly sensitive to imperfections and eccentricities (Cash et al., 2015).

Industrial Origami has proposed a method of precisely bending sheet metal by placing a series of curved slits along the notional bending line on sheet metal, see Figure 1. The area between slits, termed 'straps', connects adjacent edges and is twisted during fabrication, greatly reducing the required bending force (Durney and Pendley, 2005). Slit locations and thus bends can be precisely controlled with the use of CNC machines such as a waterjet or laser cutters. Additional benefits of the specific proposed slit geometry include a reduction in stress concentrations at the curved slit ends, and the 'edge to face' engagement whereby during the bending process, the strap will be twisted and pull the face toward the edge (Durney and Rangarajan, 2008). As a result, under vertical loading the face will be able to transfer shear forces directly across folded edges.

This paper presents a design method, folded proof-of-concept prototype, and preliminary numerical analyses of novel self-braced folded structural sections and frames. Section 2 describes a new foldable modular geometry and two basic uniaxial triangular elements generated from the module. Section 3 describes extended assemblies including floor slab and frame assemblies. Section 4 describes the manufacture of a proof-of-concept steel prototype manufactured with integral hinge and self-lock connections. Section 5 presents preliminary numerical investigations comparing typical hollow and the new folded self-braced triangular sections.

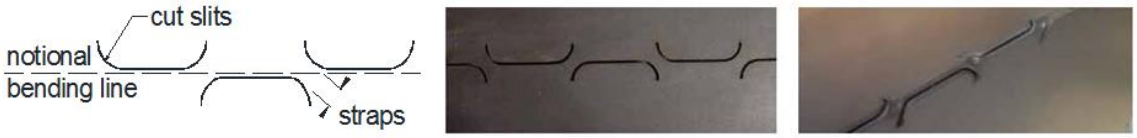

Figure 1 Precision sheet-metal bending with slits and straps connection crease line detail.

MODULAR UNIT AND UNIAXIAL SECTIONS

Figure 2a shows a portion of a typical triangular hollow section with axial length L, side length W, and wall thickness t_p. It can be unfolded to a configuration with area $L \times 3W$. An equivalent triangular module is shown in Figure 2b with hexagonal plates embedded into two sides of the section such that they can be folded internally to brace all section walls at two points each. For the hexagon to contact all three walls, it must have side length $W_H = W/3$. An expansion ratio λ can be calculated as unfolded volume over folded volume V_U / V. Given $V = LW^2\sqrt{3}/4$ and $V_U = 3LWt_p$, expansion ratio λ can be shown to vary linearly with slenderness ratio $\lambda = (12t_P)/(\sqrt{3}W)$. The flat-packed compacted state and the resultant slenderness relationship are substantially different to deployable bar structures (Chen and You, 2005). These typically have a minimum packaged size dictated by the structural section dimensions, for example CHS diameter.

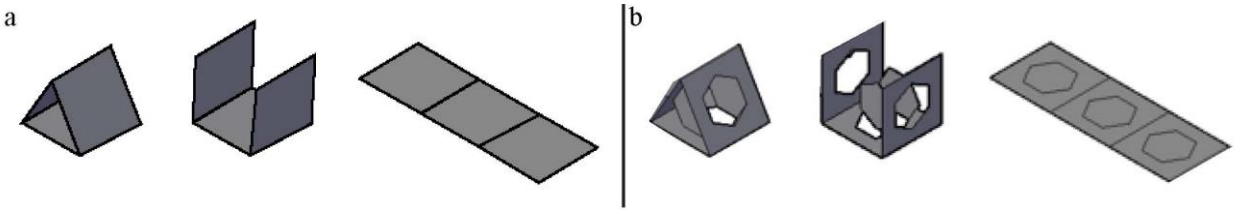

Figure 2 Foldable modules of a) triangular hollow and b) self-braced triangular sections.

The module can be directly tessellated to create uniaxial structural elements. If the module is tessellated longitudinally, a configuration shown in Figure 3a is created. Deployment from unfolded to folded occurs in two stages as for the module, with internal hexagonal plates folded upwards and then adjacent sectional walls folded inwards to form the self-braced triangular element. A concept preliminary packaging stage is also shown whereby the unfolded section is rolled to reduce shipping volume. If the module is tessellated laterally, a truss-like configuration shown in Figure 3b is created. Every two additional side panels generate a single additional triangular module and sufficient hexagonal plates to provide the required internal self-bracing. Deployment is able to occur sequentially, i.e. module-by-module. Either tessellation is easily designed based on the initial module definition and so a folded section can be designed with conventional methods. This design method avoids geometric complexities typically encountered in origami-inspired folded structure designs.

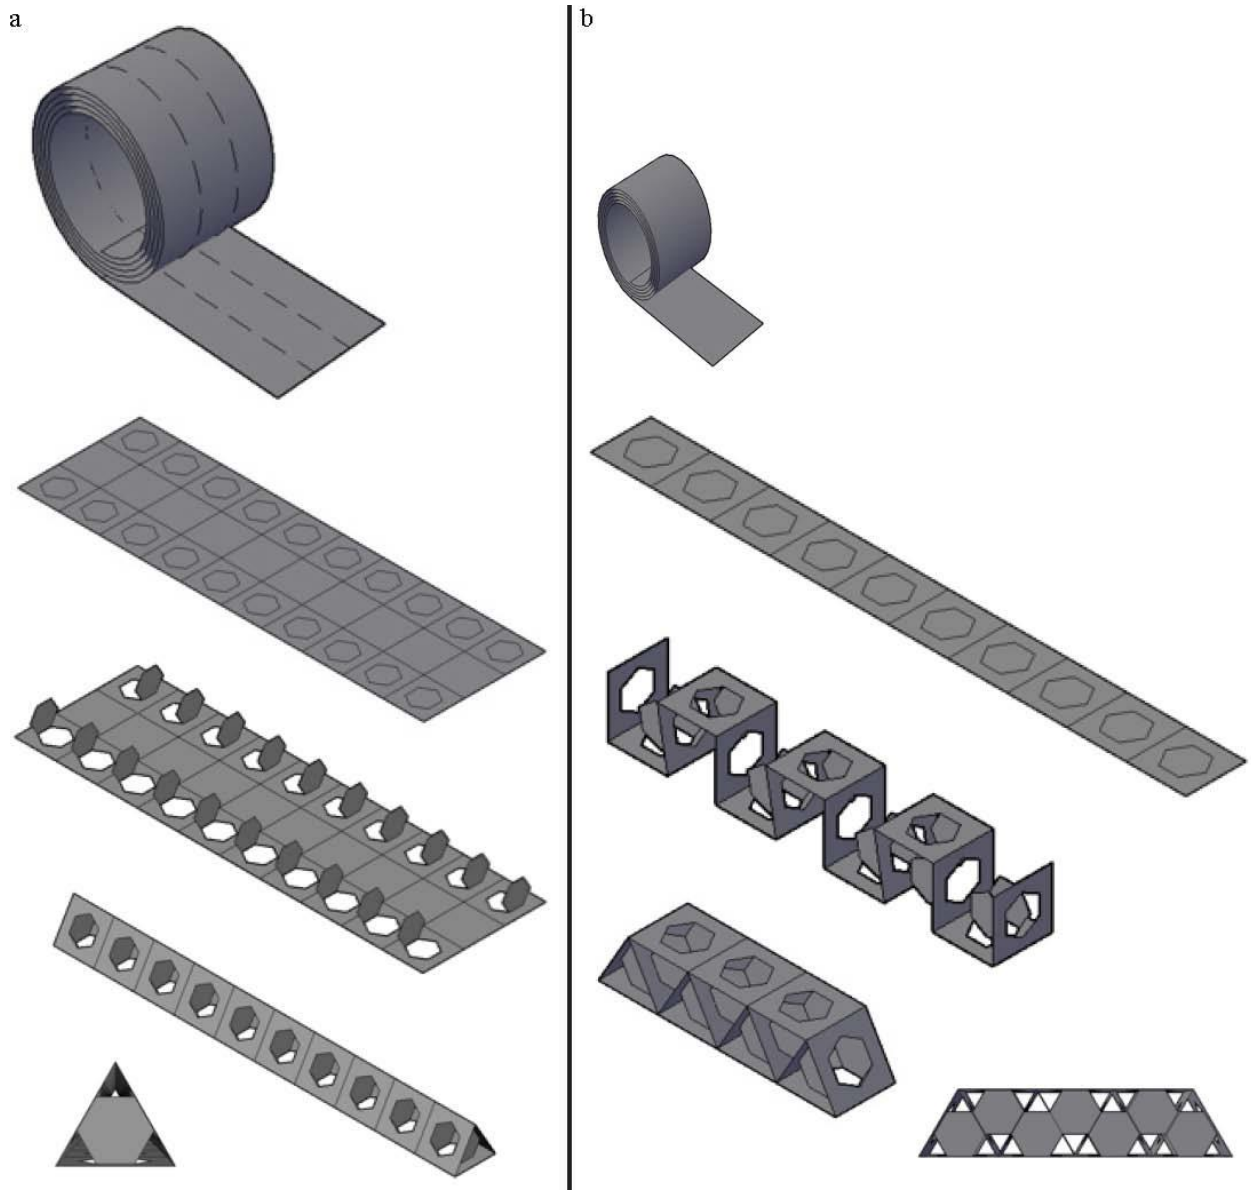

Figure 3 Deployment sequence of a) longitudinally and b) laterally tessellated uniaxial configurations.

EXTENDED ASSEMBLIES

There are several ways by which to adapt or assemble the above sections to form a wider range of folded sections and frames. Rectangular or nested self-braced sections as shown in Figure 4a can be formed with simple geometric adjustments to the basic module. Simultaneous tessellation in both longitudinal and lateral directions generates a space-filling structure, shown in Figure 4b and 4c, that could be used for example as a floor slab. Selective assembly as shown for example in Figure 4d enables the creation of a complete frame structure. The structural feasibility of such assemblies is not known at this early stage of development, but these examples serve to show that the simple geometry of the folded component module enables simple and rapid design of conventional and unconventional sections and frames.

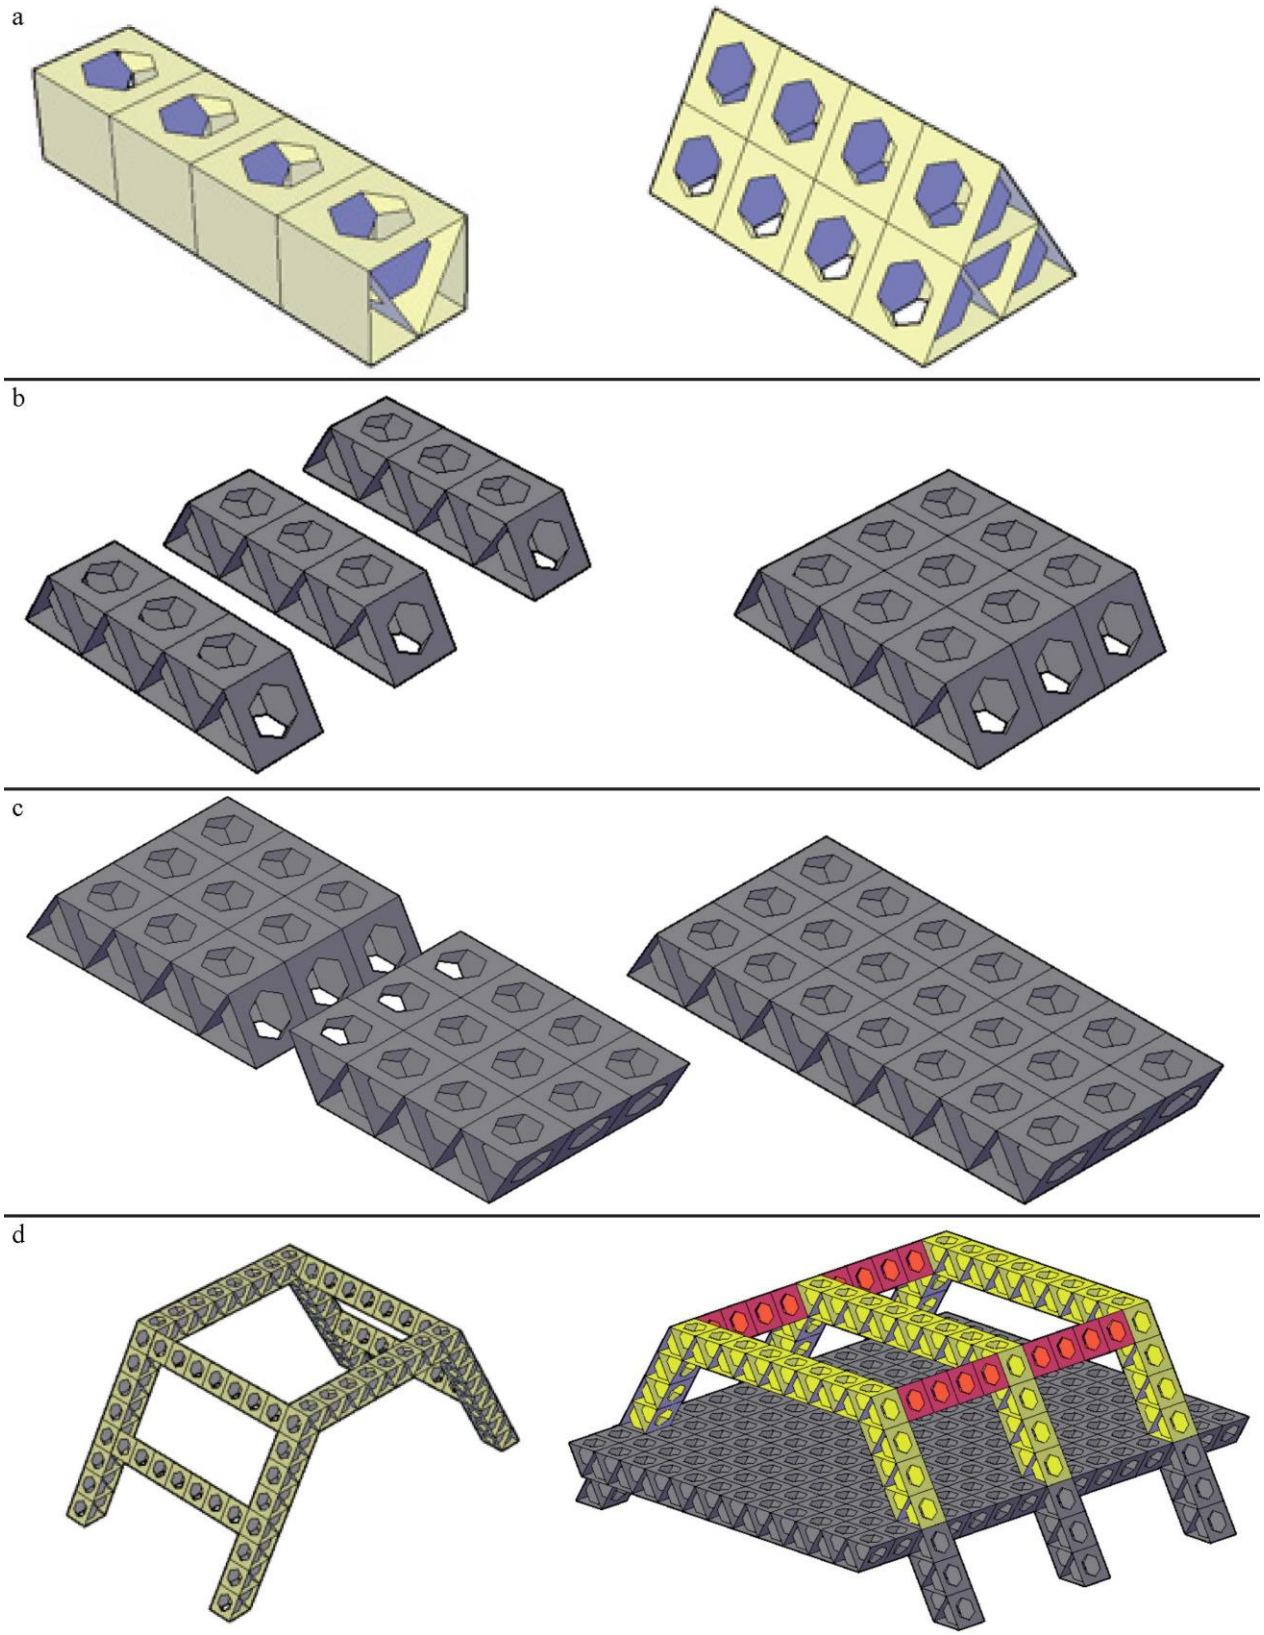

Figure 4 Extended and assembled forms of self-braced folded sections. a) Non-triangular sections. b), c) Floor slab assembly. d) Frame assembly.

STEEL PROTOTYPE FABRICATION

For practical use of the self-braced triangular structures, on-site deployment must be achievable either manually or with low-force machinery, depending on the thickness of the plate. Construction must require a minimum number of additional connection components, i.e. all items necessary for assembly should be contained within the transported package or the sheet material itself. From inspection of the foldable module in Figure 2b it can be seen that there are two functions employed during deployment: folding about hinge lines and connection of free edges. The former occurs at two panel junctions and a single hexagon edge. The latter occurs at a single panel edge and two hexagon edges.

Integral connection details were designed to achieve these two functions. A hinge connection was designed based on Industrial Origami connections (Durney and Pendley, 2005). A self-lock connection that joins two free edges was designed based on slot-and-tab joints typically seen in packaging design (Cash et al., 2015). Connection details are shown in Figure 5a. Connection locations on a double-module with dimensions $L = W = 0.3m$ are shown in Figure 5b. Hinge locations are designated 'H', and male and female self-lock locations designated 'Tm' and 'Tf', respectively. The superposition of connection details at appropriate locations generates the part drawing shown in Figure 5c.

A full scale prototype was cut from a sheet of 0.9mm thick Galvanneal Steel with a CNC waterjet cutter. The manufactured sheet and the folded structure are shown in Figure 5d. Waterjet cutting took approximately two hours and subsequent manual folding took approximately 10 minutes for one person. Manual folding was found to be extremely easy, with hinge and self-lock alignment both working to produce an accurate folded form. The hexagonal bracing plate was also seen to provide good bracing to wall panels, although this will be quantified properly in future experimental investigations. For thick plate (t_p >10mm) applications, both hinge and edge connections could be subsequently welded to secure the connection. A second larger prototype was constructed with eight modules and took approximately eight hours to waterjet cut and approximately one hour for four people to fold.

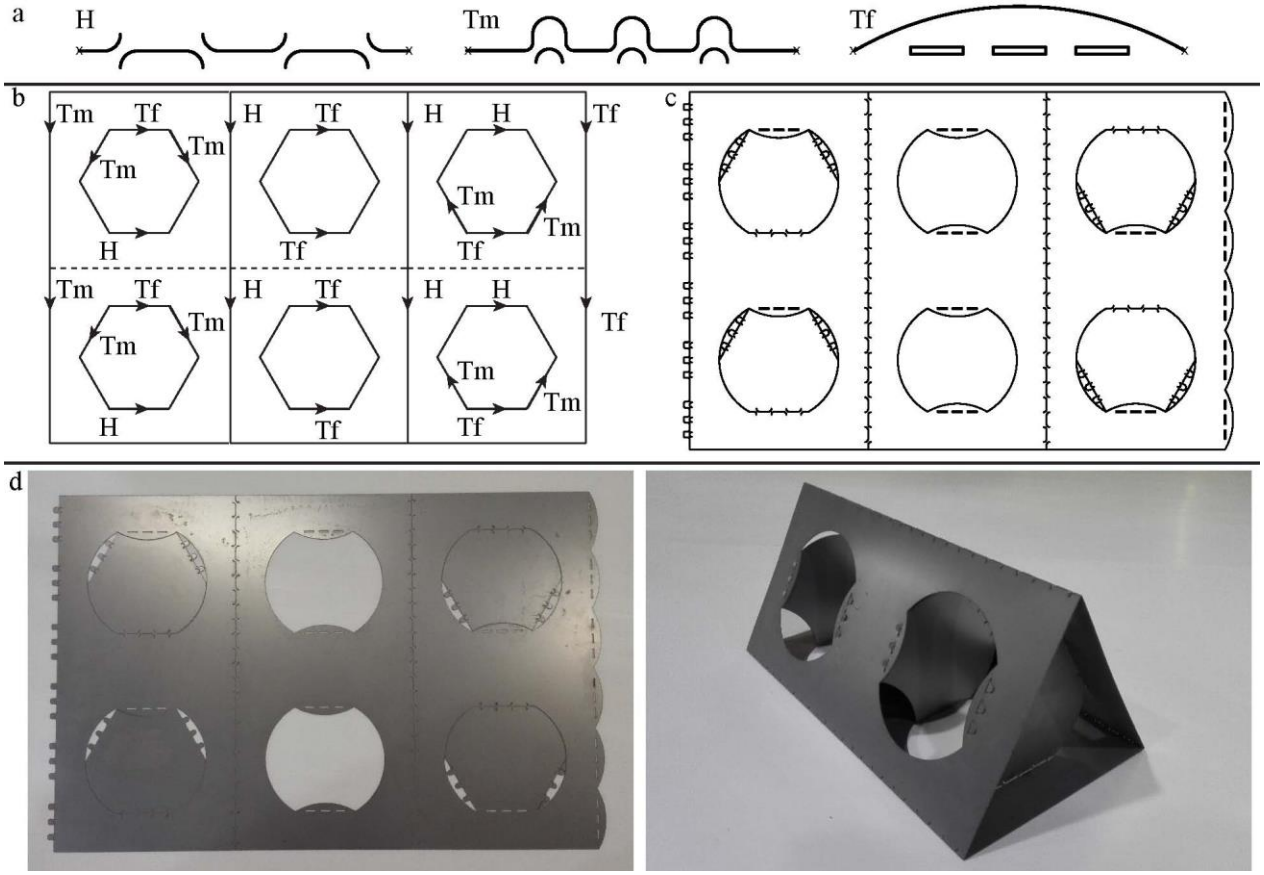

Figure 5 Steel prototype fabrication. a) Integral connection types. b) Connection locations. c) Part drawing. d) Waterjet cut and folded part.

PRELIMINARY NUMERICAL ANALYSIS

A preliminary numerical investigation was conducted using Abaqus finite element software. A linear buckling analysis was conducted on a self-braced folded section and an equivalent hollow section subjected to uniaxial compression. Part geometry had dimensions corresponding to the prototype described above and was meshed with S3R and S4R shell elements with an approximate mesh size of 10mm, shown in Figure 6a. Material elastic properties were taken as typical steel values of E =210 GPa and v =0.3. Pinned boundary supports were applied to the column base edge and a uniform compressive load to the top edge. The first buckled mode of the self-braced section occurred at an eigenvalue of 10.7MPa and had an eigenmode shown in Figure 6b. The first buckled mode of the hollow section occurred at an eigenvalue of 7.8MPa and an eigenmode shown in Figure 6c. These values are preliminary only, as the numerical model did not consider geometric imperfections or folded edge stiffness reductions generated from the folded fabrication method. These will have a significant effect on buckling capacities, however these early results are promising. Ongoing work is being conducted towards experimental studies to improve and validate numerical models, a full nonlinear buckling analysis with consideration of geometric imperfections and stiffness reduction will be carried out.

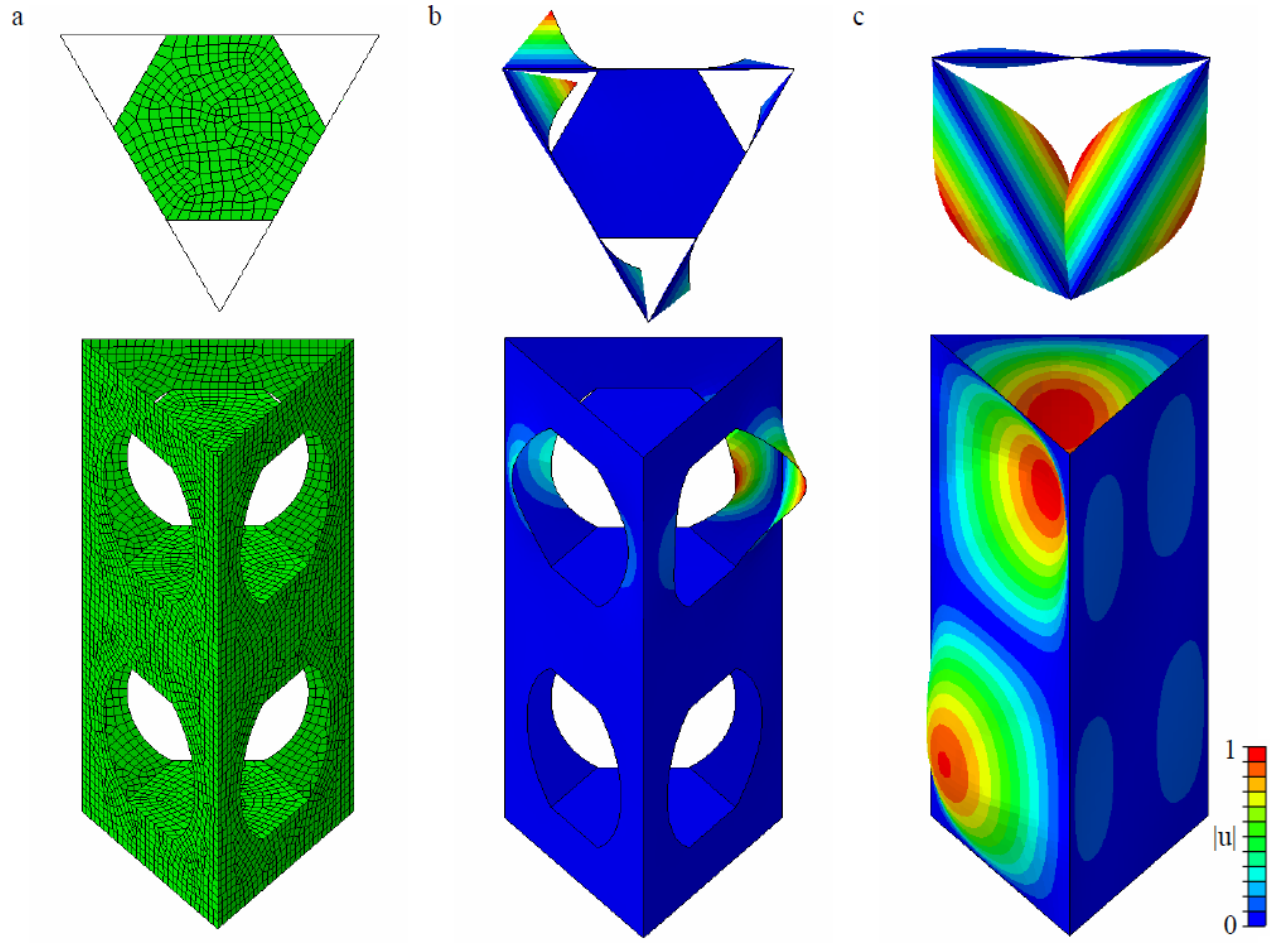

Figure 6 Section and isometric views of numerical models. a) Meshed part. b) Buckled mode of self-braced section. c) Buckled mode of triangular hollow section.

CONCLUSION

The above paper introduces geometric design and folded fabrication procedures for a new type of self-braced triangular structural section. Preliminary numerical results are also presented and indicated the structural form may have significant improvement in buckling capacity compared to a typical extruded hollow section. Future work will develop extended geometric procedures for non-triangular and assembled forms of the self-braced section. The fabrication procedures will also be used for experimental procedures and validated extended numerical investigations.

Special Session on Performance under Wind Loading

RELATION BETWEEN DESIGN LOAD LEVEL AND LIFETIME OF INDIVIDUAL BUILDING AND ITS ELEMENTS

Yukio Tamura*, Di Wu and Qingshan Yang
Beijing's Key Laboratory of Structural Wind Engineering and Urban Wind Environment, School of Civil Engineering, Beijing Jiaotong University, Beijing, China. *Email: yukio@arch.t-kougei.ac.jp

ABSTRACT

The common wisdom is to design cladding and components using a lower level wind load than the main structural frames, i.e. a shorter recurrence period wind load is used for cladding design than for frame design. This paper first discusses the design wind load levels for structural frames and for cladding and components. Next, the design wind loads of scaffolds for building construction, those of buildings in the construction stage, and those of so-called "temporary" structures such as site offices are discussed. In Japan, the design wind load for scaffolds is defined as 1-year-recurrence wind load, because its average setting period at one construction site is around 6 months, but this paper clearly proves the inappropriateness of this design wind load estimation concept. Then, it is shown that there is no relation between the design wind load level and its lifetime at an individual site. Finally, even for the design wind load for main structural frames, it is clearly demonstrated that the design load level may not be able to be determined based on the lifetime of an individual building. Therefore, although the LCC concept is applied in design load estimation, it is strongly recommended that the optimal design load level should be decided considering total LCC for the city or nation as a whole, and treat design as involving a group of buildings, rather than attempting to optimize the LCC of individual buildings. Clearly, the cost associated with social or national security must be included.

KEYWORDS

Design load level, building life time, cladding and components, temporary structures, individual use, LCC.

INTRODUCTION

There are several problems in the current codes and standards that need to be rectified if we are to produce wind-resistant buildings and structures. One of them is the recurrence period of the design wind load for structural frames and for cladding/components, namely the design wind load levels for structural frames and for cladding/components. The tendency is to design cladding/components using a lower wind speed than the main structural frames, i.e. a shorter recurrence wind load is used for cladding design than for frame design in some countries. For example, according to the Building Standard Law of Japan (BSLJ), allowable-stress design criteria are combined with 50-year-recurrence wind loads for structural frame design, and the same recurrence wind loads are used for cladding/components design. However, 500-year-recurrence wind loads are applied for the ultimate state structural frame design, while cladding/component design is not obligated to reach this design level. Accordingly, structural designers tend to ignore this level in cladding/component design. Some consider only 100 or 200-year-recurrence loads for cladding/components, leaving the 500-year-recurrence load for structural frames. Thus, it is implicitly understood that the design load level of cladding/components can be lower than that of structural frames. However, the validity of this understanding should be re-examined carefully. A similar problem is seen with the design wind loads of scaffolds for building construction, and for those of so-called "temporary" structures such as construction site offices. For example, in Japan, the design wind load for scaffolds is defined as the 1-year-recurrence wind load, because the average setting period at a construction site is around 6 months (SCEAJ-TRSSW, 1999). However, this design wind load estimation concept is completely inappropriate as discussed later.
In this paper, a very primitive problem, namely the relation between the design load level and the lifetime of individual buildings or their parts is discussed.

LOAD LEVELS FOR MAIN FRAMES AND CLADDING/COMPONENTS OF BUILDINGS

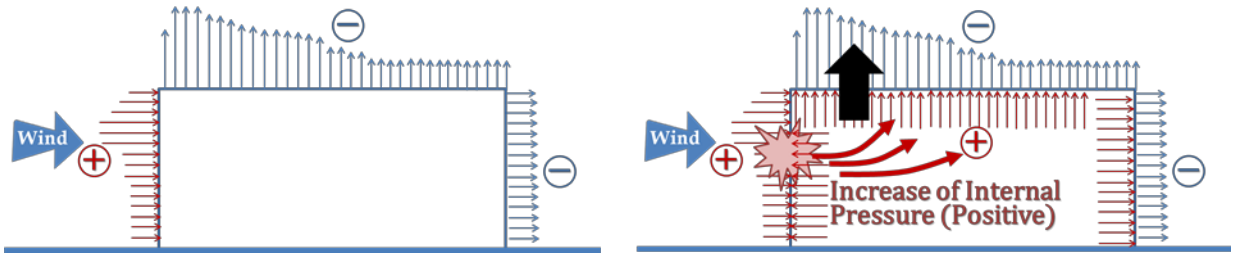
Design Wind Load Estimation

There are some problems with the wind loads used in building design as mentioned in INTRODUCTION such as the different wind load levels for main frames and cladding/components. Even for just frame design, there are many problems. One of them is the Gust Loading Factor (GLF, Davenport 1967) or the Gust Response Factor

(GRF) used in the majority of building codes and standards in the world. Basically, the same GLF or GRF, which is based on the dynamic behavior of the building, is used for serviceability state design and also for ultimate state design. It is necessary to confirm conformance to "elastic GLF" or "elastic GRF" in the ultimate design stage, in which the building behaves in a plastic manner. Incidentally, in Japan, the ultimate design criteria for main structural frames allow member stresses to be within 1.1 times the allowable stress, i.e. only 10% larger than the elastic limit, so the building can behave in an "almost elastic manner". Thus, fully plastic behavior is not permitted and is not checked in design. Further studies are needed in this regard.
Furthermore, in general, the structural design of main frames uses the aerodynamic coefficient of the pristine building without cladding damage, so that the cladding and components are implicitly assumed to keep their original integrity. Therefore, theoretically, there is no reason to accept a lower level of wind load for cladding/components, except for cases considering the possibility of change in the aerodynamic coefficient or reaching a consensus with building owners and occupants or guaranteeing preventive measures of damage coherence or chain of damage. A minor failure of cladding/components can trigger destructive damage to the entire building.

Coherent Phenomena and Chain of Wind-Induced Damage

Structural designers are interested in main frame design, but not so much in cladding design. However, wind-induced damage is generally triggered by localized damage to cladding/components. This damage can propagate to much larger scales and even damage the main frames.
In general, positive pressures act on the windward wall, but negative pressures act on the other surfaces such as side walls, leeward wall, and roof surface as shown in Figure 1(a). In general, the internal pressure coefficient is negative. The wind force coefficient C_f acting on the roof structure is the difference of the external pressure coefficient C_{pe} and internal pressure coefficient C_{pi}, say $C_f = C_{pe} - C_{pi}$. Once a window pane on the windward wall is damaged, the air enters the building and the internal pressure coefficient C_{pi} becomes a high positive value. Therefore, the uplift (negative) wind force coefficient C_f suddenly becomes large through combination with the inherent negative external pressure coefficient C_{pe}. As shown in Figure 1(b). The same damage progression can happen with just minor damage to the eaves.



(a) Wind pressure distribution (b) Sudden increase in roof force

Figure 1 Wind pressure distribution and effects of sudden partial failure of the windward wall

This "coherent phenomenon" in damage progression is a special feature of wind-induced building damage. The separated parts of cladding and components can easily become wind-borne debris, and strike downstream buildings. Debris impacts also initiate cladding/components damage to downstream buildings. This "chain of damage" is another special feature of wind-induced damage to buildings in urban areas.

Property Losses due to Damage to Cladding/Components

If the window panes and claddings of a tall building fail, property inside the building would be seriously damaged and lose its value. This property loss can be very significant, especially if only the main structural frames remain. The miserable situation of a building with damaged window panes is often reported after extreme wind attacks in urban areas, e.g. Brewick *et al*., 2009 (Figure 2).
Super typhoon Haiyan attacked the Philippines on November 8, 2013, and caused serious disaster to this country and other surrounding countries. The recorded maximum 3s gust was 57m/s at Roxas City, Capiz, and the lowest pressure was 910hPa at Guiuan, Samar (PAGASA). The dead and missing numbered 7,986 (NDRRMC, January 14, 2014).

(a) Damage to window panes (b) Inside situation

Figure 2 Damage due to Hurricane Ike, 2008 (Brewick *et al*., 2009) (Courtesy of A. Kareem)

(a) Damage to roof cladding materials of EGS Contact Center

(b) Serious property damage inside and failure of business continuity planning (BCP)

Figure 3 Damage to steel structure due to Typhoon Haiyan (Palo, Leyte, the Philippines, 2013)

Figure 3(a) shows a steel frame structure whose main frames suffered almost no damage but whose metal roof sheets were widely damaged. Only the claddings failed significantly but there was serious property damage inside as shown in Figure 3(b). BCP (business continuity planning) was not successful and the business stopped for a long period. The cladding damage dealt a deathblow to the building owner. If one of the purposes of a building is to ensure business viability, the cladding cannot be destroyed. Even if the main frame survives without damage, it has no value. Thus, the importance of cladding/component design should be recognized, and it is essential to understand that “Wind Resistant Design” is equal to “Cladding/Components Design”.

(a) Partial damage to metal roof sheets

(b) Induced collapse of entrance sashes and doors

Figure 4 Partial damage to metal roof sheets induced collapse of entrance sashes/doors, and killed one person (Nobeoka tornado, 2006)

Figure 4(a) shows partial damage to the metal roof sheets of a super-market due to a tornado in Nobeoka, Japan. The opening created in the roof suddenly decreased the internal pressure and became negative because of the negative roof pressures, as can be understood from Figure 1(a). The wind loading across the windward wall increased significantly, and the entrance sashes and doors inwardly collapsed as shown in Figure 4(b). A person standing near the entrance doors was killed under the falling sashes and doors.

Cladding/component damage can propagate throughout the entire building, and can cause serious property losses to the building owners and society. Furthermore, even the partial failure of cladding/components can cause human loss.

These facts suggest that there is generally no reason to allow a lower design wind speed for cladding/components than main frames, unless property or human life are protected effectively and the damage chain is terminated. Thus, in general, the design wind load level for cladding/components should be the same as that for the main frames.

DESIGN LOADS FOR TEMPORARY-USE BUILDINGS AND STRUCTURES

Building Codes for Temporary Buildings

Design loads for temporary use buildings and structures including construction work offices are specified in the Building Standard Law of Japan. Their design loads can be lower than those of general buildings. Building codes specify the minimum requirement to keep social and national security. BSLJ specifies temporary buildings in Article 85. Temporary buildings include emergency structures after devastating disasters, emergency buildings for the public good after disasters, temporary buildings for construction works, and temporary stores/theaters/exhibition halls. AIJ-DRBLL (2013) recommends reduction of the design loads for the allowable stress design level excitations (almost 50y-recurrence level), if the occupants' safety is guaranteed for the ultimate limit state level excitations (almost 500y-recurrence level). ASCE 7-10 does not specify requirements for temporary structures. Accordingly, engineers may consult another standard, called ASCE 37, which addresses design loads on permanent structures in the construction stage, similar to temporary structures. For temporary structures with design life less than 6 weeks, a reduction factor of 0.75 is recommended to be applied to the design wind speeds. The Australian/New Zealand Standard (AS/NZS 1170.2:2011) defines structures with design life greater than 5 years as "permanent" and structures with design life less than or equal to 5 years as "temporary". The design wind speeds of temporary structures with varying design lifetimes are lower than is true for permanent structures. As shown in Figure 4, it might be difficult to guarantee the safety of human lives, but basically they simply believe that they can reduce the design load for temporary buildings.

Design Load for Scaffoldings

As mentioned in INTRODUCTION, the design wind load for scaffoldings is defined as the 1-year-recurrence wind load in Japan, because of its short average setting period at one construction site, 6 months for bare scaffolding and 4.5 months if sheets are used (SCEAJ-TRSSW, 1999). The British standard (BS EN 12812:2008) allows the wind pressure to be modified to take account of the period of use of the scaffolding; it is the recommendation of this standard that the minimum value of probability on a scaffolding structure be based on a two year return period. The Chinese standard (JGJ130-2011) recommends 10-year-recurrence wind loads for

scaffolding design. However, this principle is not necessarily appropriate for design load estimation as mentioned in the previous section.

(a) Damage to scaffolding and induced car accidents (Hokkoku Shimbun, 2007)

(b) Damage to scaffolding and induced damage to neighboring buildings (Ohdo, 2007)

Figure 5 Damage to scaffolding

Figures 5(a) and (b) show damage to scaffolds in Japan and induced car accidents and damage to a neighboring building. In some cases, people working at the construction site or walking outside can be killed or injured. These facts suggest that the damage to scaffolds can cause secondary failure of/damage to others. As the structural system of scaffolding is not stand-alone, once it is damaged, the effects imposed on others are more significant than is true with general buildings.

Figure 6 Damage to construction work offices due to a tornado in Saroma-cho, Hokkaido, Japan, on November 6, 2006 (Tamura *et al*., 2007)

Figure 7 Simple foundation system of construction work offices shown in Figure 6 (Tamura *et al*., 2007)

Design Load for Construction Work Offices

Figures 6 and 7 show damage to construction work office buildings due to a tornado in Saroma, Hokkaido, 2006. Nine people died due to this damage. The foundation part is seen in Figure 7. Simple embedded short vertical posts supported wooden foundation girders and the superstructure was attached to them with iron clamps. Such buildings have clearly weaker ground anchorage than general buildings. As mentioned in the previous section, temporary buildings and structures can be constructed with lower design loads.

However, we cannot find any reason to accept lower design loads than general buildings. This kind of building is used in much the same way as a general building. Workers at a construction site have meetings, make drawings, conduct analyses, perform administrative works, meals, sleep, and so on in this type of building. There is no difference from other general buildings including their headquarter office building. Once a person takes a job in the construction company as a construction engineer, he should stay and work in this type of building until he retires, say for 40 years.

On the other hand, a person assigned as a designer of the same company can stay in a high quality building such as the headquarter office for the same 40 years, and do almost the same things. The site staff does not quit his job after finishing his 1 or 2-year work term at a certain construction site. He continues to work in construction work offices at different construction sites. Thus, the construction work office is a kind of permanent building for him. If the quality of the construction work office is lower than that of general buildings in term of safety level, he would face more risk than the office staff, but this should not be accepted.

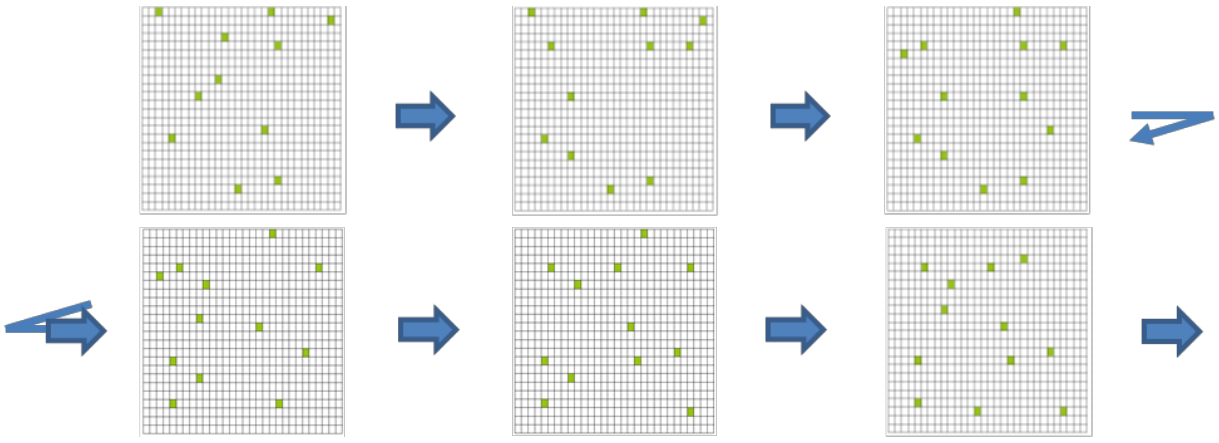


Figure 8 Schematic diagram of movement of scaffolding or construction work offices in a city model (6 month snapshots)

LENGTH OF LIFETIME AND INDIVIDUAL USE

Can Shorter Lifetime of Temporary Building for Individual Use be Reason of Lower Design Load?

Let's discuss the lifetimes of temporary buildings such as construction work offices or scaffoldings. Figure 8 shows a schematic diagram of a very simple city model, in which there are 30 × 24 = 720 buildings including construction sites. Each rectangular block represents a building, and green blocks indicate construction sites. The figure gives six snapshots of the city taken at 6 month intervals. The locations of the construction sites indicated by green blocks are basically different from snapshot to snapshot, which suggests the construction sites are moving but the number of construction sites remains basically constant. This mirrors real life.

If a strong earthquake or a strong typhoon attacks this city, all buildings, including general buildings (white blocks) and scaffolding or construction work offices (green blocks) would experience the same level of seismic load or wind load. There is no difference between the permanent and temporary blocks in terms of the existing period and the external environment.

Although a specific scaffold remains at an individual site for only a short period, i.e. average of 6 months, it moves to other places such that scaffolding is almost always present in the city or area. Although a specific scaffold is not be used for a long period, generic scaffolds always exist. The same is true for construction work offices.

If you look at a specific construction site, e.g. "construction site *i*", it disappears after a certain period, and so it seems to have a short fixed lifetime. However, if you look at construction sites in general, one or more always exist somewhere in the city the same as general buildings. Even for general buildings, a specific building has a certain lifetime, but similar structures are "always present". Staff assigned to work at construction sites are "always working" at a one or another construction work office, although the site often moves.

This suggests that the length of individual use of buildings and structures, i.e. the average period of 6 months for scaffolds or a few years for construction work offices, has no meaning with determination of design loads. We should design scaffoldings or construction work offices as permanent structures, rather than as temporary structures as they now are. The staff assigned to construction work offices do not see them as temporary, only as permanent structures.

Easier to understand examples are as follows. Even if the average rental period of an individual rental car is one day or one and a half days, the car cannot be designed based on this length of use. The renters will change but the car itself always exists. The fact that the users are temporary short has no meaning in terms of design, only the long-term use is important for car design. Even if some parts or bolts of an airplane are periodically replaced at predetermined intervals, those parts and bolts cannot be designed weaker than the main body based on the replacement interval. They should have the same performance as the main body.

Replacement of Cladding/Components for Maintenance

It is said that claddings and components are replaced more frequently than main structural frames, so the existing return periods for them are shorter than that of main frames. However, as explained by rental car example and airplane example in the previous section, this replacement has no meaning. A specific cladding element may be replaced at short predetermined intervals, but identical cladding element will replace it, and the cladding itself exists as long as the building exists.

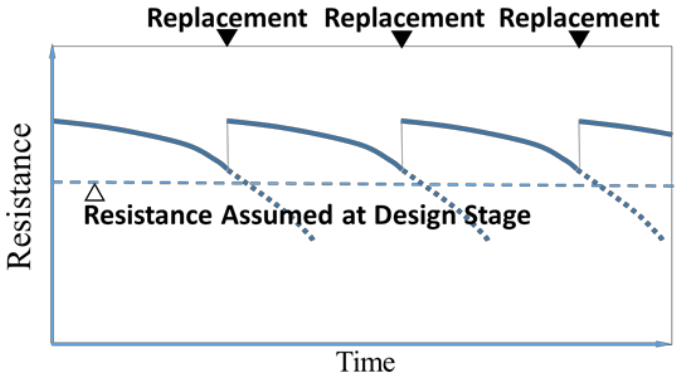

Figure 9 Replacement of elements for maintenance

The replacement is only maintenance to keep the element's quality or resistance up to the level assumed in the design stage as shown in Figure 9. The resistance level or design load level must not predicated on the replacement interval.
Thus, short replacement periods for specific cladding elements has no meaning in terms of wind load estimation. As cladding and component damage directly impacts the safety of the building and property, the structural designer should play an important role in guaranteeing their performance during strong winds.

Removal of Nets and Sheets for Strong Tropical Cyclones

By the way, the conventional wisdom is that the early warning systems of tropical cyclones allows nets or sheets covering scaffolding to be removed if strong wind is immanent, so a lower level of wind loads can be applied for scaffolding design, e.g. 1-year recurrence wind speed as specified in SCEAJ-TRSSW (1999). This is also obviously wrong.
Removal of nets and sheets changes only the physical parameters such as wind force coefficient C_f and projected area A_f. It cannot be a reason for accepting a reduction of design wind speed level V_d. The resultant wind force

$$F_d = (1/2)\rho V_d{}^2 C_f A_f \tag{1}$$

can be smaller because of the smaller wind force coefficient C_f or the smaller projected area A_f, but the recurrence year of the design wind speed V_d cannot be smaller. Thus, we can change and use appropriate C_f and A_f values depending upon the situation, but there is no relation between the design load level, i.e. design wind speed level V_d, and the removal of nets or sheets, and this point should be clearly noted.
Anyway, it should be clearly understood that there is no reason to use such a short design recurrence period, e.g. 1-year-recurrence wind load (SCEAJ-TRSSW, 1999), for scaffolds.

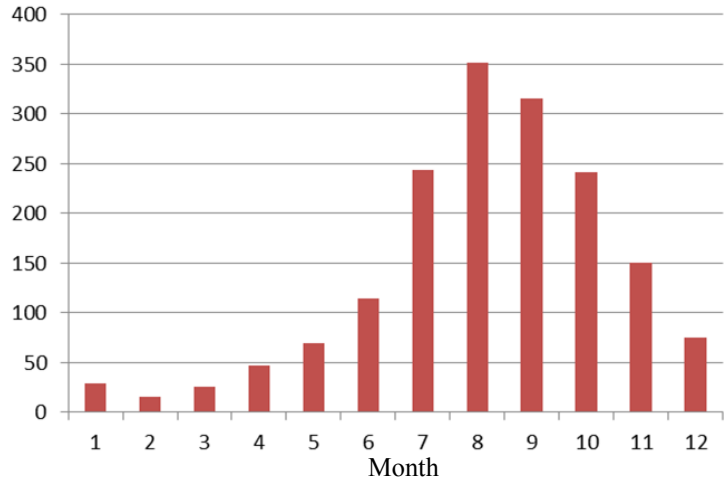

Figure 10 Monthly variation of number of typhoons (JMA, 1951-2014)

Seasonal Effects, Local Effects and others

Typhoons appear in the West Pacific region mainly in the warm season as seen in Figure 10, and there are significant seasonal effects. However, this is a wind climate problem. If a particular building is utilized only in the winter season, of course you need not consider the typhoon winds when you calculate design wind speed V_d. You can estimate design wind speed V_d based on wind speed records in winter seasons, or a seasonal factor can be used. This is similar to the geographic location effects. We can estimate design wind speed V_d based on the local wind climate.
It seems needless to say that these effects cannot be a reason for accepting a reduction in the recurrence period for the design wind speed estimation.

No Relation between Individual Lifetime and Social Importance or Damage Impacts

The discussions made above make it obvious that there is no relation between the design load level and the length or lifetime of individual use of cladding/components, scaffolds, and so-called temporary buildings.

It follows that the design wind load should be determined with clear recognition of the fact that so-called "temporary" buildings and structures never disappear and are always "present". Their design load level should be determined based on their acceptable collapse rate or damage rate in human society. Of course, it is not easy to determine an acceptable level of damage, because it depends on the importance of the target, social, economic and physical impacts of the damage, the economic situation of the society/nation, historical aspects, and so on.
So-called temporary buildings and structures tend to be treated as less important to society, but this is not necessarily true either. There is no essential relation between the social importance and the individual lifetime of a building part or an entire building. This should also be clearly noted.

RAISED PROBLEMS OF MINIMUM LIFE CYCLE COST APPROACH

Even for designing main structural frames to resist wind loads, the design load level may not be able to be determined based on the lifetime of an individual building. We use individual buildings, but each building is an important element forming the city or nation. The function of an individual building is of course important and should be considered in the design load estimation, but the function of the city and the nation is also very important. As such, the failure or damage rate of the assemblage of elements is important, not that of any one particular element.
As is well known, there is a concept for determining the optimal design load level based on a probabilistic consideration of the minimum Life Cycle Cost (LCC) of a building including initial construction cost and estimated repair cost over its estimated lifetime. However, although each building generally belongs to an individual as private property, it is one of the cells or elements composing a city or nation, and they are strongly related to each other through economic functions as well.
Business Continuity Planning (BCP) is an important issue not only for the private sector but also for a city or a nation, and securing BCP can be a key to the security of the city or nation. In particular, tall buildings have an aspect of social property, and damage to them has significant economic and social impacts on the community.
Under the above situation and considering the fact that the design load level cannot be decided based on the lifetime or length of individual use of a building or its parts, the concept of LCC should be re-examined. This raises the following question. Can "Life Cycle" be the length of the lifetime of the individual building? As it has been demonstrated, we should address the assemblage of buildings rather individual buildings. We have to re-examine whether we can decide the design load level based on the length of the individual building use.
When we make building codes or standards, we aim to specify the minimum requirements in order to keep essential and necessary security or safety level of our society which is undergirded by the vast number of buildings and structures. All of them must be designed as an assemblage and not in isolation. It is especially important that building codes and standards should be made based on this principle. It is strongly recommended that we re-examine the design load levels specified in some current codes, standards, and recommendations such as SCEAJ-TRSSW (1999), BSLJ Article 85 (2000), AIJ-DRBLL (2013), and so on.
Although the LCC concept has been adopted for design load estimation, the optimal design load level should be decided considering the overall LCC of the city or nation, rather than optimization of the LCC of an individual building. In that case, the costs imposed by securing social or national security should be addressed.

CONCLUDING REMARKS

The relation between the design load level and the length of individual use of a building or its parts was discussed. Most codes or standards tie the design load level to the lifetime of the individual building or building parts. However, it was clearly demonstrated that there is no rational reason for adopting this principle.
The aim of this paper was to merely clarify the problem of the relation between the design load level and the length of lifetime of buildings which has not necessarily been correctly understood.
More scientific discussion is needed to properly define so-called "temporary buildings". There might be more than two different types of temporary buildings. If we wish to decide the design load level of a building based on the length of its individual use, we should find a rational reason for it. Acceptable impact to society and acceptable probability of infrastructure failure should be directly discussed when determining design load levels. The acceptable criteria can be also depend upon the nation's economic situation. Anyway, many relevant problems remain to be solved.

ABSTRACT

Contemporary houses in many parts of Australia are brick veneer structures with metal or tile clad roofs that are built by trained builders using skilled labourers working to engineering design specifications. However, windstorms can cause significant damage to houses hence; there is a need to study the load sharing and response of these structural systems to assess their vulnerability. A full-scale test was carried out on a representative brick veneer contemporary house to assess the loading effects on roof to wall connection and load sharing. Tests were carried out at each stage of construction: bare frame followed by the installation of roof battens and cladding, wall lining, ceiling etc. These construction stages were used to assess the contribution of the structural and non-structural (i.e. ceiling, ceiling cornice and wall lining) elements to the load sharing and response of the timber-framed house structure to wind loading. The full-scale test, results show that the vertical load sharing of the timber-framed house through the roof to wall connection depends on the stiffness of the connection and the truss location (i.e. whether located at the end or middle). The contribution of the non- structural elements to the load sharing is about 15% to 20%. The outcome of this study can be used to assess the response (i.e. vulnerability) of these houses to windstorms.

Timber-framed structure, full-scale test, load sharing, house construction.

INTRODUCTION

The timber-framed house structure is a complex three-dimensional (3D) structural system, an assembly of several component structures such as the wall structure, floor structure and roof structures. These components are connected at cladding to batten, batten to truss, roof to wall, and wall to foundation connections. These complex structural systems are subject to wind loads but little is known about the structural behaviour and load sharing between each component structure through the inter-component connections. Determining the structural response and load sharing between the components are necessary to assess structural performance of timber-framed houses.

Boughton and Reardon (1982, 1983, and 1984) carried out a range of full-scale tests on houses at the Cyclone Testing Station, James Cook University, Townsville, Australia. These studies qualitatively investigated the performance of Australian timber-framed houses. These tests were focused on the response of wall stud, and roof (uplift strength). Based on the applied load and displacement, Reardon and Henderson (1996) showed improvement in the strength and stiffness of the house system with the addition of various structural and non-structural components such as wall lining, ceiling and ceiling cornice. However, these studies are did not quantify the load sharing within the timber-framed house structure. Morrisson (2010), Gupta and Kuo (1987), and He *et al* (2001) studied the performance of timber- framed houses in North America using full-scale test and numerical model analyses. The structural systems and construction methods of North American houses are different from that of the Australian houses. These types of differences in house structural systems cause differences in the stiffness and deformation of structural system to wind load.

This paper presents a full-scale study on a timber-framed house that determines the load sharing between components through their connections based on the reactions measured at the roof to wall connection and the foundation (i.e. bottom plate). This study also evaluates the effect of the non-structural components (i.e.wall lining, ceiling and ceiling cornice) on the load sharing.

Representative Contemporary House

Contemporary houses in many parts of Australia are brick veneer structures with metal or tile clad roofs that are built by trained builders using skilled labourers working to engineering design specifications. These houses were

designed and constructed to wind classifications specified in AS 4055 (2012) and 1684.2 (2010). The metal cladding is fixed to metal top-hat battens, which are attached to timber trusses that are spaced at regular intervals along the walls. The roof trusses are fixed to the wall top plate using various methods, depending on wind loading and building regulations. The schematic diagram of a brick veneer contemporary house structural system is shown in Figure 1.

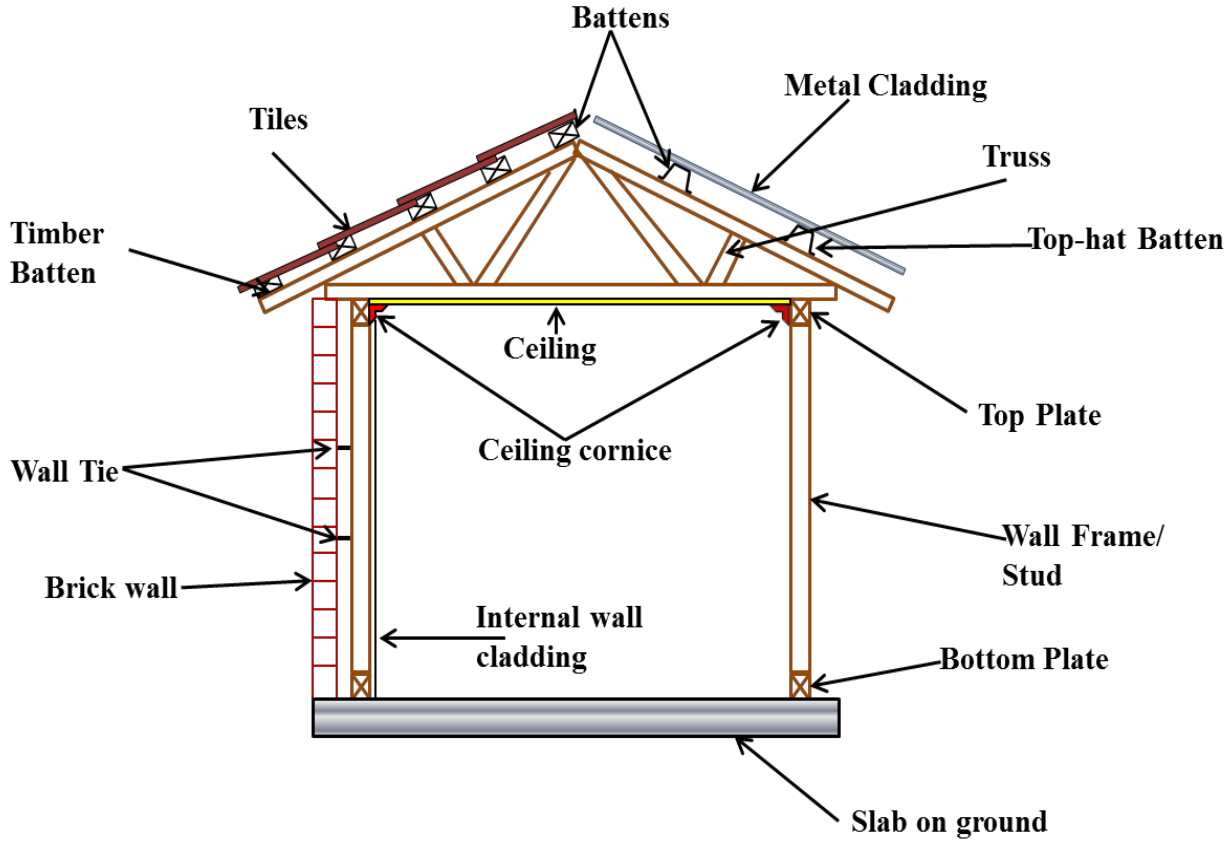

Figure 1 Schematic diagram of a brick veneer contemporary house structural system

This study involved a field survey of contemporary houses under construction around Brisbane, Australia (Figure 2) by a team from the Cyclone Testing Station to determine houses' structural system. Based on the field survey a contemporary representative house was obtained, which is a single storey, timber framed brick- veneer construction with 21.5º pitch hip-end roof. The spacing of timber trusses is at 600mm and the metal top-hat battens at 850mm. The roof cladding was metal sheet, which is attached to battens and the trusses are fixed to the wall top plate with triple grips.

This study investigated the loading effects and load sharing of the general truss region of the representative house by conducting a full-scale test. The test house consists of five general trusses, top hat battens, corrugated steel roof cladding, ribbon top plate, wall studs, bottom plate, wall lining, ceiling and ceiling cornice.

Figure 2 Contemporary house under construction

FULL-SCALE TEST HOUSE

Tests were conducted at seven different stages of construction, described in Table 1. Figure 3 shows the initial stage, full-scale test set-up, with five MGP 10 grade timber trusses, ribbon top plate, bottom plate and wall studs. Triple grips with hand nails are used to connect the truss and the top plate. The aim of testing for Stages 1 to 4 was to evaluate the load sharing within the roof structure and obtain the truss hold down forces, as well as evaluate the contribution of the ceiling to the response of the roof to wall connection. Testing from Stages 5 to 7 evaluated the whole house response and load sharing through the wall structure. Figure 3 also shows the loading beam attached to the steel reaction frame.

Table 1 The detail of each Stage of the full-scale test

Stage	Construction details	Location of applied load	Location of the reaction force measurement
	Roof Structure		
1 (S1)	Five trusses, two ribbon top plates, twelve wall studs and two bottom plates were installed	Loads were applied along the Truss at the batten to truss connection position	At the roof to wall connection on the top plates position which are connected to load cells via rods (i.e. LA, LB, LC, LD, LE, RA, RB, RC, RD and RE)
2 (S2)	Twelve battens were added to the construction Stage 1	On the battens at the same positions as Stage 1	Same as Stage 1
3 (S3)	Roof cladding was added to the construction Stage 2	On the roof cladding at the same positions as Stage 1	Same as Stage 1
4 (S4)	Ceiling was added to the construction Stage 3	Same as Stage 3	Same as Stage 1
	Roof and Wall Structure		
5 (S5)	Steel rod joint was disconnected from the top plate of the Stage 4	Same as Stage 3	Reaction forces measured on the bottom plate at the same location in Stage 4 (i.e. LA, LB, LC, LD, LE, RA, RB, RC, RD and RE)
6 (S6)	The wall lining was added to the Stage 5	Same as Stage 3	Same as Stage 5
7 (S7)	Ceiling cornice was added to the Stage 6	Same as Stage 3	Same as Stage 5

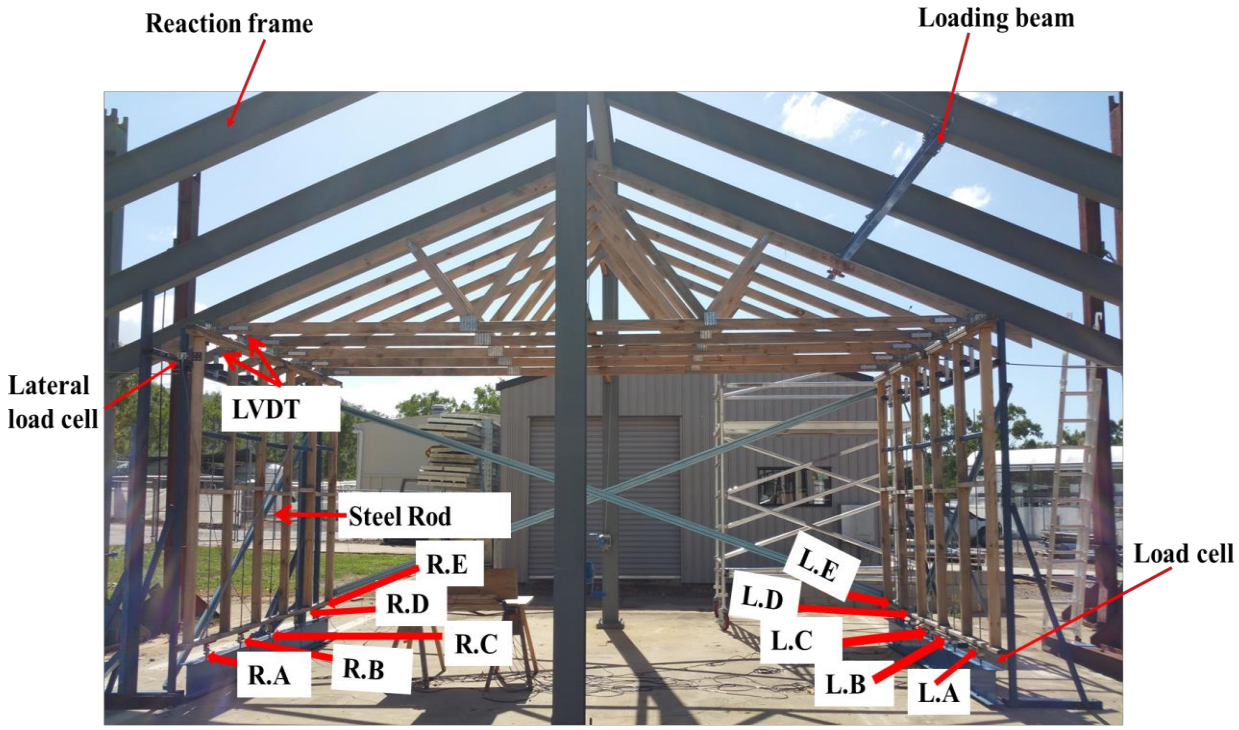

Figure 3 Full-scale test house at Stage 1 and the load cell locations

Figure 4 is a schematic diagram of the plan view of the test house. The structural system of the test house was symmetric; therefore, the loads were only applied to one side of the roof. Loads were applied normal to the roof surface at batten to truss connection locations with a hydraulic ram, which was connected to the loading beam located parallel to the batten as shown in Figure 3.

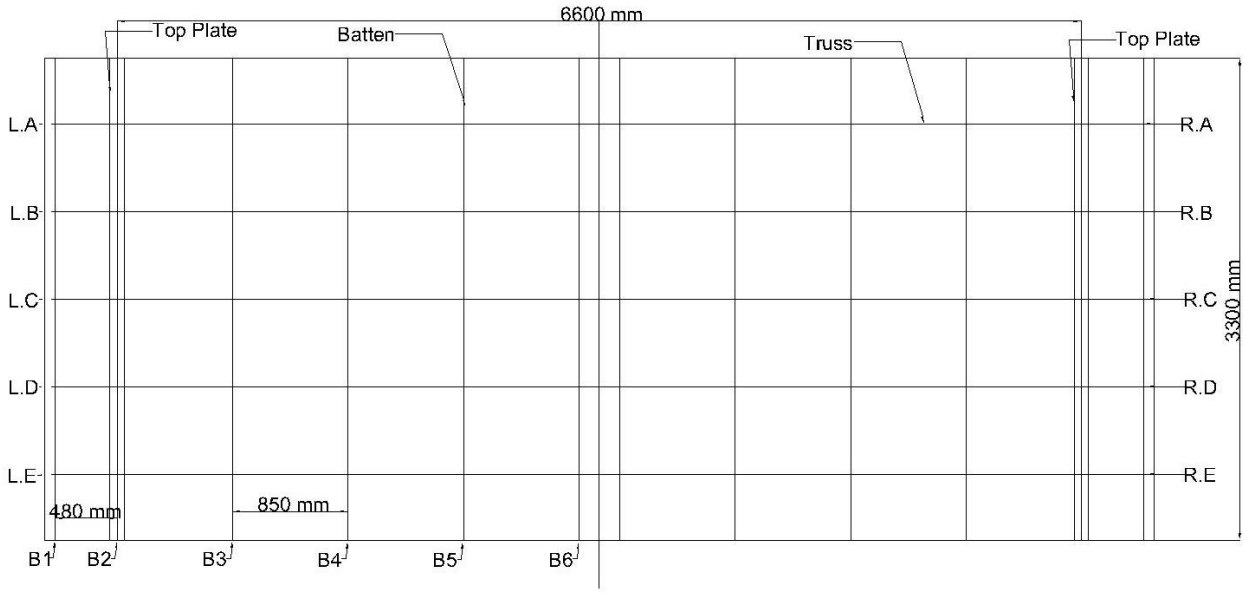

Figure 4 Schematic diagram of the plan view of test house

TEST RESULTS AND ANALYSIS

In the full-scale test, the loads were applied in the perpendicular direction to the roof surface, in order to represent wind loading. The applied loads were within the serviceability limit state of the house structure. This serviceability limit state load did not cause failures of the structural, non-structural components and the inter-component connections at each stage of testing. The response (i.e. the measured reaction forces and displacements) to applied loads ranging between 0.7kN and 1kN at batten to truss connections along Trusses A, B and C, are presented in this paper. A reaction coefficient, a normalized reaction force, is defined as the reaction force divided by the applied load.

Figures 5, 6, 7 show the vertical reaction coefficient (i.e. vertical reaction force divided by the vertical applied load) variation of the roof to wall connection support (i.e. L.A, L.B, L.C, L.D, L.E, R.A, R.B, R.C, R.D and R.E) at construction Stages (S1), (S2), (S3) (S4), (S5), (S6) and (S7), when the test load was applied along Truss A (i.e. TA), B (i.e. TB) and C (i.e. TC). Figure 5a shows the variation of the reaction coefficient for construction Stages 1, 2, 3 and 4, whilst Stages 5, 6 and 7 are shown in Figure 5b, when loading at Batten B1 on Truss A. Figure 5a shows that the reaction coefficient of the roof to wall connection Truss A at the loading side support (i.e. L.A) was high at Stage 1. This is because, in Stage 1, the ribbon top plate is the only structural element available to share the load to the adjacent trusses' supports. About 20% of applied loads were shared to the adjacent trusses through the wall top plate. The reaction coefficient at Truss A roof to wall connection (i.e. L.A) at Stage 1 is reduced by about 20% at Stages 2 and 3, whilst about 25% of the reaction coefficient was reduced at Stage 4 when compared to Stage 1. Figure 5b illustrates that Stages 6 and 7 produced similar reaction coefficient magnitudes, indicating that the contribution of ceiling cornice on the vertical load sharing is less compared to wall lining.

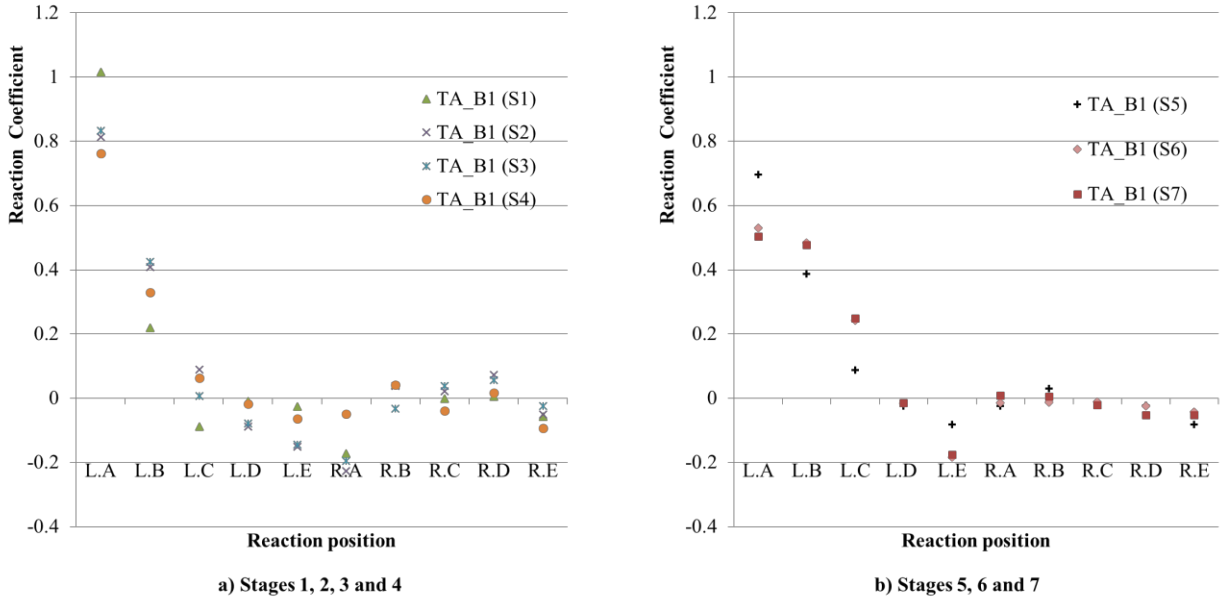

Figure 5 Reaction coefficient variation when loading along Batten B1 at Truss A

Figure 6 illustrates the reaction coefficient variation when the test load was applied along Batten B2 at Truss B. The reaction coefficient at the Truss B support (i.e. L.B) in all the Stages was less than that the reaction coefficient obtained when loading along Batten B1 at the Truss A support (i.e. L.A). This is due to the location of the trusses. The Truss A was located at the end of the top plate and could share the load only on one side of the house, whilst Truss B was located between two trusses (i.e. Truss A and Truss C) and could share more loads between these two truss supports. The reaction coefficients at Truss A (i.e. L.A) were generally higher than the reaction coefficients of Truss C (i.e. L.C) when loading along Truss B. This is due to the stiffness variation of the roof to wall triple grip connections, the roof to wall connection stiffness varies with material non linearity, construction practices and workmanship. This figure indicates that the stiffness of the Truss C connection is less than that of Truss A.

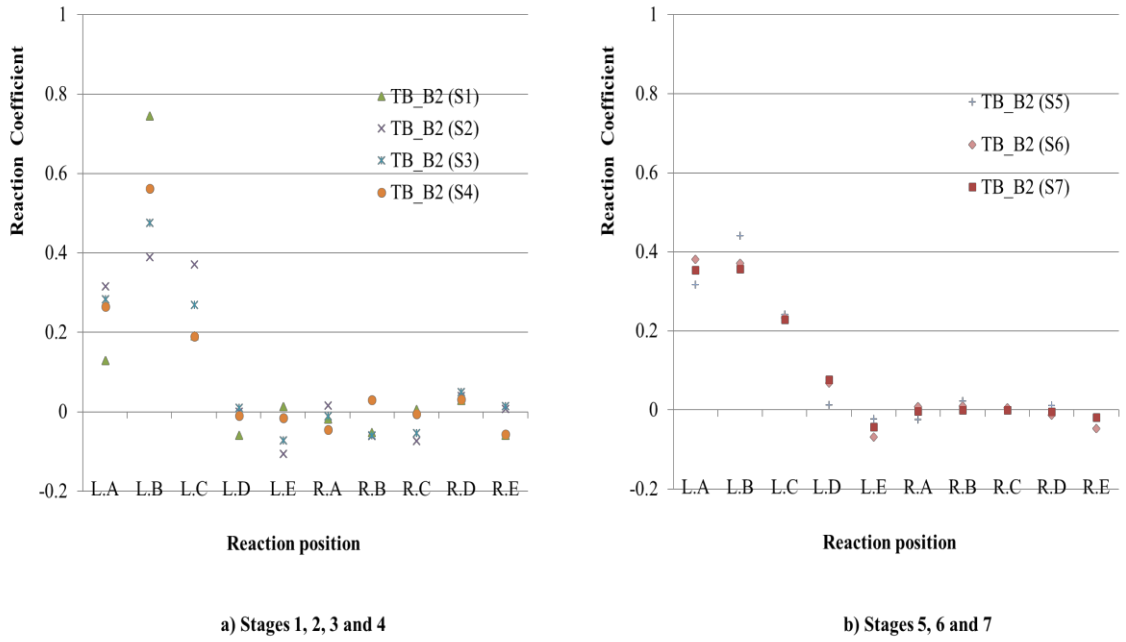

Figure 6 Reaction coefficient variation when loading along Batten B2 at Truss B

Figure 7 presents the reaction coefficient variation when loading along Batten B3 at Truss C. The reaction coefficient of the Truss C support (i.e. L.C) in all the Stages was less than the reaction coefficient obtained with loading applied along Battens B1 and B2 at Trusses' A and B supports (i.e. L.A and L.B). Truss C was located at the middle of the test house and could share the load to the adjacent trusses' supports. This could be a reason for the lower reaction coefficient obtained when loading along Truss C. The stiffness of the roof to wall connection of Truss C was less than the other connections when compared to other trusses at Stage1. This lower connection stiffness is also a reason for the reduced reaction coefficient found in all stages when loading along Truss C.

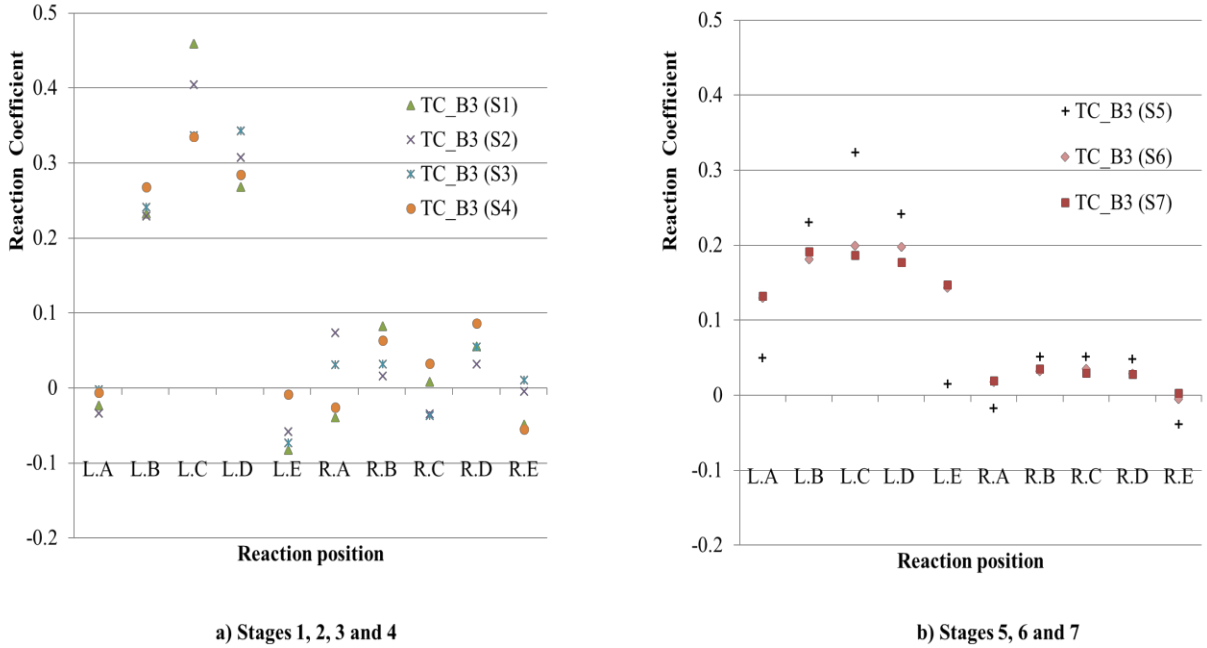

Figure 7 Reaction coefficient variation when loading along Batten B3 at Truss C

The measured roof to wall connection vertical displacement was divided by the applied load to quantify the flexibility of the connection in mm/kN. Figure 8 shows the flexibility of the roof to wall connection on Trusses A, B and C, on loaded side by considering vertical displacement variation at each construction stage. This shows large displacement at Stage 1 then progressively decreasing when the structural (i.e. S2 and S3) and non-structural (i.e. S4, S5, S6 and S7) elements were added to the system. Figure 8 also shows that the vertical displacements of the Truss A connection was high in all the stages compared to other trusses (i.e. Truss B and C). This because, Truss A shared less load to the adjacent trusses (Figure 5) due to their location.

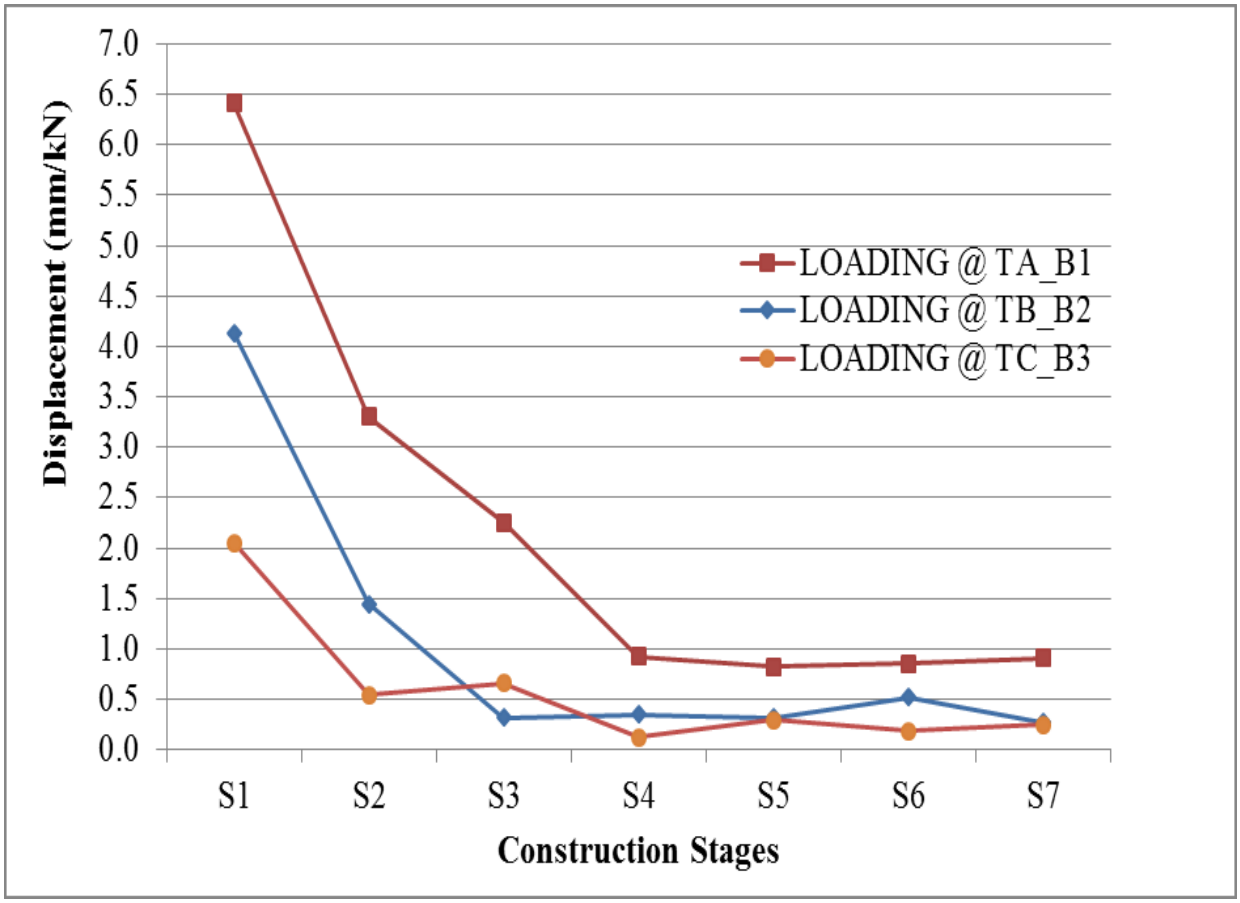

Figure 8 Roof to wall connection vertical displacement at Trusses A, B and C supports L.A, L.B and L.C

Load Sharing

The test results found during in this study provide a clear indication that the load distribution (Figures 5 to 7) and hence, the load-sharing characteristics of timber-framed structure depends on the inter-component connection stiffness. Figure 9 gives the percentages of vertical applied loads that were shared to the adjacent trusses when the loads are applied at B1, B2, B3, B4 and B5 on Truss A. This figure shows 10% to 20% of loads were shared to the adjacent trusses at Stage1, which then increased to 30% to 40% at Stages 2, 3, 4 and 5. About 45% to 50% vertical applied loads were shared to the adjacent trusses at Stages 6 and 7. This indicates that the non-structural elements (i.e. Ceiling, Ceiling cornice and wall lining) increase the load sharing characteristics by about 15% to 20%.

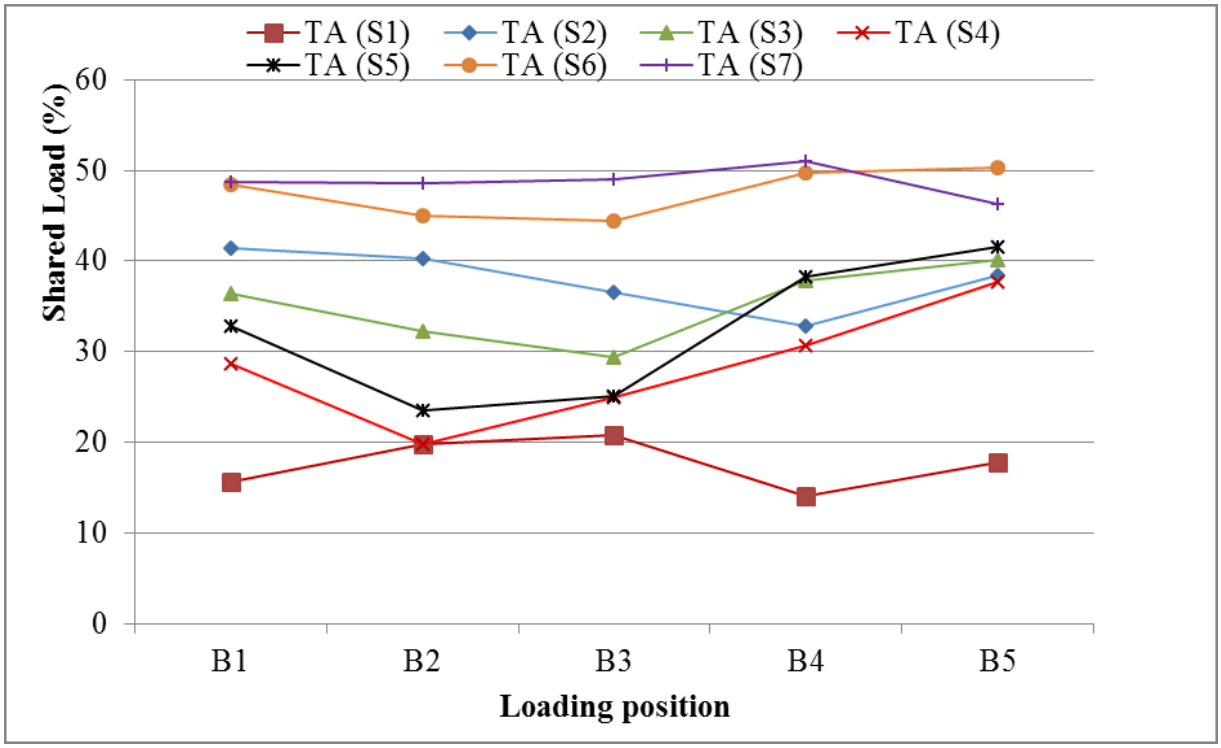

Figure 9 Percentage of applied loads are shared to the adjacent trusses when loading along Truss A

Figure 10 presnts the percentge of vertical applied loads shared by the adjacent trusses when loads were appled on Truss B. About 30% to 45% applied vertical loads were shared by the adjcanet trusses at Satge 1, which increased to 55% to 72% at Stages 2 and 3. After the ceilling was added to Stage 3, which is Stage 4, the load sharing was reduced to 50% to 55%. The self weight of the ceiling held down the truss and reduced the vertical displacement of the roof to wall connection, eventually increasing the support stiffness therefore, the percentge of load sharing was reduced at Satage 4. The contribution of non-structral elements to the load sharing was about 15% to 20% when loading along Truss B.

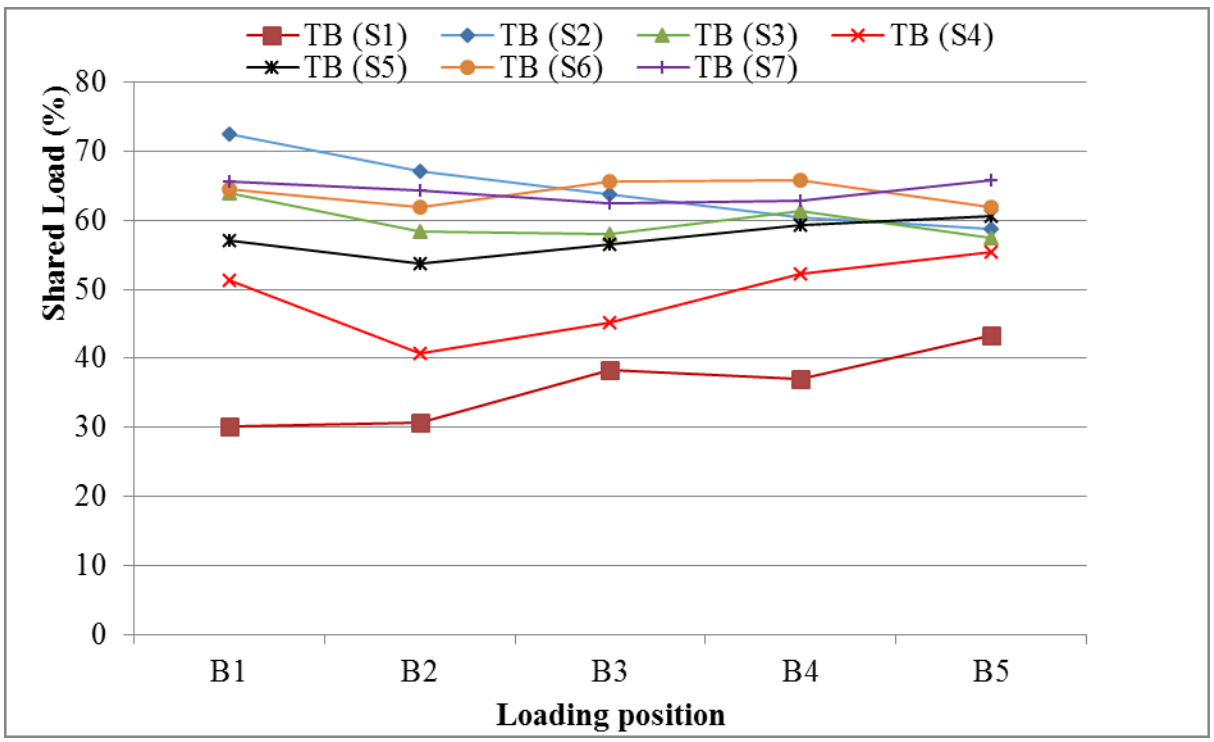

Figure 10 Percentage of applied loads are shared to the adjacent trusses when loading along Truss B

Truss C is a middle truss in the test house, and the stiffness of that truss to the wall connection was less than the other connections. Therefore, compared to other trusses, a higher percentage of loads were shared to the adjacent trusses in all the stages when loading along Truss C (Figure 11).

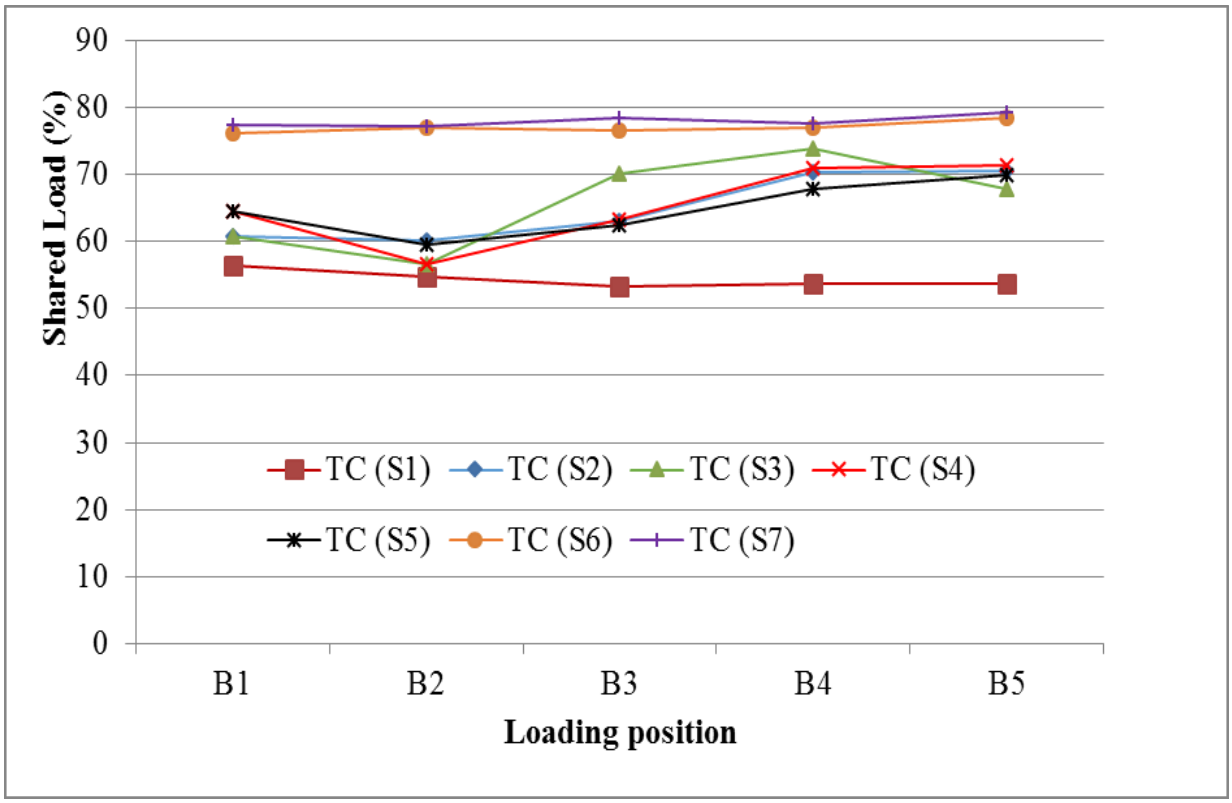

Figure 11 Percentage of applied loads are shared to the adjacent trusses when loading along Truss C

CONCLUSIONS

The determination of load sharing within the structure of timber-framed houses is important for assessing their response (i.e. design and vulnerability) to wind loads. A full-scale test was carried out to determine the response and load sharing of a representative, contemporary Australian timber-framed house. The following observations and conclusions were reached.

- Load sharing characteristics in timber- framed structure is dependent on the inter-component connection stiffness.
- Self-weight of the ceiling increased the roof to wall connection stiffness by reducing the vertical movement of the connection.
- The non- structural elements (i.e. ceiling, ceiling cornice and wall lining) contributed significantly to the load sharing of the timber-framed structure this contribution was about 15% to 20%.
- The reaction force and displacement is high when loading along the end truss, this indicates the end truss should use a high stiffness connection.

ACKNOWLEDGEMENTS

This study is part of the research conducted by Climate Adaptation Engineering for Extreme Events Cluster funded by CSIRO Land and Water Flagship. The authors gratefully acknowledge the funding support of CSIRO and the support of the technical staff of the Cyclone Testing Station, James Cook University, Townsville. Authors also wish to thanks Mr Mitchell Humphreys a graduate student from James Cook University, for his help and support in conducting the full-scale test.

ABSTRACT

Performance-based engineering (PBE) is a methodology that requires specification on a range of performances or target reliabilities for structures of different importance. Information on these 'performance levels' require a probabilistic assessment of the potential factors that may influence a design, including information on the hazard, load, resistance, loss estimates, expert opinion and public perception. This paper describes one such probabilistic assessment in the development of empirically-based fragility functions for tornadoes using damage assessment data and a tornado wind field model for the 22 May 2011 Joplin, MO tornado. The damage assessment data was collected during field surveys of more than 1,240 structures in the aftermath of the tornado, using provisions of the Enhanced Fujita (EF) Scale to assess the damage. The wind field model was developed from the tree-fall patterns noted in the damage path of the tornado. Fragility functions were developed for the Degrees of Damage (DOD) associated with One- and Two-Family Residences in the EF Scale. The empirically-derived fragility functions were progressive in nature, with median wind speeds varying from 33.6 m/s for initiation of visible damage to 85.2 m/s for complete destruction. These functions were compared to existing fragility functions for straightline winds to evaluate potential differences in failure mechanisms for structures exposed to tornadoes. Wind speeds associated with the median failure probability were used to estimate load factors, defined as the square of the ratio of the straightline wind speed to the tornado wind speed. Structures tended to fail at lower wind speeds in tornadoes than in straightline winds, with load factors between 1.32 and 1.51. A fragility assessment in the context of PBE naturally requires attribution and quantification of all uncertainties. Uncertainties in the both the damage and wind speed estimation in the development of fragilities are quantified and assessed using Monte Carlo methods. Preliminary results show variance in fragility parameters is higher for higher damage states but all damage states have relatively low coefficients of variation.

Tornado, Fragility, Near-Surface Wind Speed, Uncertainty.

INTRODUCTION

Tornadoes in the United States have caused an estimated $5 billion in losses (2011 dollars) each year since 1950 (Simmons et al., 2012). The potential exists for even greater economic losses however, evidenced by years such as 1965 with an estimated $40 billion in total economic loss in 2011 dollars, and 2011, with $26 billion in economic losses (Simmons et al., 2012). The majority of the economic losses in tornadoes is to residential structures, nearly 90% of which in the US are wood-frame construction (van de Lindt and Dao, 2009). Failures in wood-frame structures during extreme wind events are commonly encountered because most wood-frame residential structures are built to prescriptive requirements that nominally provide life safety during a design wind event, which for most of the US is 115 mph (ASCE, 2010). Prevention of damage during tornadoes has typically not been considered, however recent work has highlighted the need for a new design paradigm for tornadoes that would include both life safety and reduced damage as objectives in the design (van de Lindt et al., 2012; Prevatt, D. O., van de Lindt et al., 2012). For such a paradigm, it is important to determine an acceptable wind speed for tornado design. This can be accomplished through the development of fragility relationships, which are commonly used to assess the performance of structures against hazards, including tornadoes, by relating the probability of damage to a hazard level, such as wind speed. A significant body of work exists for the determination of analytically-derived fragility curves for wood-frame structures and their structural components in hurricane winds (Amin and van de Lindt, 2013; Ellingwood et al. 2004; Li and Ellingwood 2006; Rosowsky and Ellingwood 2002), but fragility relationships for wood-frame structures in tornadoes have only recently been developed. Amini et al (2013) performed a probabilistic assessment of sheathing and roof-to-wall connection failures assuming a fully sealed, wood-frame structure during a tornado using wind pressures from

ASCE 7-10, modified for tornado loads using simple amplification factors based upon Haan et al (2010). As of yet however, no studies have provided empirical results for comparison to this and any future models, as the spatial distribution of near-surface wind speeds in tornadoes, necessary for comparison to observed damages, is difficult to obtain. Empirically-derived fragility relationships are common in seismic studies (Shinozuka et al., 2000; Rossetto and Elnashai 2003; Miyakoshi et al., 1997), but have not been used to any great extent for wind hazards. Ellingwood et al (2004) made limited comparisons between theoretical fragilities for roof panels and roof-to-wall connections and damage observations from Hurricane Andrew and observed qualitatively consistent results between the two methods, but noted that validation using empirical data was a challenge due to the complexity of the hurricane hazard as well as the wide variety of building configurations present in actual communities. Limited studies are also available as validation of hurricane catastrophe models (Pinelli et al., 2004; Federal Emergency Management Agency 2012), but currently no studies exist which develop empirically-based fragility functions for residential structures considering tornado hazards.

BACKGROUND

On May 22, 2011, a powerful tornado struck Joplin, MO, a city with a population of approximately 50,000. The tornado, rated an EF5 using the Enhanced Fujita (EF) Scale (McDonald et al., 2006), caused 161 fatalities and over $2 billion in insured losses, destroying over 4,000 homes and damaging 3,500 others (NWS. 2011). The extensive damage to both the built and natural environment provided an opportunity to further our understanding of near-surface wind speeds in tornadoes, despite the tragic circumstances. Research teams from the National Institute of Standards and Technology (NIST) and the American Society of Civil Engineers (ASCE) separately surveyed the damage caused by the tornado. The independent findings of each team are available in the published literature (Kuligowski et al. 2014; Prevatt et al., 2011). One outcome of the NIST team survey was the documentation of tree-fall patterns, which were used to develop a spatio-temporal tornado vortex model for the Joplin tornado. This provided a means of estimating the wind speed and direction for any point within the entire tornado path. The ASCE team used the Enhanced Fujita (EF) Scale (McDonald et al. 2006) to classify damage to 1,349 geo-located damaged homes in the path and estimate the wind speed causing the damage. The EF Scale classifies damage to specific Damage Indicators (DI), which include One- and Two-Family Residences. Damage to each DI is described using progressive damage states, known as Degrees of Damage (DOD), which have a range of wind speeds associated with them from which to estimate the wind speed necessary to cause the damage. These damage-estimated wind speeds were compared to the wind speeds estimated by the tree-fall wind field model. A detailed comparison of the two wind speed estimation methodologies used by these teams found reasonably good agreement between the two independent methods, although in general the tree-fall estimated wind speeds were higher than those estimated from the EF-Scale (Lombardo et al., 2015). The objective of this study is to use a best-fit wind field model developed from both the tree-fall patterns and building damage observations to develop empirically-based fragility functions for wood-frame residential structures damaged during the 2011 Joplin, MO tornado. The empirically-based fragility functions for specific damage states will be compared to fragility functions for equivalent damage states found in HAZUS-MH for hurricane winds, and to Amini et al (2013) representing numerically-modeled damage states for tornadoes.

DEVELOPMENT OF CONSENSUS NEAR-SURFACE WIND SPEED MODEL

The direction and location of tree fall for approximately 5,000 trees in the Joplin tornado were determined by NIST using post-storm aerial photos (Kuligowski et al. 2014). A Rankine vortex (RV) model was developed to match these tree-fall patterns, using methodology given in Holland et al (2006) and was used to estimate maximum wind speeds. This model was developed independently and then compared to the wind speed estimates from the ground survey which used the EF Scale (e.g., EF3 damage represents wind speeds between 60.8 m/s and 73.8 m/s). For the current study, a best fit model was developed based upon the two estimation methods. The objective was not to simply match the vortex model to either method, as there are potential inaccuracies in each, but rather to determine the vortex model parameters that best agreed with both models. This was accomplished by means of a full factorial design as described in Kuligowski et al (2014), in which a plausible range of values for each RV model parameter were initially used. A wind speed model for every possible combination of RV parameters was generated and compared to the wind field estimated from the damage survey at a given cross-section representative of a large portion of the tornado path photos (Kuligowski et al., 2014). Normalizing the distance by the radius of maximum wind, the values of wind speed from the tree-fall based model were compared to damage-based wind field at the locations where the damage-based model was evaluated. The tree-fall based model resulting in the least total mean square error when compared to the damage-based model was chosen as the best fit model, provided its properties fell within predetermined observed properties of the tornado (e.g., width of tree fall damage).

DEVELOPMENT OF FRAGILITY FUNCTIONS FROM EMPIRICAL DATA

The probability of failure during a natural hazard is often defined using the concept of fragility, which in performance-based engineering applications is defined as the probability of a certain limit state being reached or exceeded, given some hazard level. This can be expressed as the conditional probability P[LS|D>x], where LS is the system Limit State of interest, and D is the demand on the system, which is often taken as the 3-sec gust wind speed in wind engineering applications (Lee and Rosowsky, 2005). The fragility of a structural system is typically modeled using

$$F(x) = \Phi\left[\frac{\ln(x) - x_m}{\beta}\right] \quad (1)$$

where Φ(.) = standard normal cdf probability integral; xm = logarithmic median of the demand, x; and β = logarithmic standard deviation of the demand, x.

Fragility functions can be developed using structural analysis, expert elicitation, experimental testing and empirical observations during a natural event. A standardized approach to developing fragility functions using each data type is given by Porter et al (2007).

The data available from the Joplin tornado consists of the final damage state of individual homes and the maximum wind speed experienced by the homes, estimated using the consensus wind field model described above. Although time histories of wind speeds are available, information on the wind speed at the time of the actual failure is unknown. Porter et al (2007) classifies empirical data of this sort as Type B: Bounding EDP data, meaning that each individual damage data gives a binary value of whether a specific damage state was met or exceeded or not and the maximum EDP to which it was exposed.

Use of Logistic Regression in Developing Empirically-based Fragility Functions

The damage data was first classified for each DOD according to whether the observed damage state met or exceeded the damage state of interest, so that for a specific damage state, for example DOD4, all structures with an observed DOD less than 4 would have a binary value of 0 (i.e., probability of failure or Pf = 0), while those with an observed DOD greater or equal to 4 would have a binary value of Pf = 1. The fragility functions were then fit to the damage data by performing maximum likelihood estimation on the binary failure data, assuming the data fit a lognormal distribution of unknown parameters. Logistic regression with a probit link was used to transform the binary failure data into a continuous lognormal probability distribution (Kutner, 2005).

Degrees of Damage (DOD) from the EF-Scale are chosen as the damage limit state for this study because the progressive nature of the DODs for one- and two-family residences cover the primary damage states of residential structures, and are thus easily comparable to analytically-derived fragility functions for wood-frame structures under wind loads. DODs for 1241 individual homes within the domain of the consensus wind field model were also previously documented during the ground survey, allowing this entire database to be quickly used in the development of the empirical fragilities with little modifications. The fragilities developed here for a given DOD implicitly incorporate all uncertainties in the potential factors leading up to the damage state being reached, including roof type, orientation, house density, debris, and many others. Further work is needed to parse out the effects of each of these factors on the probability of failures for the various damage states.

Table 1 Degrees of Damage (DOD) for 1- and 2-story Family Residences from Revision 2 of the EF-Scale (McDonald et al., 2006).

DOD*	Damage description	EXP[m/s]	LB[m/s]	UB[m/s]
1	Threshold of visible damage	29.1	23.7	35.8
2	Loss of roof covering material (<20%), gutters and/or awning; loss of vinyl or metal siding	35.3	28.2	43.4
3	Broken glass in doors and windows	42.9	35.3	51.0
4	Uplift of roof deck and loss of significant roof covering material (>20%); collapse of chimney; garage doors collapse inward; failure of porch or carport	43.4	36.2	51.9
5	Entire house shifts off foundation	54.1	46.0	63.0
6	Large sections of roof structure removed; most walls remain standing	54.5	46.5	63.5
7	Exterior walls collapsed	59.0	50.5	68.4

8	Most walls collapsed in bottom floor, except small interior rooms	67.9	56.8	79.6
9	All walls collapsed	76.0	63.5	88.5
10	Destruction of engineered and/or well-constructed residence: slab swept clean	89.4	73.8	98.3

The methodology for developing the empirical fragilities is demonstrated in Figure 1, which shows the binary data associated with DOD4 observations (uplift of roof deck, loss of >20% roof covering, chimney collapse, or garage door collapse) and the lognormal fragility fitted to the binary data using logistic regression. While there were observations near the maximum wind speed of the tornado that both failed and survived, it is obvious that the failed data is much denser at higher wind speeds than the surviving data, as would be expected. Also shown are the failure rates for 4.47 m/s (10 mph) wind speed bins, which closely matched the fragility functions fit using logistic regression. This demonstrates the robustness of the lognormal fragility to the fitting method and provides greater confidence in the overall fit obtained (Porter, 2007).

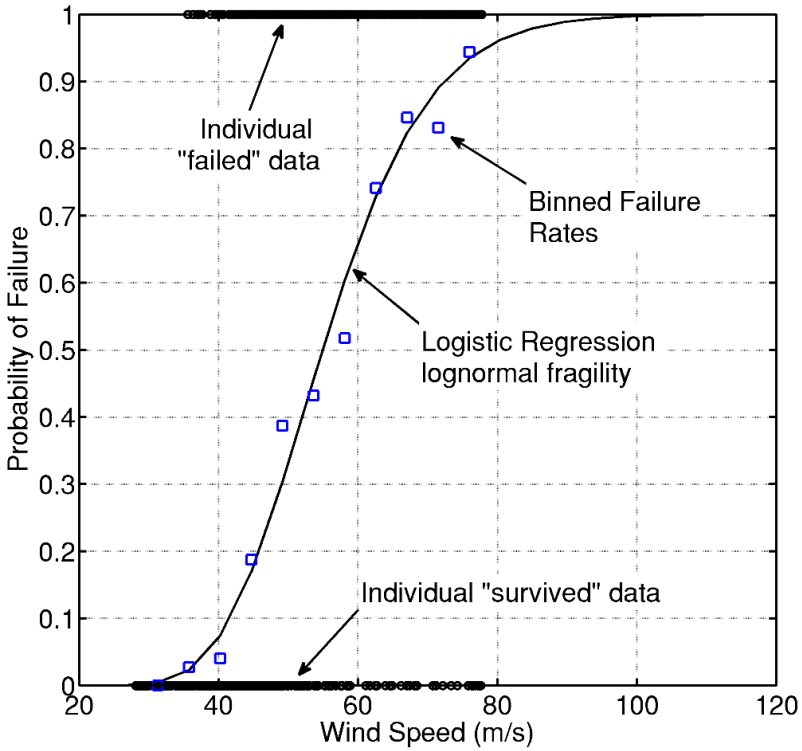

Figure 1 Illustration of the logistic regression method for fitting lognormal fragility. The data in this example represents a damage measure corresponding to DOD4.

Empirical Fragilities for Damage Measures Corresponding to Degrees of Damage (DOD)

Lognormal fragility functions were fitted for each DOD of DI2 and the best fit for each are shown in Figure 2. As would be expected, the fragilities demonstrate the progressive nature of the damage states, with each successive damage state having a higher median wind speed than the one before and no crossing of fragility functions, which can be an indication of poor quality data (Porter et al., 2007). The similarity of fragility functions for DOD5 and DOD6 is simply due to there being only four observations for DOD5. Table 1 summarizes the fragility functions for each damage state, and includes the number of observations and the lognormal fit parameters obtained using logistic regression.

Table 1 Lognormal fit parameters (location, x_m and scale, β) of fragility functions for Degrees of Damage

DOD	0	1	2	3	4	5	6	7	8	9
n	126	153	116	170	105	4	227	103	99	132
x_m	-	4.32	4.47	4.58	4.72	4.81	4.81	5.01	5.12	5.25
β	-	0.18	0.23	0.23	0.22	0.21	0.21	0.23	0.24	0.26

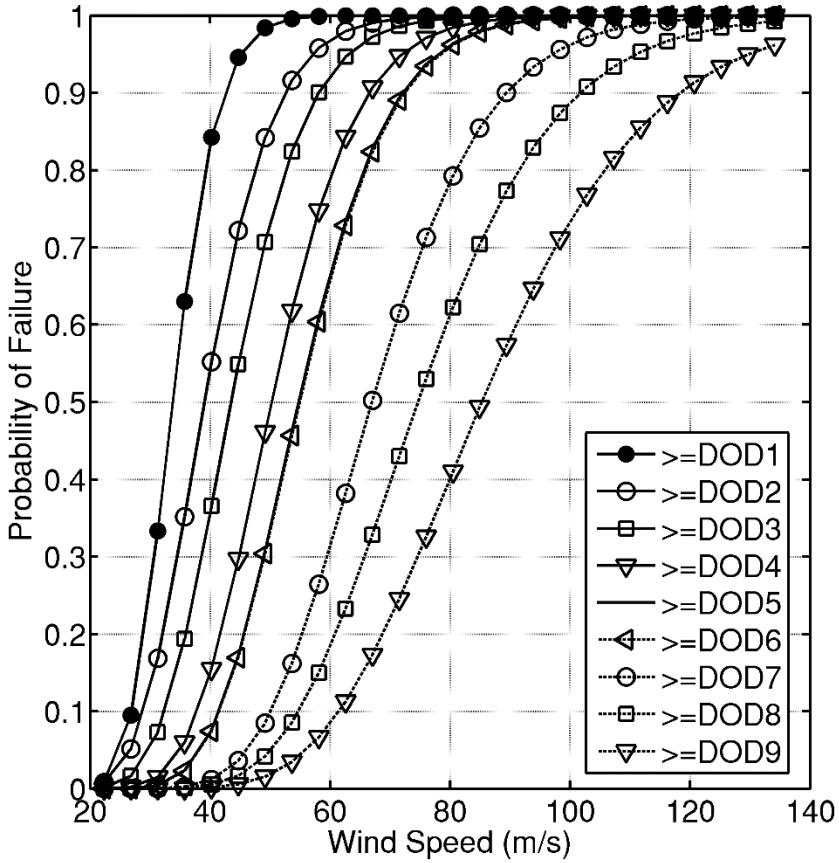

Figure 2 Empirical fragilities for damage measures corresponding to the nine Degrees of Damage for FR12 (One- and Two-Family Residences) of the EF-Scale

Comparison of Empirical Tornado Fragility Functions to Analytically-Derived Functions

Fragility functions for light wood-frame structures have been analytically derived for both straightline and tornado winds. But there has been a lack of validation of these functions with empirical data, particularly for tornadoes. The empirical fragility functions derived above, although they represent a single tornado, provide a means of validation for the existing body of analytical work available in the published literature. Further, significant differences exist between tornado and straightline winds. Tornadoes typically have significant radial, tangential and vertical components (Davies-Jones et al., 2001; Lewellen, 1993), rapid changes in wind speed and direction and possibly have higher turbulence than straightline winds (Baker and Church, 1979). In addition, the rapid pressure drop associated with the tornado vortex is not present in straightline winds, although its effect on building loads is limited when building leakage is present to equilibrate external and internal pressures. These factors may enhance tornado loads and cause buildings to fail at lower wind speeds than in a straightline wind event (Roueche et al., 2015; Haan et al., 2010). However, tornadoes are also typically of much shorter duration than hurricanes, and therefore during the passage of a tornado, buildings may experience fewer damaging gusts and thus less damage. With many unknowns about these factors, and how they combine to effect overall building damage, the effect of the differences between tornado and straightline winds on building damage is not well understood. By comparing empirical fragility functions from tornadoes to analytically-derived fragility functions for both straightline and tornado winds, the differences between tornadoes and straightline winds as they relate to building damage can begin to be quantified.

Comparison of Empirically-Based Fragility Functions for Tornado Hazards to Straightline Winds

For straightline winds, we compare empirical fragility functions to analytically derived fragility functions from HAZUS-MH Hurricane (Federal Emergency Management Agency 2012). To make this comparison it is necessary to have equivalent limit states. For the empirical functions, the limit states are the DODs for DI2 of the EF-Scale. For the analytical functions, the limit states are the four damage states given in Vickery et al (2006) and summarized here in Table 2. These damage states are reasonably equivalent to specific DODs, which are also given in Table 2.

Table 2 Comparison of HAZUS damage states with Degrees of Damage for FR12

HAZUS Damage States	Degrees of Damage for FR12
DS1 – Roof cover failure between 2% and 15%; a maximum of one window, door, or garage door failure; no roof sheathing failure. No roof structure failure.	DOD3 – broken glass in doors and windows. Also would include DOD2, which is described as loss of roof covering (<20%), gutters and/or awning; loss of vinyl or metal siding.
DS2 – Roof cover failure between 15% and 50%; between one and three window, door or garage door failures; and between one and three sheathing failures. No roof structure failure.	DOD4 – uplift of roof deck and loss of significant roof covering material (>20%); collapse of chimney; garage doors collapse inward; failure of porch or carport.
DS3 – More than 50% roof cover failure; more than 20% or three window, door or garage door failures; and between three and 25% roof sheathing failures. No roof structure failure.	
DS4 – More than 50% roof cover failure; more than 50% window, door or garage door failures; more than 25% roof sheathing failure. Roof structure failure occurs.	DOD6 – large sections of roof structure removed; most walls remain standing.

The HAZUS-MH Hurricane Model uses fragility functions for wood-frame homes representing a variety of construction characteristics, roof shapes and exposure conditions. The eight specific conditions used in this study are summarized in Table 3 and were selected based upon the observations from the ground survey of the damage in Joplin. A single compound fragility was developed from the eight individual fragility functions for each damage state to compare with the empirical fragilities. Further, a compound fragility was developed for the combination of DS2 and DS3, in order to be equivalent to DOD4. The use of compound fragilities better reflects the variability inherent to the empirical functions, which are differentiated by the final damage state only, not by building type, roof shape or exposure.

Table 3 Building and exposure types from HAZUS used for comparison to empirical fragility functions

Parameters	**Values Used to Develop Compound Fragilities**
Roof Type	Hip or Gable
Sheathing Attachment	6d or 8d at 6/12 spacing
Roof-to-Wall Connection	(3) 8d toe-nails
Garage Door	Weak
Exposure	Light Suburban (z_0 = 0.35 m) or Light Trees (z_0 = 0.7 m)

The resulting comparison is shown in Figure 3. In all three comparisons the empirical fragilities are to the left of the HAZUS-MH Hurricane fragilities, suggesting that under tornado winds buildings tend to fail at lower wind velocities than in straightline winds. The differences are more pronounced in the higher damage states. This may be a result of the more complex tornado wind flow causing the higher damage states as compared to the lower failure states, which are generally located further away from the tornado vortex where the wind flow is more similar to straightline wind flow. The differences between the fragility functions for different limit states are summarized in Table 4. Included is an estimated load factor for each limit state, based upon the square of the velocity ratio for the median wind speed value at Pf = 0.5. This load factor gives an empirically-based estimate for how much loads based upon straightline winds would need to be amplified to match the loads for an equivalent tornado wind speed.

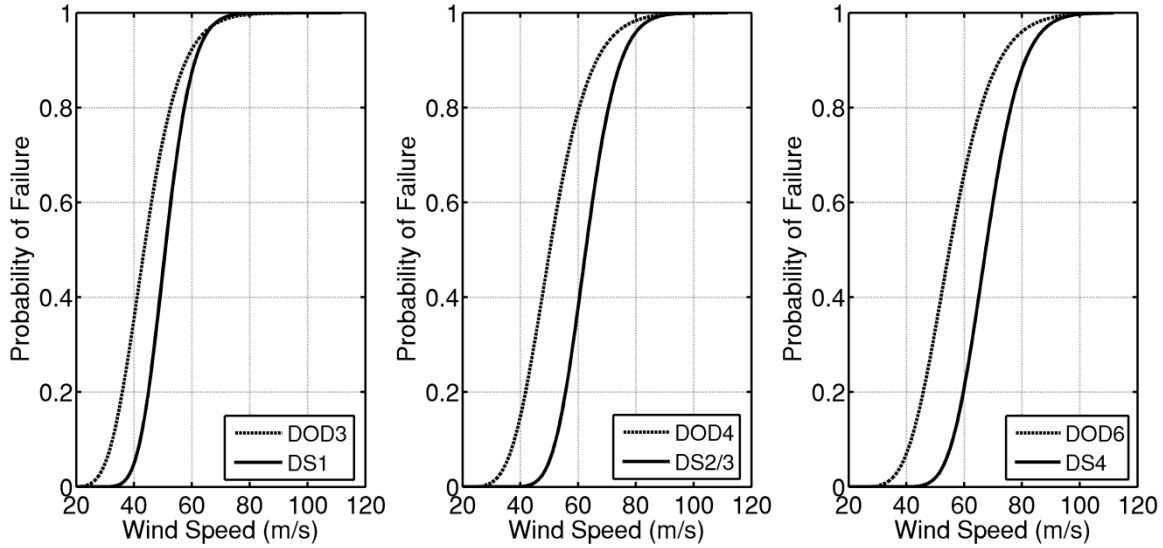

Figure 3 Comparison of empirical fragility functions based upon Degrees of Damage (DOD) to fragility functions based upon HAZUS damage states (DS). The damage descriptions associated with each level are given in Table 2.

Table 4 Summary of comparisons between empirical fragility functions and HAZUS damage functions

Limit State	DOD3	DS1	DOD4	DS2/3	DOD6	DS4
μ	4.58	4.73	4.72	4.94	4.81	5.02
σ	0.23	0.15	0.23	0.14	0.22	0.14
Median (m/s)	44.6	51.3	51.4	63.3	56.2	68.1
Load Factor[a]	1.32		1.51		1.47	

[a] Load Factor = $(\text{Median}_{DSi} / \text{Median}_{DODi})^2$

In the proposed commentary for ASCE 7-16 (Prevatt et al., 2014), voluntary provisions for designing for tornado loads are given which include a table of tornado load factors to account for potential increases in loads in tornadoes as compared to equivalent wind speeds for straightline winds. Load factors are given for both enclosed and partially enclosed buildings, for Main Wind Force Resisting System loads and Component and Cladding loads, and for Exposures B or C and D. In our study, the majority of the homes would fall into Exposures B or C, and would most likely be partially enclosed since the debris clouds associated with tornadoes often result in breaches of the envelope. For partially enclosed buildings then, designing for component and cladding loads, the proposed load factors in the ASCE 7-16 commentary are 1.05 for Exposure C or D and 1.45 for Exposure B. The load factor for Exposure B matches that of the empirical data almost exactly. The load factor for Exposure C or D may be somewhat low, but the effect of exposure on the empirical fragility functions would need to be parsed out before any definite conclusions are made.

Comparison of Empirically-Based Fragility Functions to Analytically-Derived Functions for Tornado Hazards

Figure 4 compares the fragility functions for tornadoes from Amini et al (2013) to the empirical fragility functions developed in this study. The limit state for roof sheathing is the failure of at least one roof sheathing panel, which is assumed equivalent to DOD4 from the EF-Scale. A compound fragility function was developed to represent all five building types and a sheathing fastener schedule of 8d nails at 6/12 spacing from the Amini et al (2013) study. Similarly, for roof-to-wall (R2W) connections the limit state is the failure of at least one roof-to-wall connection, assumed to be a toe-nail connection, which is deemed comparable to DOD6 from the EF-Scale. The Amini et al (2013) functions appear to be conservative from this comparison, with the analytical fragility functions nearly 20 m/s to the left of the empirical functions. In the Amini et al (2013) study, tornado loads were estimated by using ASCE 7-10 pressures for straightline winds and amplifying them using factors between 1.8 and 3.2. These amplification factors were based upon the experimental results from Haan et al (2010), which were obtained by passing a laboratory-simulated, translating vortex directly over an instrumented building model. However the building model used in this study was fully sealed, maximizing the effect of the pressure drop associated with the vortex. Typical residential buildings have inherent leakage that is likely able to

limit the effect of the pressure drop (Roueche et al., 2015; Kikitsu et al. 2011), which may explain the conservative results in the Amini et al functions. And further, some houses that incurred these damage states were outside the tornado vortex itself, and debris impacts likely breached the building envelope. Each of these factors would also limit the effects of the pressure drop and decrease the overall loads on the structure.

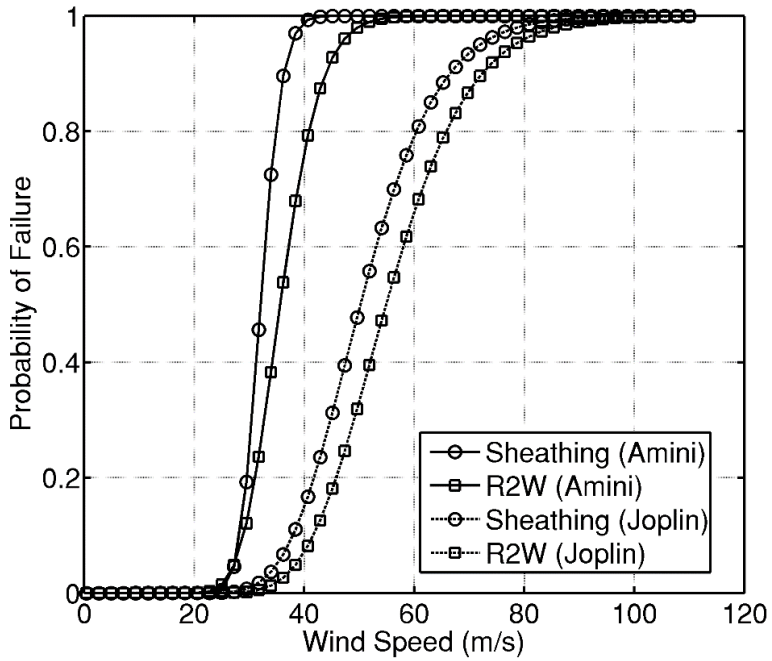

Figure 4: Comparison of fragility functions from Amini et al (2013) to empirical fragility functions from the Joplin, MO tornado. The probability of at least one sheathing panel or one roof-to-wall connection failing for a given wind speed are the limit states. For the empirical functions these represent DOD4 and DOD6 respectively.

UNCERTAINTY IN THE EMPIRICAL FRAGILITY FUNCTIONS

There are a number of sources of uncertainty in the development of the empirically-based fragility functions presented in this study, and it is important to frame the results and comparisons to other studies within the context of these uncertainties. The two primary sources of uncertainty in this work are the assigning of DOD ratings to the damaged structures during the ground survey (assessment of damage in general), and the choice of tree-fall based vortex model from which the wind speeds are sourced.

DOD ratings were assigned to the damaged structures by engineering faculty and students who were familiar with the EF Scale provisions, but with varied experience with regards to assigning DOD ratings. The ratings were assigned by teams of two to three members, requiring that a consensus be reached before assigning a rating. The damage descriptions for each DOD for DI2 are reasonably detailed, and for the majority of the homes assessed there were multiple photos of the home available from which to get a complete description of the damage sustained. Thus while there is some subjectivity to the process, there is not expected to be any large errors in DOD ratings from the review process. There are possibilities for other errors however. For example, if the available photos for each home were not adequate to capture the entire damage sustained, or if multiple homes were in a photo and the wrong one was used to assign a rating. As such, for the Monte Carlo simulations it is assumed that the DOD rating assigned has a 70% probability of being the "correct" rating, 10% probability of being either +/- 1 DOD rating in error, and 5% probability of being either +/- 2 DOD ratings in error.

Uncertainty is also expected in the wind speed estimation that is associated with each damaged home, as there were a number of wind field models that could reasonably match the observed tree-fall patterns (Kuligowski et al., 2014). There were 244 different wind field models available (3^5 or 243 assessed using full-factorial design plus the consensus model), however not all of these were equally likely, as some models fit the tree-fall and damage patterns better than others. Since neither the treefall or damage patterns necessarily provide a "correct" wind field model, each of the 243 different models were assessed for their fit to tree-fall and damage properties. For the agreement with treefall properties, the mean squared error (MSE) was calculated for each model based upon the error between the predicted damage width (DW) and damage ratios (DR) of treefall and the observed DW and DR at ten cross-sections throughout the tornado path described in Kuligowski et al. (2014). For

agreement with the damage-based wind field model (whose development was described previously in the building of consensus wind field model), the MSE was calculated the same way, using a single average cross-section at each of the ten locations. The resulting MSE for the treefall and damage comparisons were then proportionally transformed into a score such that the lowest MSE had a score of 100 and the highest MSE had a score of 0. The joint MSE score was then taken as the square root of the squares of the MSE scores associated with the treefall and damage properties. Weights for each of the 244 models were then assigned as the joint MSE score (varying from 0 to 100) divided by the sum of the MSE scores so that the weights summed to a value of one.

Monte Carlo simulation methods and weighted averages were used to assess the uncertainty of the fragility functions as illustrated in the flow chart shown in Figure 5. The wind field model, from which the maximum wind speed for a given structure is taken, was sampled sequentially. The effect of the DOD rating uncertainty was evaluated through a Monte Carlo simulation with 500 simulations for each wind field model. Within each of the 500 simulations for each wind field model, DOD ratings were assigned to the 1241 structures based on the previously described weighting function. The maximum wind speed associated with each structure was taken from the selected wind field model. The parameters of the lognormal fragility functions for each DOD were then estimated for each of the 500 simulations using the logistic regression methods described previously. With 500 simulations, variability in the lognormal fragility fit parameters x_m and β for each wind field model were limited to less than 1%. The average x_m and β for each DOD were determined for each of the 244 wind field models, and then the weighted average and weighted standard deviation was taken across the wind field models to estimate the expected x_m and β and the variability of these parameters for each DOD. The weighted averages and standard deviations of the exponential of x_m (representing the wind speed associated with 50% probability of failure, and henceforth referred to as the median wind speed) based on all 244 wind field models are provided in Table 5, along with the values of the median wind speed from the consensus wind field model.

Weighted standard deviations of the median wind speed varied for each DOD from 2.29 to 3.62 m/s, with the highest variability observed in the highest damage state, DOD 9. An uncertainty of +/- 2 standard deviations is assumed to reasonably represent the full uncertainty in the fragility functions (Figure 6). The consensus model agreed reasonably well with the weighted average model, with median wind speeds differing by no more than 7%.

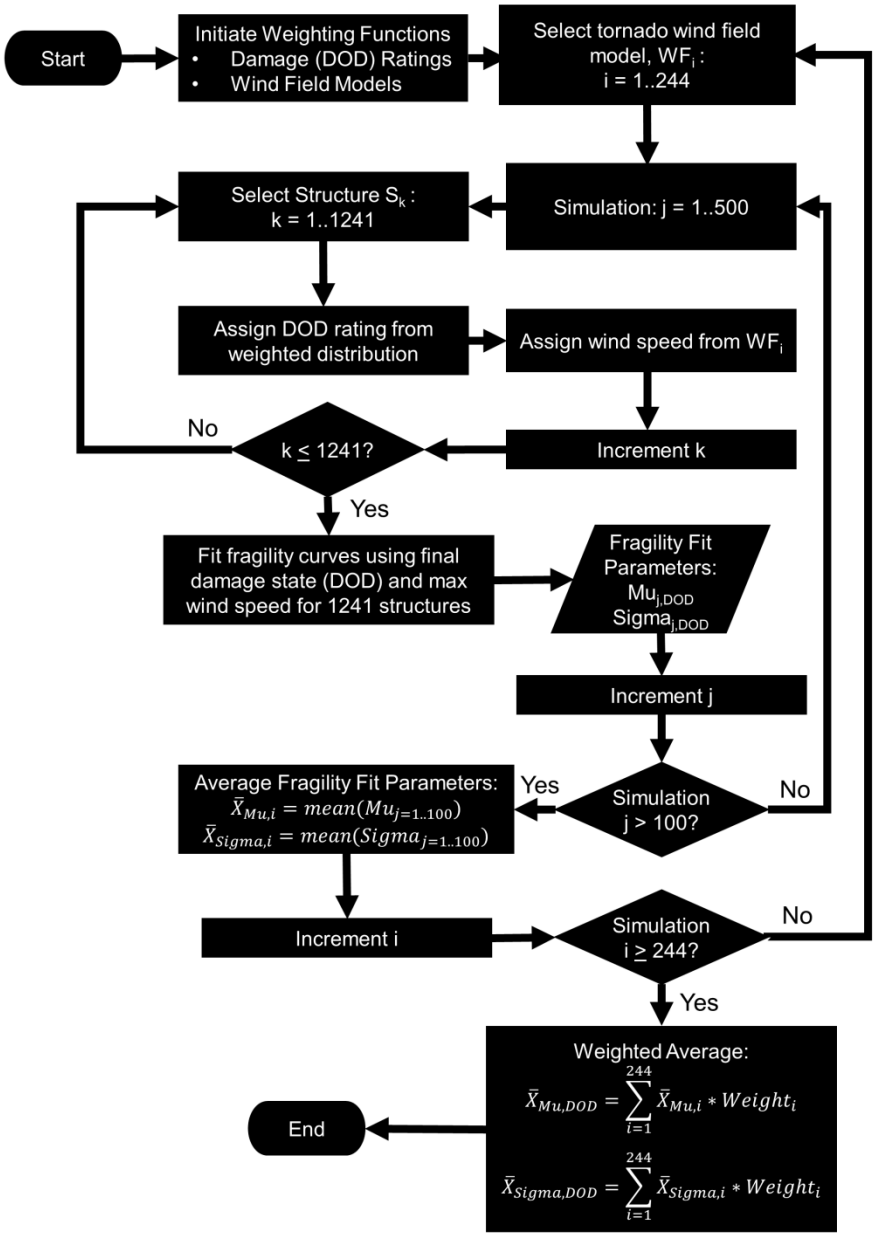

Figure 5 Flow chart of the Monte Carlo simulation used to quantify uncertainty in the fragility functions.

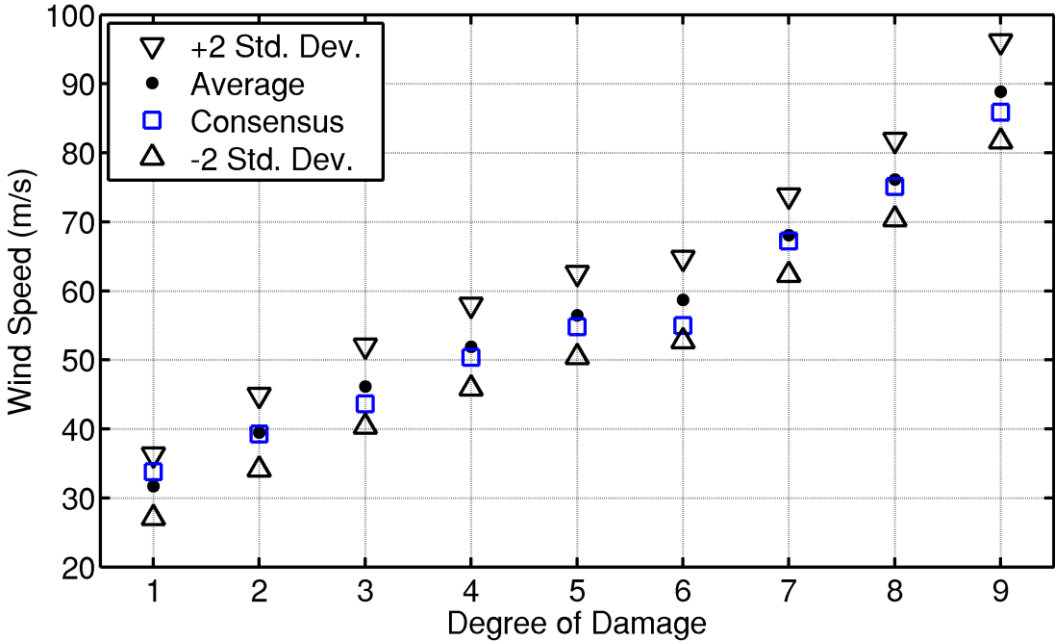

Figure 6 Uncertainty in the wind speed associated with the median probability of failure for the nine damage states considered. The solid dots represent the weighted average, and the triangles represent the weighted standard deviation, of the wind speed associated with the median probability of failure for the 244 wind field models. The square represents the median wind speed from the consensus model.

Table 5 Weighted average and standard deviation of the wind speeds associated with the 50% probability of failure for the 244 wind field models. The wind speeds associated with the 50% probability of failure for the consensus model alone are also provided for comparison.

	Degree of Damage (DOD)								
	1	2	3	4	5	6	7	8	9
Consensus Model (m/s)	33.8	39.2	43.6	50.3	54.8	55.0	67.2	75.1	85.8
Weighted Average (m/s)	31.7	39.5	46.2	51.9	56.5	58.7	68.1	76.1	88.9
Weighted Standard Deviation (m/s)	2.29	2.68	2.93	3.02	3.03	3.01	2.87	2.87	3.62
COV	7.2%	6.8%	6.3%	5.8%	5.3%	5.1%	4.2%	3.8%	4.0%

CONCLUSIONS

A consensus wind field model was developed for the 2011 Joplin, Missouri tornado using tree-fall patterns and observations of structural damage in the aftermath of the tornado. The model was used to estimate the peak wind speed at the location of 1,241 damaged structures that were rated for damage during a ground-based assessment using the Degrees of Damage (DOD) from the Enhanced Fujita (EF) Scale. The probabilities of specific damage states occurring given a certain wind speed were estimated using logistic regression methods to develop the fragility functions. The DODs for FR12 of the EF-Scale were used as the limit states in this study. The empirically-derived fragility functions were progressive in nature, with median wind speeds varying from 33.6 m/s for DOD1 (threshold of visible damage) to 85.2 m/s (all walls destroyed) for DOD9. The empirically-based fragility functions were compared to those from straightline winds provided in the HAZUS-MH Hurricane Model, with the empirically-based fragility functions from the Joplin tornado falling to the left of those for straightline winds. The resulting load factors varied from 1.32 to 1.51 which agree reasonably well with load factors proposed in the proposed ASCE 7-16 commentary. Comparisons to analytically-derived fragility functions for tornado hazards demonstrated that the assumptions of a fully sealed building under tornado loads may be overly conservative, which agrees with other recent studies (Roueche et al., 2015; Kikitsu et al., 2011; Sabareesh, 2012). Further research is needed to address uncertainties related to the fragility functions. The effects of specific factors, such as exposure, structural characteristics, and orientation of the structures, on the developed fragility functions also need to be established with further research. Although the development of fragility curves are one step in quantifying uncertainty there are many sources uncertainty in the quantities used

to develop the fragilities themselves (i.e., wind speed and damage assessment). Uncertainties in both the damage and wind speed estimation were quantified and likelihood (weighting) functions for all feasible scenarios were employed using Monte Carlo methods. Preliminary results show that variance in the statistical parameters related to fragilities are higher for higher damage states. However, COV values were relatively low for all damage states, and the lowest for higher damage states. The weighted average fragility model showed minimal differences from that of the developed consensus model, with differences in median wind speed associated with the 50% probability of failure not exceeding 7%. Although results are promising, there are many possible uncertainties that were not taken into account in this paper and are a subject for future research.

ABSTRACT

This paper follows from a series of recent studies conducted by the authors and Suncorp Group Limited which analysed insurance claims from Tropical Cyclone (TC) Yasi (Queensland, 2011) to determine typical drivers of insured loss (i.e. roofing failures, etc.) for residential housing. Using the claims data from TC Yasi, the benefits of mitigation were broadly estimated by reducing claim values based on survey results from builders and assessors on expected loss reduction in properties with mitigation features. This information was provided to Urbis (project consultant to Suncorp) for cost-benefit analysis of the projected benefits of mitigation over the next 50 years in Queensland. In this paper, the claims manipulation approach to modelling loss mitigation is presented and the results for TC Yasi are briefly discussed.

KEYWORDS

Structural retrofitting, legacy housing, insurance, claims analysis, wind resistance, Cyclone Yasi.

INTRODUCTION

Damage investigations carried out by the Cyclone Testing Station (CTS) following severe wind storms have typically shown that Australian houses built prior to the mid-1980s do not offer the same level of performance and protection during windstorms as houses constructed to contemporary building standards (Boughton and Falck, 2007, Boughton et al, 2011, Henderson et al, 2006, Henderson and Leitch, 2005, Henderson et al, 2010, Reardon et al, 1986, Reardon et al, 1999). A significant decrease in wind-induced damage to housing can be achieved if these legacy homes are upgraded to the current construction minimum. In the wake of recent severe wind events (i.e. 2014 Brisbane Thunderstorms, 2015 TC Marcia, etc.), there is a renewed vision for large-scale wind damage mitigation programs in Australia. A practical and economical retrofit program to reduce wind-related damages has the potential to dramatically reduce losses from future wind events. To inform the selection of upgrading techniques for various Australia construction types, rational modelling of the benefits is required.

METHODOLOGY

Claims data were used to estimate proportions of housing population expected to incur a certain level of loss for range of wind speeds (i.e. fragilities). Based on construction age, the policies were grouped into three "generic" house types. The analysis used the policy and claims data from TC Yasi (policies with and without claims). The use of such data for modelling does not account for ongoing incremental improvements to new buildings (i.e. changes to garage door standards, roofing tile standard, etc.) that should result in reduced damage to new housing with these components.

Approach Overview

A program was developed to perform the fragility analysis. Proportions of homes expected to incur varying levels of loss for a given wind speed were estimated for four mitigation scenarios: a) structural roof upgrading (applies to pre-60s and 1960-80s housing), b) opening protection for windows and roller doors (applies to all housing ages), c) community preparedness upgrades (applies to all housing ages), d) no mitigation upgrading.

The program was written based on five variables from the claims data including: sum insured value, claim value ($, includes null claims), loss ratio (computed as claim value / sum insured value), age of construction (in three bins: pre-1960, 1960-80s, post-1980), and estimated wind speed during TC Yasi.

From the unaltered claims data, a baseline performance case for non-mitigated structures (item d above) was generated by assuming all policies had not been upgraded (by the methods above) prior to TC Yasi. This baseline case was established by quantifying the proportion of homes falling within four loss ratio groups (0, 0-0.1, 0.1-0.5, >0.5) for each of the three housing age groups and wind speeds ranging from 22-70 m/s.

The effects of mitigation were simulated by reducing claim values in the original data set, and re-evaluating proportions of homes falling into the various loss ratio groups. The criteria for modifying claim values were dependent on the type of mitigation action, age of construction, estimated wind speed, and loss ratio (as an indication of more/less extreme damage modes). The amount of reduction for each mitigation action was estimated from survey of builders and assessors in Queensland. The criteria and assumptions used for applying modifications are detailed in the following sections.

Statistical assumptions for the proportions of claims modified by (e.g., the proportions of policies with avoided damage) were estimated based on damage modes extracted from assessors' reports (Table 1) from Cyclones Yasi and Larry (Smith and Henderson, 2015). The number of available reports on claims with high loss ratios was limited, and is noted as a source of uncertainty in the extrapolation of statistics from these samples to larger claim sets in the fragility analysis. All adjustments that result in claim values below zero were assumed equal to zero. Storm tide damaged properties were not considered.

Table 1 Damage modes (by word mention) from claim assessor's reports for Cyclones Yasi and Larry grouped by loss ratio and analysis region (Smith and Henderson, 2015).

Loss Ratio	Cyclone/ Region	# of Claims	Tree	Roof	Window	Ceiling	Roller Door	Water Damage
0-.09	TC Yasi/ Townsville	157	21%	31%	15%	17%	2%	30%
0.1-.49	TC Yasi/ Townsville	9	22%	89%	33%	67%	0%	78%
0.1-.49	TC Larry/ Innisfail	43	14%	91%	67%	56%	16%	88%
>= 0.5	TC Larry/ Innisfail	13	15%	100%	77%	69%	31%	92%
>= 0.5	TC Yasi/ N. QLD	13	31%	100%	85%	100%	8%	100%

Structural Roof Upgrades

Damage to the roofing structure is a well-known driver of loss during cyclones and other high-wind events (Figure 1). In addition to direct loss, roofing damage often leads to water ingress and additional wind-borne debris. The basic engineering design principles for wind loads on roofing structures require that each element of the system (i.e. cladding, battens, and rafters) be connected to each other and to the foundation of the structure through supports in the wall system. Roofing failures generally occur when one or more of the connections in the system fails. Contemporary housing is constructed with stronger connections than legacy housing (pre-1980s) due to enhanced building standards. Therefore, modelling for structural roof upgrades was focused on pre-1960s and 1960-80s housing as follows: a) strapping at batten/rafter and ridge connections (pre-1960s and 1960-80s), b) collar ties between rafters (pre-1960s), and c) vertical tension members between rafters and ceiling joists (1960-80s).

Figure 1 Wind-induced roofing failure due to poor framing connections in Yeppoon, Australia following Cyclone Marcia (2015)

In order to quantify basic estimates for the performance increase achieved by structural roof upgrading, simple structural analysis models were generated for pre-1960s and 1960-80s typical roofing shapes using a structural engineering software package (SPACE GASS). Using SPACE GASS, before and after upgrade versions of a simple two-dimensional roof systems were subjected to wind uplift loads based on approximations from AS/NZS 1170.2 (Standards Australia, 2011). As severe roofing failures typically occur due to failed connections (e.g., batten/rafter, ridge, etc.), the upgrades were designed to disperse loading throughout the roofing structure and down to the foundation supports, thus reducing the concentrated loads at critical connections. The upgrades also strengthen the load capacity of critical connections (via strapping). The combination of these effects creates a situation where the strength of connections are increased and the load they are required to resist is decreased.

Pre-1960s roofing structures (Figure 2) generally consist of high-slope, pitched frame hip construction. The mitigation upgrades selected for this roofing type include additional strapping at batten/rafter and ridge connections as well as collar ties to join rafters. Roofing structures from the 1960-80s generally consist of low-slope, pitched frame gable construction (Figure 2). The mitigation upgrades selected for this roofing type include additional strapping at batten/rafter and ridge connections as well as tension members to join rafters down to ceiling joists.

Figure 2 Typical Pre-1960s (left) and 1960-1980s (right) residential structures in Queensland, Australia

To estimate the performance benefits of upgrading, the loads at the rafter/batten interface (a critical connection for wind uplift) were estimated for a range of wind speeds (10 m height, suburban terrain) both before and after the upgrades using SPACE GASS.

In order to simulate the effects of these upgrades during TC Yasi, assumptions were made about the likelihood of roofing failure and severity of loss, based on the wind speed and loss ratio of policies in the data set. These assumptions were used to form criteria for modifying policy claim values based on the estimated loss mitigation resulting from the upgrade. From Table 1, the following statistical assumptions were made for claims with pre-1960s and 1960-80s housing:

- 30% in the 22-40 m/s wind band and the <10% loss ratio band had minor roofing damage
- 40% in the 40-47 m/s wind band and the <10% loss ratio band had minor roofing damage
- 50% in the >47 m/s wind band and the <10% loss ratio band had minor roofing damage
- 90% in the 22-47 m/s wind speed bands and the 10-50% loss ratio band had moderate roofing damage
- 100% in >50% loss ratio band had severe roofing damage

From these assumptions, and correspondence with claims assessors in Queensland, the criteria for reducing claim values in the data set were established. Specifically, the claim reduction value ($) and the proportion of policies it applies to were estimated for various combinations of wind speed and loss ratio (Table 2). For example, if the wind speed and loss ratio associated with a claim was 45 m/s and 30% respectively, the claim would be reduced by $30,000. This adjustment would have been made to 90% of claims that fit these criteria. Building code changes in the 1980s emphasized a continuous load path from the roof structure to the foundation, significantly decreasing the risk of severe roofing failures. Therefore structural roofing upgrades were applied only to homes constructed prior to 1980.

Table 2 Applied criteria for reducing claim values based on structural roofing mitigation upgrades

Wind Speed (m/s)	Loss Ratio (%)	Mitigated Loss ($)	Proportion of Claims Modified
22-40	<10	2,000	0.30
	10-50	25,000	0.90
	>50	70,000	1.00
40-47	<10	2,000	0.40
	10-50	30,000	0.90
	>50	100,000	1.00
>47	<10	2,000	0.50
	10-50	70,000	0.90
	>50	150,000	1.00

The roofing upgrade solution was presented in "scenario" format to assessors, builders and engineers in Queensland to provide cost estimates for implementation in an undamaged structure (i.e. prior to a severe wind event). The upgrade scenario included replacement of the metal cladding and then strapping of the rafter to top plates. A rectangular housing plan of 12 m x 8 m was assumed with a hip roof 22.5 degree slope. The costing scenario included battens to be strapped or screwed to rafters, collar ties installed for each rafter pair, strapping at rafter to top plate connections, and strapping struts at ridge to hip beams down to ceiling joists. The estimated cost varied from $30,000 to $53,200.

Opening Protection

Damage to openings in the external shell of a building (e.g., windows, roller doors, etc.) during cyclonic or severe storm events often exposes the interior of the home to both wind and water ingress. Wind flow into the building can create positive internal pressure, adding to the overall loads on cladding elements (i.e. roofing, etc.) and increasing the likelihood of roofing or other failures.

Water ingress into the building can cause extensive damage to building contents and is well-known to increase insured losses. Opening protection is focused on reducing the likelihood of these damages by protecting vulnerable openings (i.e. windows, roller doors) from wind-borne debris impact and pressurized water ingress. The types of upgrades that can be used to protect windows differ from those of garage doors and thus the two upgrades are discussed separately below.

Garage door upgrades

Garage door failures generally occur due to loads generated by wind-induced pressures (Figure 3). At lower wind speeds, damage is typically limited to buckling failure. However, at higher wind speeds buckled doors can become dislodged from tracks, causing additional damage to the surrounding structure and becoming wind-borne debris in some cases. To mitigate these damages, the upgrade model for garage doors includes aftermarket bracing to restrain the door from buckling in either the inward or outward direction.

Figure 3 Wind-induced garage door failure due to poor bracing in Yeppoon, Australia following Cyclone Marcia (2015)

Based on consultation with representatives from the building industry in Queensland, it was estimated that ~20% of pre-1960s and 1960-80s housing is equipped with a roller door. Alternatively, ~90% of post-1980s housing are equipped with a roller door. Therefore, the benefits of garage door upgrades were applied to these proportions of claims for each age group. For example, of all the claims for post-1980s housing, a random subset including 90% of those claims was selected, to which the mitigation criteria in Table 3 were applied. From Table 1, the following statistical assumptions were made to form the loss reduction criteria:

- 2% in the low loss ratio band (0-10%) had roller door damage
- 15% in the medium loss ratio band (10-50%) had roller door damage
- 30% in the high loss ratio band (>50%) had roller door damage

Table 3 Applied criteria for reducing claim values based on roller door mitigation upgrade

Wind Speed (m/s)	Loss Ratio (%)	Mitigated Loss ($)	Proportion of Claims Modified
22-40	<10	1500	0.02
	10-50	1500	0.15
	>50	1500	0.30
40-47	<10	3000	0.02
	10-50	5000	0.15
	>50	5000	0.30
>47	<10	3000	0.02
	10-50	8000	0.15
	>50	10000	0.30

The costs associated with roller door upgrading were estimated at $300 for aftermarket supports (on a per house basis) from discussions with product manufacturers.

Fenestration upgrades

Fenestration-related damage modes may include direct damage from wind-borne debris (Figure 4), which can also increase the likelihood of roofing failure from internal pressure increases, and water ingress damage to the

building walls and contents from poor window casing or sealing performance. The primary damage mode varies by wind speed, the amount of wind-borne debris or rain, etc.

Figure 4. Wind-borne debris failure of fenestration without opening protection in Yeppoon, Australia following Cyclone Marcia (2015)

For modelling, the fenestration mitigation upgrade was assumed to effectively reduce the loss associated with each of these damage modes, the positive benefits of which increase with wind speed. The upgrades include plywood covering (homeowner installation) and commercially available shuttering systems. Table 4 shows the applied criteria for fenestration upgrades in the model. These upgrades were applied to housing of all ages. From the Table 1, the following statistical assumptions were made to form the loss reduction criteria:

- 15% in the 0-10% loss ratio band had fenestration related damage
- 50% in the 10-50% loss ratio band had fenestration related damage
- 80% in the >50% loss ratio band had fenestration related damage

Table 4 Applied criteria for reducing claim values based on fenestration mitigation upgrades

Wind Speed (m/s)	Loss Ratio (%)	Mitigated Loss ($)	Proportion of Claims Modified
22-40	<10	1,000	0.15
	10-50	2,000	0.50
	>50	5,000	0.80
40-47	<10	2,000	0.15
	10-50	5,000	0.50
	>50	10,000	0.80
>47	<10	5,000	0.15
	10-50	10,000	0.50
	>50	15,000	0.80

The costs associated with window upgrading were estimated (on a per house basis) from correspondence with building contractors in Queensland. To establish a single costing value, each home was assumed to have eight windows with upgrades being applied to all windows. It was assumed that the number of windows, window performance, and cost of upgrading were independent of the building age or construction type. The two upgrading scenarios (plywood vs commercial systems) were assumed to have the same performance benefits

once installed. The costing estimates were $1360 for plywood shutters and $3200 for commercial window protection shutters/screens.

Community Preparedness

From the Smith and Henderson (2015), minor claims represent 86% of the total number of filed claims for Cyclone Yasi in the North Queensland Coastal Region. These minor claims typically include damage shade sails, minor water ingress, minor debris damage, etc.

Community education/awareness campaigns, with emphasis on cyclone preparation (e.g., removing shade sails, pruning trees, removing debris and unsecured items from the yard, etc.), may be an effective method of reducing the frequency of claims of this size. Past experience suggests that 100% implementation of these "preparation upgrades" is unlikely, and actual implementation rates will be much lower, depending on the method of dissemination adopted by the community outreach campaign. Therefore, for modelling purposes, it was assumed that the positive benefits of these upgrades were realized in only 30% of claims. The magnitude of benefit was determined by consultation with builders and assessors in Queensland and assumed to increase with loss ratio as $2000, $3000, and $5000 for <10%, 10-50%, and >50% respectively. The cost estimate for a community awareness campaign was assumed at $1 million annually over the 50 year projection period used by Urbis.

RESULTS

The outputs of fragility modelling for simulated mitigation were based exclusively on claims data from TC Yasi and are likely to vary significantly for future events. The fragilities for this event and the estimated cost of selected upgrades were provided to Urbis for cost-benefit modelling of the projected impacts of mitigation over the next 50 years in Queensland. The authors refer readers to the Urbis report (Hutley and Batchen, 2015) for results of the cost-benefit analysis. The results for TC Yasi are discussed briefly in this section. Figure 5 shows the effect of TC Yasi claims data modification for simulated structural roof upgrading in pre-1960s housing. The effect of this modification was most significant in claims with higher loss ratios as expected with the criteria in Table 2. There were 8,089 homes constructed prior to 1960 in the data set, 1,911 of which filed a claim. The true net loss for this group of policies was $45.5 million after TC Yasi. The simulated roof upgrades produced a 47% reduction, yielding net loss of $24.1 million.

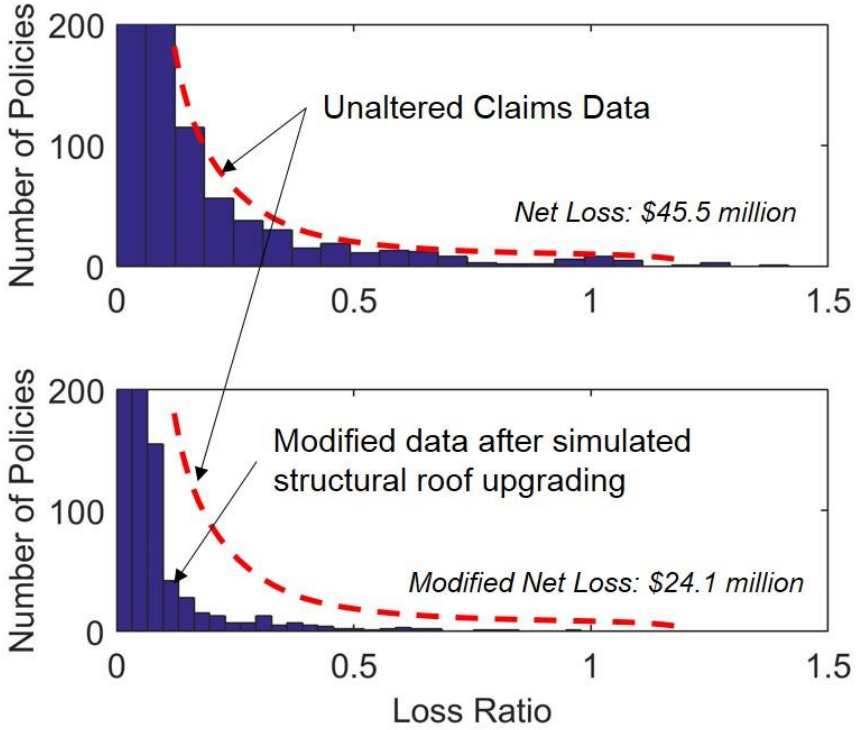

Figure 5 Claims data with and without the simulated effects of structural roof upgrades from Tropical Cyclone Yasi (2011) for residential housing constructed in the Queensland coastal region prior to 1960

There were 14,315 homes constructed between 1960 and 1980 in the data set, 3,967 of which filed a claim. Figure 6 shows the effect of structural roof upgrades on these policies. The trend is very similar to that of pre-1960s housing. As expected, the effects the simulation are most significant in claims with higher loss ratios. The net loss for these policies was reduced from $81.5 million to $44.5 million, a 45% decrease.

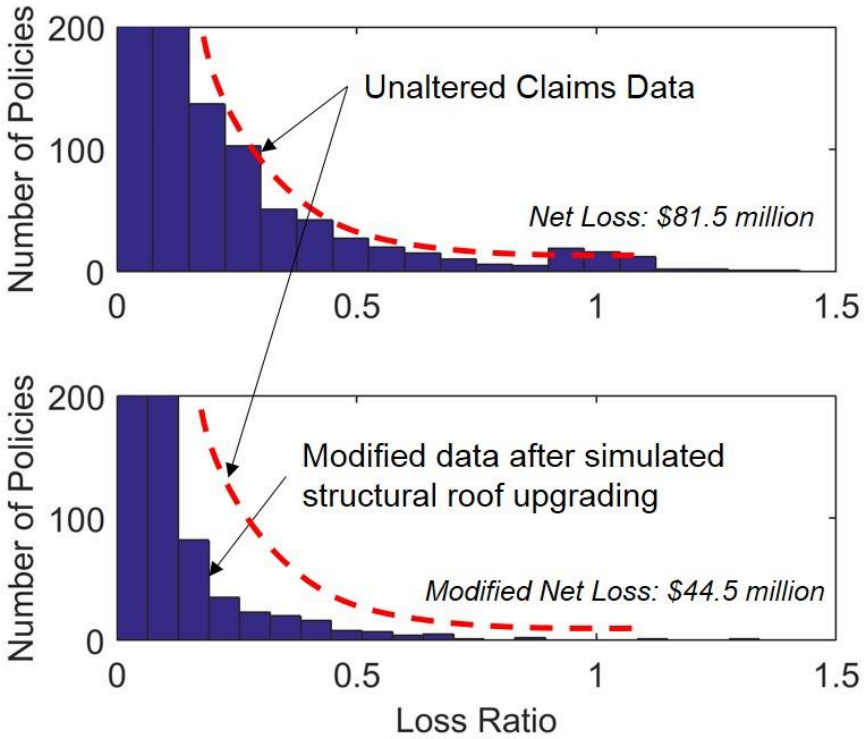

Figure 6 Claims data with and without the simulated effects of structural roof upgrades from Tropical Cyclone Yasi (2011) for residential housing constructed in the Queensland coastal region from 1960 to 1980

In addition to roof upgrades, the effects of opening protection and a community preparedness campaign were also simulated. These simulations were applied to all ages of housing in the data set. For all housing constructed prior to 1980, opening protection and community engagement yielded net reductions in loss of 7% and 3% respectively. There were 32,478 homes constructed after 1980 in the data set, 7,292 of these filed a claim. Despite damage severity being significantly lower for these contemporary homes, the net contribution to loss was $115 million. This loss was reduced by 5% and 3% in the simulations for opening protection and community engagement respectively.

DISCUSSION

Mitigation pricing and associated reductions in loss for cyclone intensities were estimated from claims data and estimates from assessors, builders and manufacturers. The considered upgrades included:

- Retrofitting to roof structure for pre 1980s houses (upgrading roof framing connections)
- Protection of windows and doors to reduce wind driven rain ingress and reduce likelihood of a windward dominant opening
- Community awareness measures (effective ongoing maintenance of house, dismantle for shade cloth awnings, cleared gutters, pruned trees, appropriate tie down for garden sheds, etc.)

The fragility models be developed further to include probabilistic components for wind speed, component capacities, and damage/loss of building elements. The resultant models should validated with other cyclone loss data and include other loss reduction measures such as ongoing improvements in building codes (e.g. changes to garage door standard following Cyclone Yasi).

AN EVENT-BASED MODELLING APPROACH FOR ASSESSING DOWNBURST RISK TO STRUCTURES

Matthew Mason [1*]
[1] School of Civil Engineering, University of Queensland, Brisbane, Australia.
*Email: matthew.mason@uq.edu.au.

ABSTRACT

This paper proposes a stochastic event-based modelling approach for estimating downburst wind hazard. Unlike existing models it makes use of large scale atmospheric information to build upon observational records so that a broad range of input model parameters can be generated. Coupling this information into such a model means it may be applied in regions where no observational records currently exist, or they are of poor quality. Progress towards full model development has thus far focused primarily on the methodological approach required to couple atmospheric and observational data so that input model parameters can be developed. An example of this coupling is provided for the south east Queensland region of Australia, and estimates of annual downburst-producing storm counts are generated. This example shows the proposed model can reasonably replicate historic trends in mean annual event counts, but was unable to capture the full inter-annual variability in these counts. Future work will refine this approach and continue to develop the full hazard/risk model.

Downburst, wind, reanalysis, wind risk, wind hazard.

INTRODUCTION

Localized high intensity wind storms (downbursts) damage buildings and infrastructure throughout the world every year. Transmission line networks are particularly vulnerable to this type of wind storm and numerous large-scale failures have been reported (Letchford and Hawes 2000, CIGRE 2012). Figure 1 shows an example of such a failure (CIGRE 2012). In fact, downbursts, as opposed to larger scale cyclones, govern the wind statistics of importance for the design of a range of structures in many parts of the sub-tropical world (Holmes 2002). Unfortunately though, given the small spatial and temporal scale of these wind storms most measurement station records do not capture enough events to allow reliable extrapolation of wind statistics out to return periods of interest for structural design. A similar problem exists for extrapolation of tropical cyclone (hurricane, typhoon) wind statistics, but for these storms simulation-based methods have been utilized to better understand their low probability wind characteristics (e.g. Vickery et al. 2009, Yeo et al. 2014). It is proposed that similar methods could be employed to reduce (or simply quantify) the uncertainty in estimates of downburst wind hazard and risk.

In this paper an event-based modelling approach is proposed as a tool for improving understanding of wind hazard posed by severe downburst wind storms. Techniques used for tropical cyclone wind hazard estimation are modified here for application to downburst events. While many of the same concepts can be applied, downbursts are spatially and temporally quite dissimilar and must be treated differently in some respects. An example of such a difference is the sourcing and reliability of baseline data upon which any model could be built. Little information is often available for describing a region's downburst climate, and even for areas where this information is available it is often subject to observational or methodological biases that must be removed from records. As such a greater reliance on inference is required for model parameter development.

The proposed downburst hazard assessment methodology is based on event-based simulation of each storm's wind field. Unlike existing models, a method for coupling simulations with large-scale climate information is proposed so that assessment can be carried out in regions where data records are poor or non-existent. Each component of the proposed modelling is discussed and their relative strengths and challenges described. Progress to date has focused on developing a method for coupling climate information with event observations and will be discussed in some detail. Results for the south east Queensland region of Australia will be used as a case study.

Figure 1 Cascading failure of transmission lines during localized wind storm, Spain (CIGRE 2008).

BACKGROUND

Downburst Risk Models

A limited amount of research has been undertaken on probabilistic or stochastic modelling methods as applied to downburst winds. Li (2000) developed a stochastic model that simulated the interaction of downbursts with transmission line segments. Each downburst was simulated as a triangular pulse signal and required information on downburst frequency, wind speed and path length to be input. In doing this Li (2000) highlights that the difficulty in stochastic modelling of these events lies in the fact that downbursts occur (at any given point) randomly in time, and given their small spatial scale, may not load the structure or system of interest; even if only separated by small geographic distances.

Oliver et al. (2000) also developed a model for assessing risk to transmission line networks. Instead of considering the downburst as a temporal pulse though, they simulate it as a 2 dimensional spatial 'footprint' as defined by Holmes and Oliver (2000). This has the benefit that it allows the spatial dimensions of the downburst to be considered, but does require this additional layer of information to be fed into the model. Oliver et al. (2000) also provide a list of assumptions that simplify their model, negating the need for a complete understanding of all downburst characteristics. These simplifications have made their model widely useable and as such has been utilized by the transmission line industry (CIGRE 2008).

Letchford and Hawes (2000) applied the Oliver et al. (2000) model to undertake a risk assessment of the transmission network across Queensland. As a simplifying assumption they imposed a conceptual failure velocity for each transmission tower of 35-45 m/s. By assessing exceedences of this threshold the failure probability of different parts of the network could be assessed. In doing so they found failure estimates far exceeded the number of observed failures, but did find that the relative risk was accurately simulated. The authors suggest the reason for the overestimation of absolute failure risk is due to conservative estimates of extreme wind distributions within the model, as well as a general conservative design and construction process within the transmission line industry.

Harper and Callaghan (1998) also developed a downburst risk model for the south east Queensland region, but in their case it was for use by the insurance industry. This model conceptually appears to be similar to that of Oliver et al. (2000), but includes a time component to the downburst events. Additionally, multiple downbursts can be simulated for each event; as often occurs in reality. Comparison with wind records at the Brisbane Airport show good agreement with modelled results, and given the extensive effort the authors put into accurate characterization of the regional climatology, the positive comparison highlight the importance of using high quality meteorological information to inform model development.

Assessing the wind climate in Brazil, Ponte and Riera (2010) developed a Monte Carlo based approach for simulating downburst wind events using the wind field model described in Ponte and Riera (2007). Similar to the Harper and Callaghan (1998) model they sample a range of storm parameters that influence the resultant surface wind conditions and simulate a large number of plausible storm events impacting a given region over a predefined time period. Comparing output from their model with observational data at two sites in Brazil they find reasonable replication of wind speed distributions. However, given many of the important storm variables (and their distributions) used to drive their model are only approximated, the resultant wind climate is not well

enough replicated to make it suitable for structural design or risk assessment application without further refinement.

Relationship between Environmental Parameters and Severe Storms

The occurrence of downbursts is generally poorly recorded. Some information can be inferred from anemometer records (Lombardo et al. 2009), but extraction is not straightforward and is only available (in a statistical sense) when an anemometer has been operational for an extended period of time. This is not a problem confined to estimation of wind statistics, most attempts at estimating any severe storm climatologies (e.g. tornado, hail) run into observational bias issues and inference or smoothing techniques are required to arrive at a solution.

Brooks et al. (2003), based on weather forecasting practice, proposed a method that uses large scale weather information output from global reanalysis models (e.g. Dee et al. 2011) to assess the relative frequency of severe storm activity across large areas. In essence they used spatially and temporally uniform (globally) historical reanalysis databases to develop pseudo severe storm climatologies. This was done by looking back through the simulated climate records to find times when large scale climate indicators suggestive of storm activity were present. Typically the joint occurrence of both high atmospheric instability and high values of shear were considered necessary for storm development, and so convective available potential energy (CAPE) and atmospheric wind shear have typically been used as indicators. Numerous researchers have since used similar techniques to assess severe storm climatologies across broad regions to assess spatial, cyclic and long-term occurrence of these events (e.g. Allen et al. 2011, Brooks 2009, Grunwald and Brooks 2011).

While this approach is useful for application to estimating the relative frequency of downburst events, it must be modified to account for the fact that not all days when the environment for storm activity existed led to downburst event/s. This can be done by 'training' the approach in regions where high fidelity observational records exist, so that the relative risk assessment approach discussed above can be used in an absolute sense. By doing this, large scale climate information previously unused by engineering-based risk models can be fully coupled into these assessments. This is useful not only for event frequency information, but supporting data for estimates of storm intensity and tracking can also be drawn from reanalysis data, as will be discussed in section 3.1.

PROPOSED MODELLING APPROACH

The proposed approach for modelling downburst wind hazard follows that used by researchers for assessing tropical cyclone wind hazard (e.g. Vickery et al. 2009, Yeo et al. 2014). It conceptually divides the modelling process into pre-, model and post- modelling tasks, with the former designed to estimate the climatological information needed to inform the model itself, based on the coupled reanalysis-observation data approach, and the latter encompassing a statistical analysis and validation of the model output. The sequential set of modelling steps required for assessing the downburst hazard in a given area are:

1. Pseudo-climatology development (Pre)
2. Event genesis modelling (Model)
3. Event/downburst track modelling (Model)
4. Wind field modelling (Model)
5. Statistical analysis and validation (Post)

Each step is described further in the following sections, with the results of work carried out towards step 1 discussed in the Results section of this paper.

Pseudo-climatology Development

Due to the lack of reliable climate information, a pre-modelling step is required to develop the pseudo-climatology from which statistical parameters necessary for modelling can be drawn. Global reanalysis data is coupled with high fidelity observational records to hindcast a pseudo-downburst climate for a given period of time. Probabilistic estimates of annual (or sub-annual) event frequencies, track direction, forward speed and downburst intensity can be drawn from this pre-modelling step to inform steps 2 and 3.

The approach for estimating downburst event frequencies is based on the concept that the probability a downburst will occur can be conditionally assigned based on the presence of large scale environmental conditions. These conditions may be as simple as a surface wind speed above a defined threshold, or as complex as integrals of multiple variable through the atmosphere. However, as discussed earlier, the most widely used predictors are atmospheric instability and vertical wind shear (i.e. the difference between winds at ground level

and those at an elevation in the atmosphere). For this paper two commonly used versions of these predictors (indices) are used, Lifted Index (LI100) and Deep Vertical Wind Shear (DVWS) (Mason and Klotzbach 2013).

To build the pseudo climatology, dates and times of downburst observations within a given spatio-temporal domain are extracted and the associated atmospheric indices calculated using the reanalysis database. By doing this a bivariate probability density function (or frequency histogram) can be developed describing the environments conducive to downburst occurrence. Dividing this by the parent histogram for that region then allows an empirical estimate of the probability an event will occur conditional on the joint occurrence of LI100 and DVWS. These probabilities allow estimates of the mean annual number of downburst events given the joint occurrence of variables in the parent reanalysis database. This can be done for a broader area and longer time period than observations alone would allow. Additionally it potentially allows estimates of future hazard using climate change projections.

In addition to calculating indices, storm movement can be inferred using known relationships with upper level winds sourced from the reanalysis database. When coupled with observations, this data can be used to determine conditional probabilities (based on the event occurring) for storm direction and movement speed. These probabilities must be tied back to the information within the parent distribution so that inference can be made on these variables in the absence of observational data.

Maximum downburst intensity is more difficult to estimate. Initially, however, the approach taken by other researchers (e.g. Allen et al. 2011) may be a sensible start. Given there is great uncertainty in estimates of storm maximum wind speeds, even for well recorded storms, intensity can be classified into two sub-categories, severe and significant severe. This is done based on the exceedance or not of a given threshold (typically around 34 m/s) by the recorded or estimated maximum downburst wind speed. This allows for events where damage survey work has determined stronger wind speeds than recorded at anemometer sites to be more suitably classified. Some judgement about the distribution of events within each of these subsets will still be required, but it does allow more information stored within the reanalysis data to be drawn out than simply assuming a distribution of maximum intensities for the entire family of downbursts. Globally there is still a lack of understanding about the distribution of maximum wind speeds for a family of downburst events and further research is required.

As a final point, all the analysis described in this section should be done on a sub-annual basis. Downbursts occur under different meteorological conditions throughout the year and as such the indices that best estimate their occurrence will also differ on these timescales.

Event Genesis Modelling

Using event frequency information derived from step 1, generation of events within a defined spatial domain can be simulated assuming a Poisson process. A similar approach to this was used by Haigh et al. (2014) (and many others) for modelling tropical cyclone occurrence around Australia. For estimating long-term wind statistics this is a suitable approach. However, if the inter-annual variability is of importance (e.g. for considering fluctuations in loss statistics), clustering of events (i.e. non-independence) may also need to be considered. Analysis of the independence of events and the suitability of a Poisson sampling process can be done, again, by analyzing the occurrence of indices (or joint indices) in the reanalysis database. Allen and Karoly (2013) undertook a similar assessment to ascertain the role of ENSO on the occurrence of severe storms in Australia, and a similar procedure could be followed here.

Depending on the way a genesis model was spatially developed, some weighting of event genesis location may be required. This would be required because there exist non-meteorological features, such as topography, that play an important role in determining where severe storms generate and track. Research is again needed to determine how topography (likely coupled with wind direction and moisture content) influences genesis, but empirically the observational set of downbursts discussed earlier could be coupled with radar analysis, topographic, and reanalysis data to inform this relationship.

Event Track Modelling

To a first approximation, bulk storm movement is linear. Given downbursts are relatively short lived, their tracks can also be approximated as linear segments. Fujita (1985) shows that this is not always the case, but for the current modelling procedure it is considered representative. This also follows the inherent assumptions made by Holmes and Oliver (2000) and Oliver et al. (2000) when deriving and applying their downburst wind footprints. Following, given the movement of a storm is predominantly driven by bulk winds in the upper

atmosphere (though systematic deviations do occur), these data should be drawn from a reanalysis database to inform model development. Some research will be required to determine what subset to use, but as with event frequency this could be conditioned on the occurrence of bulk indices (or joint indices).

A further point to consider is the occurrence of multiple downbursts during a single severe storm event. This is not uncommon and Harper and Callaghan (1988) showed that in the Brisbane region (Australia) up to five individual storm systems were often identified on days with severe storm activity. This process will need to be captured and research is underway to determine how this could be achieved.

At this point a random (or conditional) sampling of track variables through a stochastic procedure similar to that used by Li (2000) can be used to develop a stochastic set of representative downburst tracks. Track number, length (which will be a function of forward speed and intensification/decay variables) and direction will need to be simulated.

Wind Field Modelling

A number of existing empirical/analytical downburst wind field models exist (e.g. Abd-Elaal et al. 2013, Chay et al. 2006, Holmes and Oliver 2000, Vicroy 1991). Each can generate a maximum wind speed footprint or simulated spatio-temporal wind speed time histories for wind load/risk calculations. All simplify downburst outflow physics to some extent and poorly simulate the time-varying changes in outflow structure (Mason et al. 2010b). From a statistical hazard modelling stand point this may not be a significant issue, but careful consideration is required when assessing the loads these events apply to structures. Whether a more complex wind field model would significantly change (mean) model results is unclear, but is an area that must be explored.

A further point to consider with wind field modelling is the way downbursts interact with topography and terrain. This differs from the interaction that occurs within traditional wind fields (Mason et al. 2010), and must be considered within any model. This difference is not restricted to changes in topographic amplification or the mechanical influence of surface roughness, but is routed in the types of structures that such a downburst risk model may be required to analyze. For example, probably the most common use of downburst risk models to date is for the analysis of risk to transmission line systems. Many of these are embedded within surrounding terrain features, such as shown in Figure 2. This siting completely changes the loads seen by these structures and unless considered suitably the resultant risk to such a line system would be grossly incorrect.

Figure 2. Example of structure embedded within terrain. http://www.foresthiker.com/wp-content/uploads/2011/02/bpa-lines.jpg.

Accounting for all these features, a representative wind field must be assigned to each simulated track within the stochastic event set. Depending on the final use of these data this could be done through a maximum wind speed footprint, or as a series of geo-spatial wind speed time histories (or the wind field model variable to generate these) that describe the three dimensional evolution of each simulated storm. The former would be adequate for development of wind exceedance probability curves, but the latter may be required for performance based analysis of structures (or networks) or generation of potential damage statistics.

Statistical Analysis and Validation

For a given region a stochastic set of representative storms, track and footprints should be generated for a period of, say, 10,000 years. Given the length of the synthetic record, typical statistical analysis techniques can be used to analyze downburst wind hazard at individual points, or over a linear or regional area. Simple structural risk modelling could be done if vulnerability could simply be defined by a threshold wind speed, but further research developing appropriate load/response vulnerability relationships would be recommended if extending the proposed model to that point

As with all modelling work, validation is essential for ensuring the integrity of output. The simplest way this can be done is through comparison with existing wind records. Some complexities exist when doing this in that only the wind gusts generated by downbursts must be extracted from parent wind records. This is not always straightforward but must be done for any validation exercise to be useful. Of course only the low return period range of the curve will have data to validate against, but it is important to at least ensure that this regions is well replicated. Through this type of validation Harper and Callaghan (1988) showed the ability of a modelling approach similar to that proposed here to generate wind statistics that fit observed data with small overall errors.

RESULTS

To date research has focused on the development of a methodology for estimating pseudo-downburst climatologies (step 1). The aim of this research was to identify the most appropriate indices to use for model development and generate regional hindcasts. The latter would allow the assessment of the expected average annual number of downburst generating storms within a defined area (this is not necessarily the number of downbursts). For this paper, results for the greater south east Queensland (SEQ) region are presented.

Following the procedure outlined earlier, observational data and reanalysis fields were extracted from the Bureau of Meteorology's Severe Storm Archive and the ECMWF ERA-Interim databases (Dee et al. 2011), respectively. This was done for the 1989-2011 period, which was shown to be stationary through a change point analysis. A wide range of climate indices were calculated using the extracted reanalysis data and the respective predictive skill computed by assessing the separation between the joint density functions for those time steps when downbursts occurred and those when they did not. Figure 3 shows these data plot for SEQ when using LI100 and DVWS as variables. This combination was shown to perform well for the SEQ region and was subsequently used to develop the hindcast for this region.

To determine the conditional probability of event occurrence in the two-dimensional LI100-DVWS phase space, the bivariate event frequency distribution (Fig. 3) was divided by its parent. Figure 4 shows the resultant probability surface for SEQ during the warm season. The same solid grey line as used in Figure 3 is shown for reference. It is immediately clear that the probability a downburst will occur given any combination is low. This follows similar findings by Brooks (2013) and reflects the inability of a simple two variable analysis to capture all the complex physics required to actually generate a severe thunderstorm.

Considering the full reanalysis period (i.e. 1979-2012) a hindcast was made for the SEQ region to estimate historical downburst producing storm activity. To arrive at a hindcast, the full reanalysis database was analyzed and LI100 and DVWS were calculated for each time step. Segregating the data into individual years, the estimated mean number of downburst events expected in any given year was calculated using:

$$E = \sum_{I,S}\left(\sum_{j}\left[A(I,S)_j = X(I,S)\right] \cdot P(WS|X(I,S))\right) \quad (1)$$

where E is the mean estimated annual event count, $P(WS|X(I,S))$ is the conditional probability of downburst windstorm (WS) occurrence for a given combination of I (instability – LI100) and S (shear – DVWS), $X(I,S)$, and the summation of all true occurrences of the conditional statement within the Iverson bracket, […], represents a count of the number of time steps where the reanalysis data yields a multivariate combination, $A(I,S)$ equal to $X(I,S)$. Summations are done over all time steps, j, and for each I-S combination.

Figure 5 shows the hindcast results for SEQ warm seasons (October - March). Inspecting the period following 1990 it is seen that the mean trends are followed reasonably, but the large inter-annual peaks are not particularly well represented. Given it has already been suggested that not all the physics that drive severe storm activity are represented in the two indices used, this is not surprising. From a modelling standpoint it is also not entirely detrimental in that these peaks can be considered a random process on top of the underlying mean estimations.

Prior to 1990 the simulation generates much larger event numbers than observed. This highlights a particular sampling bias that existed in the observational record during this period, and is not a systematic overestimation by the model. In fact it appears that this period may in fact have been characterized by greater storm activity than recent years.

CONCLUSIONS

This paper proposes a methodology for building a stochastic event-based wind hazard model to estimate the risk downbursts pose to structures. Unlike existing models it couples large scale atmospheric information and observational records to generate model parameters. This extension allows the hazard model to be applied in regions where no observational records currently exist. Current progress towards full model development has focused on the methodological approach required to couple these data and integrate them into the wider hazard model. An example was provided for the south east Queensland region where it was shown that the proposed model can reasonably replicate historic trends in mean annual event counts, but was unable to capture the inter-annual variability in these counts. Future work will refine this approach and continue to develop the full model proposed.

Special Session on Dynamic Behaviour of Engineering Structures under Extreme Loads

CONCRETE SPALL DAMAGE OF UHPC SLABS UNDER CONTACT DETONATION- AN EXPERIMENTAL INVESTIGATION

Jun Li[1, 2,*], Chengqing Wu[1, 2], Hong Hao[3]

ABSTRACT

Concrete spallation is a typical brittle damage mode under close-in or contact explosions. Upon concrete spallation, a large number of fragments displace from the concrete surface with high speed and these fragments endanger the personnel and equipment shielded by the concrete member. It is therefore important to have a better understanding on the concrete spall phenomena. In the present study, contact explosion tests are carried out on concrete slabs. Four slabs including two made of normal strength concrete (NRC) and two ultra-high performance concrete (UHPC) slabs are tested. Different size of contact explosives are used in the tests. Test observations are compared with the predictions made by available empirical methods.

KEYWORDS

Concrete spallation, UHPC, NRC, Blast loads.

INTRODUCTION

Under blast loading environment, structures and their components can fail in multiple ways. For structural load-carrying members like columns and slabs, if damage is unavoidable, flexural damage is always the desired damage mode as such damage is most ductile and can absorb the largest amount of energy. However, in most blasting scenarios, brittle damage modes like shear damage or combined flexural and shear damage are commonly observed (Li and Hao 2013).

It is commonly acknowledged that the damage associated with blasts is dependent on the scaled distance. When an explosion is in the close proximity to or in contact with a concrete structure, on the surface facing the detonation, the concrete experiences compression and may fail under high compressive force and generate cratering. When the compressive shock wave propagates within the concrete and interacts with the free surface, it will be reflected and converts to a tensile wave. Under this condition, due to the low tensile resistance of concrete, crack will form if the net stress exceeds concrete dynamic tensile strength. Furthermore, if the trapped impulse is large enough to overcome the resistant forces such as the bond, shear around the periphery of the cracked portion, and the mechanical interlocking, the cracked off parts will displace from the backside of the structure at various velocities. Although spall damage is highly localized damage, loss of mass can influence structural loading capacity, and the out-bursting fragments can be dangerous to the personnel and valuable instruments shielded inside. Until now, although some work has been found in the literature, including both theoretical and numerical studies (Li and Hao 2014, Li and Hao 2014), more knowledge is required to understand the spall phenomenon and also propose effective means resisting such damage.

For structural protection purpose, besides concrete retrofitting technology (Wu et al. 2009, Ohkubo et al. 2008, Beppu et al. 2010), development of new concrete material with high blast and impact proof capacity has been gaining increasingly more momentum. Ultra-high performance concrete (UHPC) is a relatively new construction material with higher strength, ductility and toughness. The outstanding mechanical properties of UHPC stems not only from addition of high pozzolanic particles like silica fume but also from the reinforcement of small steel fibers in the concrete matrix. In a recent study, a novel UHPC material with nano-material addition was developed (Su et al. 2015, Su et al. 2015). The mixture of nano scale particle provides nano-size filling effect and better pozzolanic effect, both of which are beneficial to the concrete mechanical performance. Experimental study conducted on columns confirmed the superior blast resistance of this new material under free air explosions (Li et al. 2015).

To gain more information about this novel UHPC material, especially its performance under contact explosions, contact explosion tests were carried out on four slabs. In the four slabs, two slabs were constructed with

conventional concrete and the other two slabs were made of ultra-high performance concrete with nano material addition. The spall areas and crater areas are quantitatively analyzed and compared. Feasibility of utilizing existing theoretical and empirical methods predicting concrete spallation under blast loads is discussed. Furthermore the fragments from each single test were collected for a sieve analysis, and the results are used for predicting fragments size distribution.

FIELD TESTS

Sample Preparation

In total four slabs including two normal strength concrete (NRC) slabs and two micro steel fiber reinforced ultra-high performance concrete (UHPC) slabs were tested in the program. As shown in Figure 1, the dimension of slabs was: 2000 mm long, 800 mm wide and 120 mm thick. Longitudinal reinforcement rebar number in the compressive and tensile surface was both 9. The diameters of the longitudinal reinforcing rebar and stirrup rebar were 12 mm and 8 mm, respectively. Both of these two reinforcements were designed with 360 MPa yielding strength.

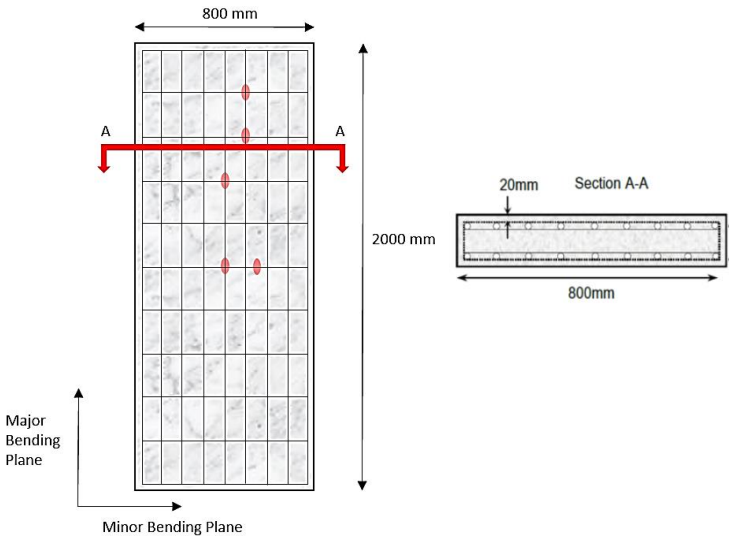

Figure 1 Slabs configuration

NRC slabs were constructed by concrete with unconfined compressive strength of 40 MPa. Ultra-high performance concrete with uniaxial compressive strength 145 MPa and tensile strength 22 MPa was used to build the UHPC slabs. For UHPC material, micro steel fibers with a length of 15 mm and diameter of 0.12 mm were mixed at a volume dosage of 2.5%, the tensile strength of the micro steel fiber was 4295 MPa.

During the sample preparation, strain gauges were attached to the reinforcement bars at different locations in each slab as indicated by red dots in Figure 1. These strain gauges were used to record the strain time history and the data obtained can be further used to derive the strain rate experienced by the slabs in each blast scenario.

Blast Scenarios

TNT explosives with different charge weights, i.e. 0.1 kg and 1 kg were used in the contact tests. These explosives were placed end-on the slabs. Based on preliminary investigations, it was determined that these two charge weights can induce different levels of spall damage in NRC slabs. For comparative purpose, the same explosive weights were used for UHPC slabs.

(a) 0.1 kg cylindrical TNT explosive (b) 1.0 kg cylindrical TNT explosive

Figure 2 Cylindrical TNT explosives

Blast Test Set Up and Results

In the tests, the slabs were placed on the steel support and bolt fixed at both ends of the longer span as shown in Figure 3. Explosives were placed end-on the slab center.

Figure 3 Test set-up

Figure 4 shows the NRC slab under 0.1 kg TNT contact explosion. Clear concrete crater and spall was noticed on the top and bottom side of the slab. The diameters of the concrete crater and spall were 20 cm and 33 cm, respectively. Neither perforation nor flexural damage was found at the slab mid-span.

Figure 4 NRC slab under 0.1 kg TNT contact explosion

Figure 5 shows the NRC slab under 1 kg TNT contact explosion. Severe blast load induced perforation failure in the slab. Fracture happened on the central stirrup reinforcement. It is also noted that significant concrete cracking occurred along the two unsupported directions near the slab boundary. As no obvious slab deformation was observed, these damages were believed also caused owing to stress wave propagation and reflection. Stress wave caused cracks along the two free ends because of the short propagation distance between the explosive and the free boundary, which generated large tensile stresses owing to wave reflection and hence scabbing failure of concrete.

Figure 5 NRC slab under 1 kg TNT contact explosion

Figure 6 depicts UHPC slab with 0.1 kg TNT contact detonation. It is noted no spall damage was observed on the bottom surface of the slab, and a small concrete crater with a diameter of 9 cm and a depth of 2.7 cm was found on the top surface. Comparing with NRC slab subjected to the same blast load, it is clear that UHPC material has much higher blast resistance capacity.

Figure 6 UHPC slab under 0.1 kg TNT contact explosion

The response of UHPC slab under 1 kg TNT contact explosion is shown in Figure 7. The slab was observed with spall and concrete crushing failure. Compared with NRC slab under the same blast load, the top surface crater diameter and the bottom surface spall diameter were reduced from 46 cm and 82 cm to 23 cm and 45 cm, respectively. Moreover, no side concrete scabbing damage as in NRC slab was observed, and no reinforcement fracture was observed either. These comparisons clearly demonstrate the better blast loading resistant capacity of UHPC than normal concrete.

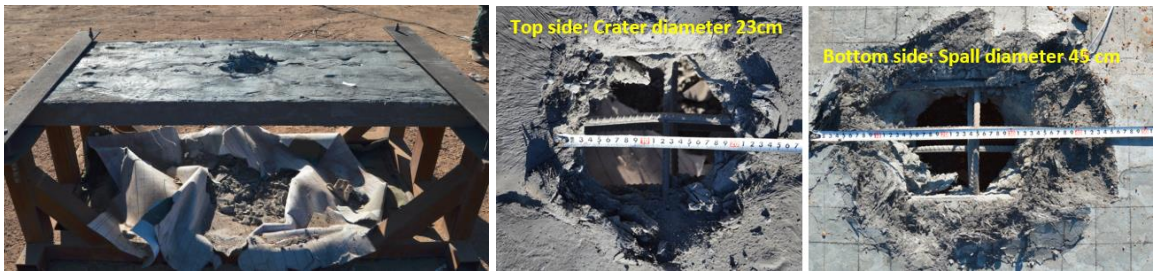

Figure 7 UHPC slab under 1 kg TNT contact explosion

DATA ANALYSIS

Comparison with Empirical Methods

McVay (1988) in his work compiled hundreds of contact or close-in blast test data and proposed empirical formulae to predict the local damage of concrete slabs subjected to bare explosive charges. As shown in Figure 8, T is the slab thickness, R is the standoff distance, and for contact explosion, R is taken as one-half of the outer diameter of the cylindrical explosive charge, W is the charge weight, T/W^1/3 and R/W^1/3 are scaled slab thickness and scaled standoff distance, respectively. After substituting these parameters into Figure 8, it is noted that the empirical evaluation can give good prediction of spall damage of the two tested NRC slabs under contact explosion. For UHPC slab under 0.1 kg TNT contact explosion, empirical predictions derived by McVay underestimate its spall resistance capacity and give wrong prediction. For UHPC slab under 1 kg TNT contact explosion, the observed spall damages, however, are substantially smaller, and these are not reflected from the empirical predictions. To more accurately quantify the damage severity, more studies, either blast testing or numerical simulations using verified numerical models, are deemed necessary.

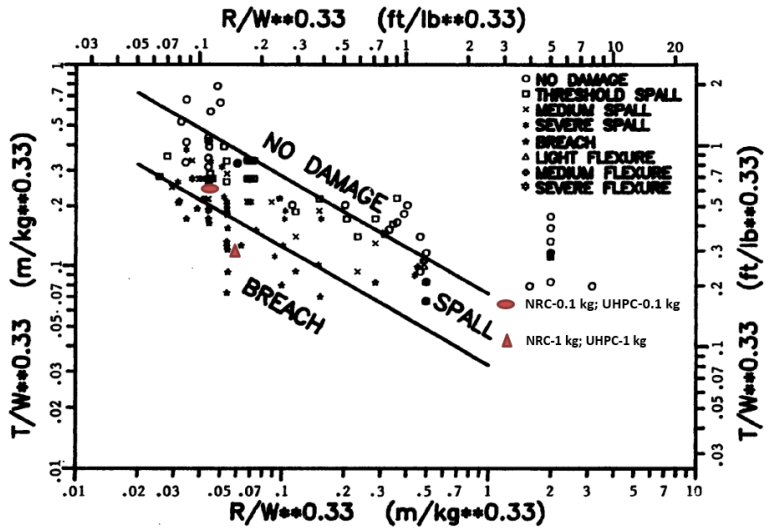

Figure 8 Prediction with empirical formulae

Fragments Size Distribution Analysis

In the current study, complete samples of fragments from both NRC slabs and UHPC slabs were collected and sieved. Six sieves with size range from 0.6 mm to 15 mm were used. The weights of fragments passing through each sieve had been measured. Typical sizes of the fragments passing through each sieve are shown in Figure 9.

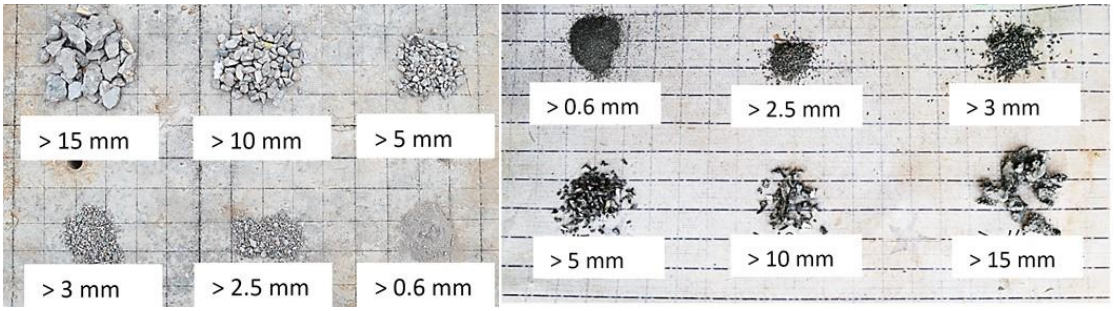

Figure 9 Typical fragments in the sieve analysis. Left) NRC; Right) UHPC.

A typical comparison between UHPC slab and NRC slab is made and shown in Figure 10. Both the slabs were subjected to 1 kg TNT contact explosion. As depicted in the figure, under the same blast loading condition, NRC slab generates more fragments than UHPC slab and the fragments weights passing through every sieve level are all higher than UHPC slab.

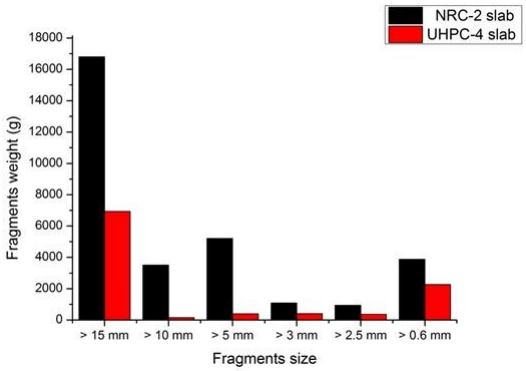

Figure 10 Samples of fragments with different sizes

To describe the fragments distribution of NRC slab, Weibull distribution is adopted, as depicted in Figure 11, Weibull distribution with modulus of 1.63 and 0.67 can well represent the size distribution of fragments from NRC slab under 0.1 kg TNT and NRC slab under 1 kg TNT. Residual sum of squares (R^2 values) are 0.976 and 0.95 for NRC-1 and NRC-2 slabs, respectively.

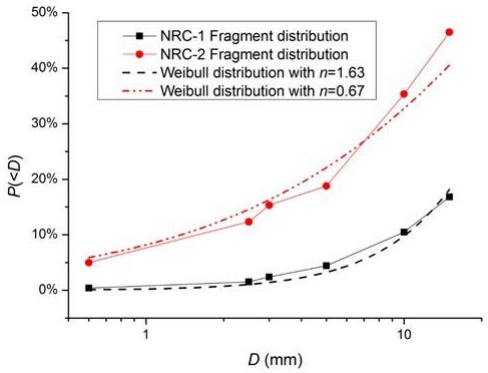

Figure 11 Weibull distribution for fragments from NRC specimens

Weibull distribution was also adopted to describe the fragment size distribution of UHPC slab, however, it was found the fitting contains large deviations, and it was deemed inaccurate to used Weibull distribution for describing the fragments from UHPC. After several trials, Log-normal distribution was used. As depicted in Figure 12, size distribution of fragments from UHPC slabs fits well the Log-normal distribution. Location parameters and scale parameters are plotted for each fitting. Residual sum of squares (R^2 values) is 0.89 for UHPC slab under 1 kg TNT contact explosion.

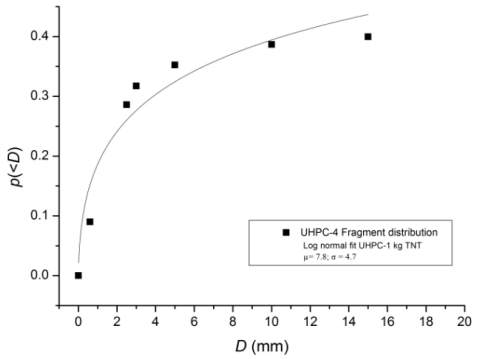

Figure 18 Log-normal distribution for fragments from UHPC specimen

CONCLUSIONS

In the present study, concrete slabs made with normal strength concrete material and ultra-high performance concrete material are tested under contact explosions. Spallation and cratering are observed and investigated quantitatively. UHPC slabs displayed significantly improved blast resistant capacity than NRC slabs. Empirical methods developed based on large number of tests are adopted to evaluate the performance of slabs in the current study and it is noted these empirical methods can give good predictions on concrete spallation of NRC slabs but can significantly underestimate the spall resistance of UHPC slabs. Size distributions of fragments are also investigated and it is noted that Weibull distribution can be used to represent the fragment sizes from NRC slabs while fragments from UHPC slabs can be fitted to Log-normal distributions.

ABSTRACT

Pipeline systems are commonly used to transport oil, natural gas, water, sewage and other materials. They are normally regarded as important lifeline structures. Ensuring the safety of these pipeline systems is crucial to the economy and environment. There are many reasons that may result in the damages to pipelines and these damages are often associated with pipeline vibrations. Therefore it is important to control pipeline vibrations to reduce the possibility of catastrophic damages. This paper carries out numerical investigations on the effectiveness of using viscoelastic material layers to mitigate seismic induced vibrations of above ground pipelines. The numerical analyses are carried out by using the commercial finite element code ANSYS. The numerical model of the viscoelastic material is firstly calibrated based on the experimental data obtained from a 1.6m long tubular sandwich structure. The calibrated material model is then applied to the pipeline system. The effectiveness of using viscoelastic materials as the seismic vibration control solution is discussed.

Viscoelastic material, above ground pipeline, vibration control, numerical simulation.

INTRODUCTION

Pipeline systems are commonly used to transport oil, natural gas, water, sewage and other materials. They are normally regarded as important lifeline structures. Ensuring the safety of these pipeline systems is crucial to the economy and environment. There are many reasons that may result in the damages to pipelines and these damages are often associated with pipeline vibrations. For example, vortex can lead to continuous vibrations of subsea pipeline and reduce its fatigue life (Kumar et al. 2008); vibrations induced by strong earthquakes may induce excessive stresses in the pipe wall and result in damage (Zeinoddini et al. 2012). Therefore, it is important to control pipeline vibrations to reduce the possibility of catastrophic damages.

Constrained viscoelastic layers have been widely used to reduce excessive vibrations of engineering structures due to its effectiveness and simplicity (e.g. Saidi et al. 2011; Borges et al. 2014). Normally a layer or multiple layers of viscoelastic materials (VEM) and a constraining layer (CL) are added to the original structure. The shear deformation of the VEM can obviously increase the damping of the original structure which in turn reduces its vibration. Extensive research efforts have been made to study the vibration characteristics of beam and plate structures with constrained damping layer. For the vibration and damping characteristics of cylindrical shells with constrained damping layer(s), the investigations are relatively less and the natural frequencies and damping of the constrained shell were generally derived based on the finite element method. For example, Chen and Huang (1999) presented a mathematical model for a cylindrical shell with partially constrained layer damping treatment. A thin shell theory in conjunction with the Donnell-Mushtari-Vlasov assumptions is employed to yield the model. Wang and Chen (2004) derived the equations of motion for the composite system based on a discrete layer theory. Many formulas were included in these studies, which impedes the application of these theories by researchers and especially engineers. A more readily applicable method, e.g. the numerical simulation method presented in this study, is deemed necessary.

This paper investigates the effectiveness of using constrained VEM layers to mitigate seismic induced vibrations of above ground pipelines. This idea originates from the recent work done by Borges et al. (2014), in which they proposed and investigated a concept aimed at suppressing vibrations in steel catenary risers by the use of viscoelastic sandwich layers. A series of experimental studies were carried out to find out the frequencies and damping of different vibration modes of the riser equipped with different scenarios of VEM. Instead of performing experimental studies, numerical simulations are carried out in the present study to investigate the effectiveness of using viscoelastic materials as the seismic vibration control solution to above ground pipelines by using the commercial software package ANSYS. The numerical model of the viscoelastic material is

calibrated based on the experimental data obtained from testing a 1.6m long tubular sandwich structure (Borges et al. 2014). The calibrated model is then applied to the above ground pipeline system. The effectiveness of using constrained VEM as the seismic vibration control solution is investigated.

NUMERICAL MODEL CALIBRATION

To carry out the numerical analysis, a reliable finite element model should be firstly developed. The experimental study carried out by Borges et al. (2014) is used as the reference to calibrate the finite element model. The numerical results are compared with the experimental data. For completeness, the experimental studies are briefly introduced in this section, more detailed information can be found in Borges et al. (2014).

Tested Original and Sandwich Tubes

Borges et al. (2014) carried out a series of experimental studies to identify the modal parameters (vibration frequencies and damping) of the original structure and structures assembled with different VEMs and CLs. The original structure consists of a brass beam with tubular cross section that is cantilevered at one end and free at the other. The length of the original structure is 1.6 m. To increase the damping of the original structure, viscoelastic layers and its associated brass constraining layers are assembled. The VEM used is the self-adhesive double face tape under code VHB4955, manufactured by 3M®. The viscoelastic and constraining layers are designed to be free at the both ends. Figure 1 shows the cross section of the sandwich beam and Table 1 presents the geometric properties of the tube layers.

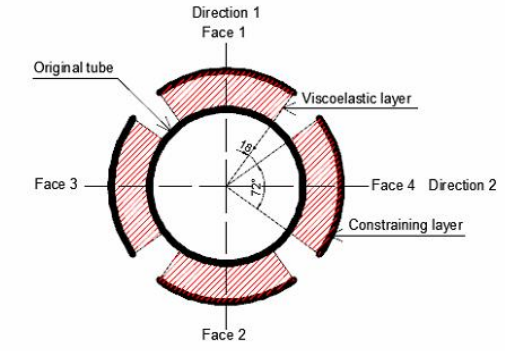

Figure 1 Tubular cross section of the sandwich beam structure (not to scale)

Table 1 Geometric properties of the tube layers (Borges et al. (2014))

Layer (material)	Length (mm)	External radius (mm)	Thickness (mm)
Internal tube (Brass)	1600	9.46	1.06
Viscoelastic material (VHB4955)	1600	11.86	2.4
Constraining (Brass)	1600	12.66	0.8

For the brass original tube and CLs, the Young's modulus is E_t=121.8 GPa and the density is ρ_t=8770 kg/m^3. For a linear, homogeneous and isotropic VEM, the complex shear modulus can be expressed in the frequency domain as

$$G^*(\omega)=G(\omega)[1+i\beta(\omega)] \quad (1)$$

where $G(\omega)$ is the storage modulus, $\beta(\omega)$ is the dissipation loss factor and ω is the circular frequency in rad/s. For the VEM used in the present study, the following parameters are identified (Stutz et al. 2009): Young's modulus E=6.88 MPa, density ρ=795 kg/m^3, Poisson's ratio υ=0.49 and dissipation loss factor β=0.75. The shear modulus is thus $G=E/[2(1+\upsilon)]$=2.31 MPa.

It can be seen from Figure 1 that the original tube was not fully covered by the VEMs and CLs, a gap was designed between different faces of cover layers. The angle of the gap was not mentioned by Borges et al. (2014). Based on the provided figure (Figure 8 in Borges et al. (2014)), the angle is estimated to be 18º and used in the present study, the angle of each constraining layer is thus 72º as shown in Figure 1.

Finite Element Modelling

The original tube, VEMs and CLs are all modelled with solid element SOLID186 in ANSYS, this element supports viscoelasticity. In the numerical model, the circumference of the original tube is divided into 40

elements. In the radial direction, the original tube and CLs are modelled by one element respectively while the VEMs are divided into two. In the longitudinal direction, the element size is 16 mm. The VEMs are rigidly connected to the original tube and CLs, namely the VEMs share nodes with the original tube and CLs. The cross section of the original tube is relatively small compared to its length, plotting the whole FE model will make the figure not clear, Figure 2 shows part of the FE model of the original tube with faces 1 and 2 (see Figure 1) constrained by VEMs and CLs.

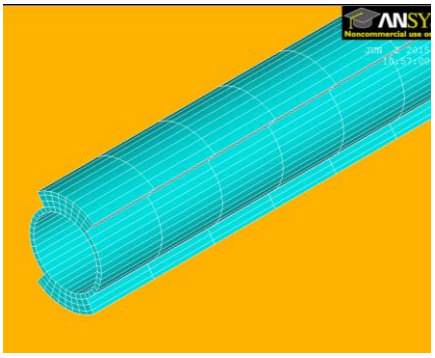

Figure 2 FE model of the original tube with faces 1 and 2 constrained with VEMs and CLs

The constraining layers are assumed to be linear elastic, while the VEM is assumed to be hyperelastic (Saidi et al. 2011). The damping is modelled in ANSYS for each material as a constant stiffness multiplier (DAMP command in ANSYS), which can be calculated from (Saidi et al. 2011):

$$\alpha_2 = \xi/(\pi f) \tag{2}$$

where α_2 is the stiffness multiplier, f is the fundamental vibration frequency of the structure, which can be obtained by carrying out an eigenvalue analysis, ξ is the damping ratio of the material. For the viscoelastic material, ξ is related to the dissipation loss factor β and can be estimated as $\xi=\beta/2$ (Nashif 1985). For the original tube, the damping ratio is 0.05% based on the test results.

Numerical and Experimental Results

Three different types of structures were tested by Borges et al. (2014), i.e. the original tube, the tube with faces 1 and 2 constrained with VEMs and CLs, and the tube with all faces constrained. The modal parameters in directions 1 and 2 (Figure 1) were experimentally identified. All these three different cases are numerically simulated. Due to the limitation of the page length, only the results of the original tube and the tube with faces 1 and 2 constrained are compared with the experimental data.

There are many methods available to identify the modal parameters once we have the free vibration data of the system. In the present study, the wavelet transform method proposed by Ruzzene et al. (1997) is adopted. This method is drawn upon the unique characteristics of Morlet wavelets, and the modal parameters are identified from the modulus and phase angle of the wavelet transform of the free vibration data. To identify the modal parameters in these two different directions, a 5 mm initial displacement is introduced in directions 1 and 2 respectively at the free end of the system and then released suddenly to simulate a free vibration test. The free vibration responses are then used as input to identify the modal parameters.

Tables 2 to 3 tabulate the identified modal parameters of the first two modes at directions 1 and 2 of different structures based on the numerical results and the corresponding values obtained from the tests. The differences between the numerical and experimental results, which are calculated from $(R_N-R_E)/R_E$, are also tabulated, where R_N and R_E represent the numerical and experimental results respectively. It is noted that the sampling frequency of the numerical results is 500 Hz in the present study. As shown in Tables 2 and 3, the modal parameters identified from the numerical results coincide well with those from the experimental tests. Large differences occur at the damping ratio of the original tube. This is because, as can be seen from Table 2 that the absolute value of the experimental results are quite small (0.03% to 0.05%), a slight deviation from the experimental results can lead to a large difference. The numerical simulation adopted in the present paper is therefore believed able to realistically model the VEM and the sandwich structure. It also can be seen from the tables that the constrained VEM can significantly increase the damping ratio of the structure. It thus has the potential to reduce the vibration of the original structure.

It should be noted that the tested original tube presented some imperfections in the test (Borges et al. 2014). The natural frequencies in the two different directions obtained from the tested data are slightly different as shown in

Table 2. In the numerical simulation, these imperfections are not considered, and the corresponding values in these two different directions are therefore the same for the original tube.

Table 2 Comparison of the modal parameters identified from the numerical results and the corresponding experimental results (the original tube)

ABOVE GROUND PIPELINES

Pipeline Details

Figure 3 shows a typical above ground pipeline supported on discrete supports at equal intervals. The pipeline is made of steel and the length of each span is 16 m. The outer diameter of the pipe cross section is 0.35 m and the thickness is 3 mm. The pipeline may undergo violent vibrations under severe earthquakes. To mitigate these adverse vibrations, VEM layers and CLs are proposed to be assembled on the surface of the original pipeline. In a real earthquake, three dimensional ground excitations are inevitable. To demonstrate the effectiveness of the proposed method, only the transverse earthquake loading is considered in the present study. The VEMs and CLs are only assembled in the transverse direction (x direction as shown in Figure 4) of the pipe.

Figure 3 A typical above ground pipeline

Seismic Ground Motion

The pipeline is located on a flat-lying soil site as shown in Figure 4. One single layer of soil rests on the base rock. The parameters of the soil layer and base rock are included in the figure, where ρ, G, ξ, υ and h represent the density, shear modulus, damping ratio, Poisson's ratio and thickness respectively. The lower cases s and b represent the soil layer and base rock. In the present study, the base rock motion is assumed to consist of out-of-plane SH wave and it is represented by a filtered Tajimi-Kanai power spectral density function as (Tajimi 1960)

$$S_g(\omega) = \frac{\omega^4}{(\omega_f^2 - \omega^2)^2 + (2\omega_f \omega \xi_f)^2} \frac{1 + 4\xi_g^2 \omega_g^2 \omega^2}{(\omega_g^2 - \omega^2)^2 + 4\xi_g^2 \omega_g^2 \omega^2} \Gamma \tag{3}$$

where ω_g and ξ_g are the central frequency and damping ratio of the Tajimi-Kanai power spectral density function, ω_f and ξ_f are the corresponding central frequency and damping ratio of the high pass filter function. Γ is a scaling factor depending on the ground motion intensity. The parameters for the transverse motion are assumed as $\omega_g = 10\pi$ rad/s, $\xi_g = 0.6$, $\omega_f = 0.5\pi$, $\xi_f = 0.6$ and $\Gamma = 0.0212$ m^2/s^3. These parameters correspond

to a ground motion time history with duration T=16 s and PGA of 0.5g based on the standard random vibration method (Der Kiureghian 1980).

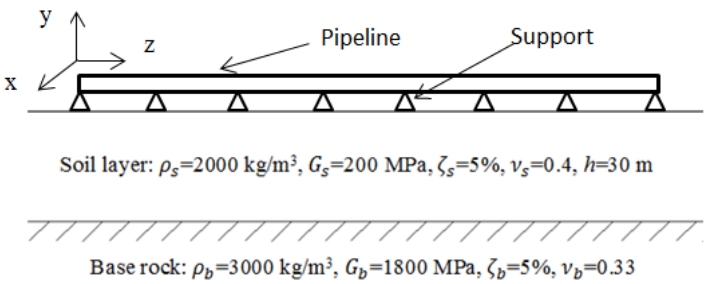

Figure 4 Numerical model of an above ground pipeline and underneath site conditions (not to scale)

The base rock motion can be further filtered and amplified by the soil layer. The transverse earthquake loading on the ground surface can be simulated based on the combined spectral representation method and one-dimensional wave propagation method (Bi and Hao 2012). Figure 5 shows the simulated transverse acceleration time history. It is worth to note that in the simulation, the sampling frequency and the upper cut-off frequency are set to be 100 and 25 Hz respectively. Figure 6 shows the comparison of the simulated power spectral density (PSD) with the theoretical value which is derived based on the one-dimensional wave propagation theory (Wolf 1985). Good agreements are observed.

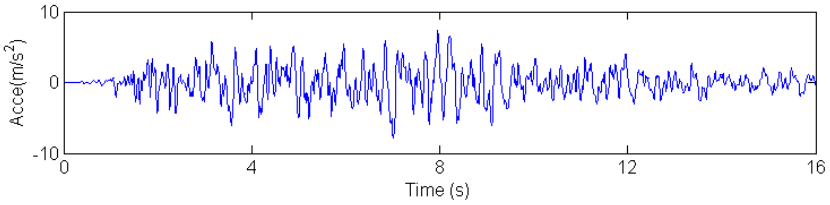

Figure 5 Simulated transverse acceleration time history

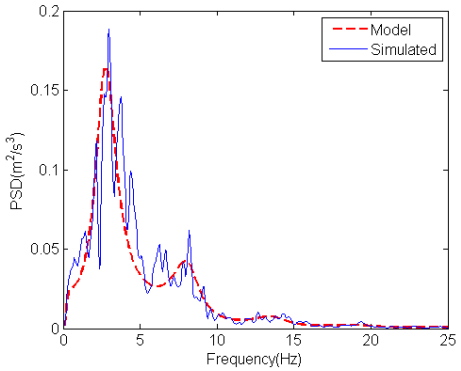

Figure 6 Comparison of the PSDs of the simulated ground motion with the theoretical model

Numerical Model

The viscoelastic material VHB4955 manufactured by 3M® calibrated in Section 2 is used again to increase the damping of the original pipeline. The sandwich pipeline is modelled the same way as the sandwich tube in Section 2. The original pipe and the CLs are made of steel and the Young's modulus, density and Poisson's ratio are 210 GPa, 7800 kg/m^3 and 0.3 respectively. Normally the pipe is not fully fixed to the supports, the transverse restraint provided by the support can be considered by a spring. The stiffness of the spring normally varies from 7.5x10^5 N/m to 6x10^6 N/m (Anderson and Johnston 1975). In the present study, the transverse restraints provided by the supports are modelled by the COMBIN14 elements, and its stiffness is 1.1644x10^6 N/m (Soliman and Datta 1996). In the vertical direction, the pipeline is assumed to be simply supported by the supports. The damping ratio of the original pipeline is assumed to be 1.2% in the present study.

Since it is impossible to model the whole length of a pipeline system, taking one span of the entire pipeline out for analysis is more practical. To simulate the restraining effects from adjacent spans to the single-span model,

rotational springs are added at the both ends of the analysed span (Bao et al. 2013), and they are modelled by COMBIN14 elements again. The rotational spring stiffness is determined by performing a numerical convergence analysis and a value of 1.465×10^5 Nm/rad is determined. Figure 7 shows part of the single-span model, in which part of the span in assembled with VEMs and CLs. In the subsequent analysis, only the single-span model with the rotational spring at the both supports is analysed. This substantially reduces the computational time for the analysis.

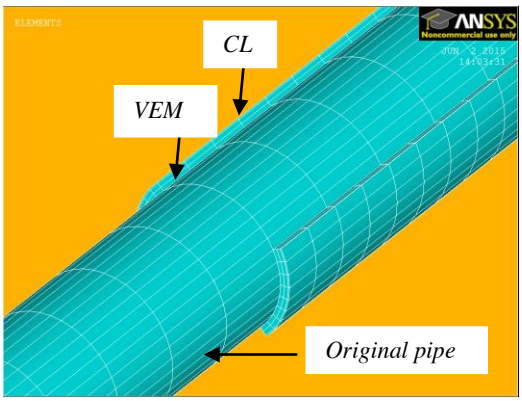

Figure 7 Finite element model of a single-span pipeline with part of the span assembled with VEMs and CLs

NUMERICAL RESULTS

This section carries out numerical simulations on the effectiveness of using constrained VEMs to mitigate the seismic induced vibrations of above ground pipelines. For comparison, the corresponding results from the original pipeline are also presented.

The acceleration time history shown in Figure 5 is used as input in the transverse direction of the pipeline. The duration of the earthquake loading is 16 sec. In the numerical simulation, a 20 sec response is calculated. In the first 16 sec, the pipeline system is subjected to the transverse earthquake loading (forced vibration), while it vibrates freely in the last 4 sec. The acceleration response in the free vibration phase is used to identify the modal parameters, i.e., natural frequency and damping ratio of the system, based on the wavelet transform method proposed by Ruzzene et al. (1997) with a sampling frequency of 100 Hz. Since the transverse input is considered in the present study, only the vibration frequency and damping ratio corresponds to the first transverse vibration mode are presented and discussed. For the original pipeline, the fundamental vibration mode is in the transverse direction with a frequency of 3.8369 Hz based on an eigenvalue analysis. By using the free vibration result, the identified frequency and damping ratio is 3.8556 Hz and 1.25% respectively, which are close to the vibration frequency obtained from the eigenvalue analysis and the assumed damping ratio of 1.2%. All the modal parameters presented in this section are the identified values based on the single-span pipeline model.

Influence of Constraining Arrangement Scenarios

Borges et al. (2014) experimentally identified the vibration frequencies and damping of the original riser with the viscoelastic sandwich layers sequentially assembled in segments along the original structure. This segmented arrangement (Figure 8(a)) as suggested by Borges et al. (2014) is firstly investigated in the study. The length for each segment is 2 m and the spacing between adjacent segments is 1 m. 1, 3 and 5 constraining segments are considered as shown in Figure 8(a). Another two arrangement scenarios, namely the compact configuration shown in Figure 8(b) and the monolithic configuration shown in Figure 8(c), are also investigated. In the compact configuration, the constraining segments concentrate at the centre of the span and there is no gap between each segment. For the monolithic configuration, all the segments are rigidly connected together to form an integral constrain. In all these cases, the thickness of the VEM layers is 20 mm and the thickness of the CLs is 3 mm.

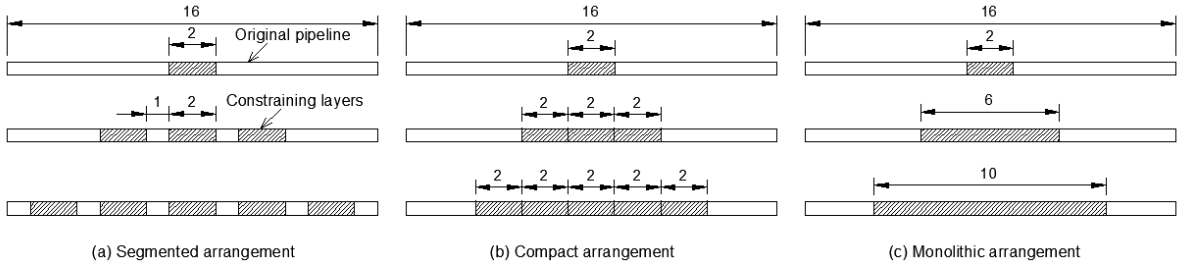

Figure 8 Constraining arrangement scenarios: (a) segmented, (b) compact and (c) monolithic configurations (unit: meter)

Table 4 tabulates the identified fundamental transverse vibration frequencies and the corresponding damping ratios of different constraining arrangement cases. The results obtained from the original pipeline (constraining length L=0 m) are also shown. It can be seen from the table that for the segmented and compact arrangements, increasing the number of constraining segments leads to the monotonous decreasing of vibration frequency of the system. For the monolithic arrangement, the vibration frequency decreases with the increasing of the constraining length if the constraining length is less than 6 m. When the constraining length reaches 10 m, the vibration frequency of the system is, however, larger than the pipeline with the constraining length of 6 m. This is because the vibration frequency is determined by the mass and stiffness of the system. For the segmented and compact arrangements, the segments contribute relatively small to the stiffness of the system because of the short length of the segments (2 m in the present study). Increasing the segment numbers, however, obviously increases the mass of the system, which in turn results in the smaller vibration frequency. For the monolithic arrangement with long enough VEMs and CLs, the constraining layers will evidently increase the stiffness of the system as well, besides their contributions to the mass. When the contribution to the stiffness is larger than that of the mass, larger vibration frequency will be obtained. It also can be seen from the table that the compact arrangement leads to smaller vibration frequency of the system compared to the segmented configuration. This is because the segments contribute more to the total mass of the system when they are more concentrated to the centre of the span.

The table also shows that the segmented and compact arrangements only slightly increase the damping ratio of the system. For the original pipeline, the identified damping ratio is 1.25%. When 2, 6 and 10 m constraining layers are assembled, the damping ratios are 1.43%, 1.67% and 1.70% respectively for the segmented arrangement. The corresponding values for the compact arrangement are 1.43%, 1.69% and 1.81%. On the other hand, the increasing in damping of the system is quite obvious if the constraining layers are assembled monolithically when the length of the constraining layers is not too short. For example, the damping ratios reach 3.53% and 4.78% when the constraining lengths are 6 and 10 m respectively. This is because the high damping capacity of structure with constrained damping layer is mostly due to the shear deformation of the VEM (Wang and Cheng 2004). With the same length of constraining layers, the VEMs and CLs undergo larger shear deformation during vibration when monolithic arrangement is considered and thus larger damping ratio is expected.

Table 4 Identified frequencies and damping ratios of different constraining scenarios

Constraining Length	Frequency (Hz)			Damping ratio (%)		
	Segmented	Compact	Monolithic	Segmented	Compact	Monolithic
0	3.8556	3.8556	3.8556	1.25	1.25	1.25
2	3.5675	3.5675	3.5675	1.43	1.43	1.43
6	3.2513	3.1927	3.3387	1.67	1.69	3.53
10	3.1749	3.0120	3.4105	1.70	1.81	4.78

The constraining layers can significantly influence the seismic responses of the system. Figure 9 shows the transverse displacement time histories at the middle span of the pipelines with different scenarios of constrains. Only the forced vibration responses are plotted in the paper. The results are compared with that obtained from the original structure. As shown, when segmented or compact arrangement is adopted, the suppressing of vibrations is not obvious because the damping ratios only increase slightly in these cases as shown in Table 4. Moreover, it can be seen that more constraining segments do not necessarily result in more effective vibration reduction. This is most evident for the case where the pipeline is compactly assembled with five segments

(L=10 m). This system vibrates even more violently than the original pipeline. This is because the addition of the segments obviously changes the vibration frequency of the system while it does not increase the damping evidently. As can be seen from Table 4, the vibration frequencies for the original pipeline and the pipeline with five compact segments are 3.8556 and 3.0120 Hz respectively. Moreover, Figure 6 shows that the energy of the earthquake loading mainly concentrates around 2.734 Hz due to the local site amplification effect. This frequency is close to the vibration frequency of the compact scenario (3.0120 Hz), which means that when the pipeline is compactly assembled with five segments, resonance can occur and larger seismic response is expected. When monolithic arrangement is adopted, the reduction of vibration is significant as shown in Figure 9(c) due to the obvious increment of damping. Of course, the decreased vibration frequency makes the system vibrates closer to the resonant frequency of local soil site, however, this effect is compensated by the increased damping ratio of the system. The results suggest that monolithic arrangement is more effective than the segmented and compact arrangements in the seismic vibration control of above ground pipeline considered in this study.

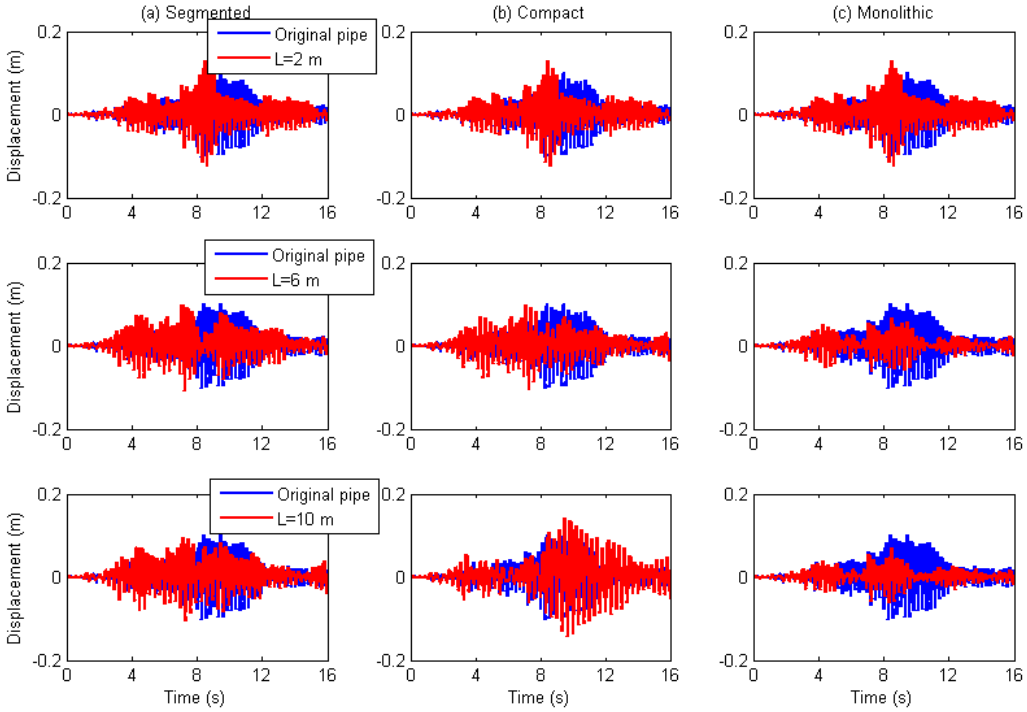

Figure 9 Influence of constraining arrangements on the seismic responses of the system: (a) segmented, (b) compact and (c) monolithic configurations

Influence of Different Earthquake Loadings

In the previous section, the artificially simulated earthquake loading is used as input in the numerical simulation. To further examine the influence of ground motion frequency content on the effectiveness of the proposed method, the seismic responses of the original and constrained pipelines subjected to two natural earthquake loadings obtained from the database of Pacific Earthquake Engineering Research Centre are also calculated and compared. The first earthquake loading is the record from the 1994 Northridge earthquake. This earthquake loading is characterized by the long-period pulse-like waveforms, and it is normally classified as near-field ground motion. The second record is from the 1971 San Fernando earthquake, which exhibits fewer long-period characteristics and it is used to represent far-field earthquake. Table 5 summarises these two earthquake components and Figure 10 shows the accelerograms of the two ground motions. Figure 11 plots the PSDs of these two earthquake loadings. It can be seen that the energies of the Northridge earthquake loading mainly concentrate in the frequency band less than 2 Hz and for the San Fernando earthquake, they are mainly in the frequency band less than 1 Hz. The dominant frequencies of these two earthquakes are far from the first vibration frequencies of the original and constrained pipelines, which are 3.8556 and 3.4105 Hz respectively as mentioned above. The changes in the seismic responses are thus mainly because of the change of the damping. Figure 12 shows the seismic responses of the original and constrained pipelines subjected to these two earthquake loadings. It is obvious that the proposed method is effective to suppress the vibrations induced by these two natural earthquake loadings.

CONCLUSIONS

This paper carries out numerical simulations on the effectiveness of using viscoelastic materials to mitigate seismic induced vibrations of above ground pipelines. The modelling of the viscoelastic material is firstly calibrated based on the experimental data obtained from testing a 1.6 m long tubular sandwich structure. The calibrated model is then applied to the above ground pipeline system. Man-made, far-field and near- field earthquake ground motions are considered as input in the numerical analyses. Numerical results show that it is effective to mitigate the seismic induced vibrations of above ground pipelines by assembling the VEMs and CLs

to the original pipeline structure. It also finds that monolithic arrangement is more effective than segmented and compact arrangements in increasing the damping of the original pipeline system and suppressing its vibration.

ABSTRACT

Concrete is strong in compression but weak in tension with brittle fracture characteristics. To increase its ductility and post-cracking load-carrying capability, intensive researches have been reported to add various types of fibres into concrete mixture. A new type of steel fibre with spiral shape has been recently proposed. Laboratory tests demonstrated that compared to other fibre types such as hooked-end, deformed and corrugated fibres, this new fibre has larger displacement capacity and provides better bonding into the concrete matrix. However, the dynamic properties, especially tensile properties, of concrete reinforced with spiral-shaped steel fibres need be further investigated for a better understanding of this material and potential application in critical engineering buildings/infrastructures against blast and impact loads. This study carries out split Hopkinson pressure bar (SHPB) tests and numerical simulations to study the behaviour of spiral fibre reinforced concrete (SFRC) under dynamic splitting tension. In SHPB tests, tapered striker bar was used to generate stress wave with half-sine shape so that stress wave oscillation and dispersion were eliminated. The simulations are implemented using commercial software LS-DYNA as a plane-stress problem. The SFRC specimens are modelled in mesoscale with distinctive consideration of mortar matrix, coarse aggregates and spiral fibres. The numerical simulation results are compared with SHPB test data. The validity and feasibility of the mesoscale numerical model in analysing behaviours and properties of SFRC under dynamic splitting tension are demonstrated. The influence of fibre contents on the dynamic splitting tensile strengths of SFRC material is parametrically studied.

INTRODUCTION

The use of fibre reinforced concrete (FRC) in constructions of long-span or high-rise structures, heavy-duty pavements, tunnel lining or critical engineering buildings has been more and more frequent due to improved ductility and energy absorption capability from fibre addition compared to plain concrete. Fig. 1 gives some examples of engineering projects using FRC.

It was observed that with the increase in fibre strength, ductility, strength and post-crack behaviour of FRC were improved because of the prevention of rupture from high-strength fibres, and the primary mode of damage was debonding of the fibres from the matrix (Holschemacher et al. 2010). Laboratory tests with consideration of three types of fibres made of polymer and steel also observed that under quasi-static and low-rate impact load, the predominant failure mode was the steel fibre pull-out, resulting in poor post-cracking and energy absorption capability (Bindiganavile and Banthia 2001a, 2001b). Although it was indicated that added fibres significantly improve the resistance capacity of concrete subjected to dynamic loadings by many studies, Li et al. (2008) observed that the added fibres had limited effect on the impact resistance of FRCs. The possible reason is that rather short fibres with lengths of about 10 to 15 mm were used by Li et al. (2008), which made the fibres vulnerable to debonding under impact loading, and the debonded fibres became ineffective to resist impact loads. The test results reported by Gao et al. (1997) indicated that with the increase of steel fibre volume dosage and fibre length, the fracture toughness and tensile strength of FRC increased because more and longer fibres are more efficient in arresting cracks. Swamy and Jojagha (1982) conducted repeated drop-weight tests considering

steel fibres with various geometries and reported that with a fibre volume fraction of 1%, impact strength and energy absorption capabilities of FRCs were substantially increased over those of plain concrete.

(b) CCTV headquarters

(c) Rock tunnel lining

Figure 1 Examples of engineering projects with the application of FRC

From review of the above studies, it can be noticed that the key factors for effective enhancement in strength, deformability and energy absorption capacity of concrete materials include the fibre strength, geometry and deformability. Xu et al. (2012) recently performed drop-weight tests on concrete specimens reinforced with 7 types of fibres. It was demonstrated by the test results that FRC reinforced with spiral-shaped steel fibres outperformed other 6 fibre types in terms of impact loading resistance, compressive strength, post-cracking resistance and energy absorption capability, because the spiral fibre has a three dimensional anchorage bond in the concrete matrix due to the fibre shape and better mechanical component of bond due to fibre deformation under impact. Impact tests on steel fibre reinforced concrete beams also indicated the superiority of spiral fibre in enhancing the energy dissipation ability (Hao et al. 2014). To further study the dynamic tensile properties of spiral fibre reinforced concrete (SFRC), in the present study, splitting tensile tests were conducted using split Hopkinson pressure bar (SHPB) system. The full length of spiral fibres ranges from 30 to 40 mm with the nominal spiralled length 15 mm, and the diameter is 0.56 mm. The fibre volume fraction of 1.0% is considered in preparing the SFRC specimens. Numerical model is also developed using commercial software LS-DYNA to simulate the SHPB tests. The SFRC specimens were modelled in mesoscale with distinctive consideration of mortar matrix, coarse aggregates and spiral fibres. The numerical simulation results are compared with SHPB test data. The validity and feasibility of the mesoscale numerical model in analysing the behaviours and properties of SFRC under dynamic splitting tension are demonstrated. Reliable numerical simulations can thus be carried out to perform intensive simulations to study the influences of fibre properties (length, dosage, random distributions and orientation, etc.) on the SFRC properties, instead of the performing physical tests. This not only results in significantly savings for conducting laboratory tests, but also allows detailed observations of the specimen failure process under high-speed impact loadings.

EXPERIMENTAL STUDY

Mixture of Specimens and Quasi-static Properties

The dimension of all tested cylindrical specimens is Ø75-37.5 mm. The diameter and full length of the spiral fibre are 0.56 mm and 35 mm, respectively. The spiral fibres have a nominal length of 15 mm. The specifications of the spiral fibre and details of the SFRC mixture are given in Table 1, and Table 2, respectively. To obtain the quasi-static properties of SFRC, uniaxial compressive and splitting tensile tests were conducted using hydraulic testing machine. The average mechanical properties of the SFRC material under compression and splitting tension of 6 specimens are summarised in Table 3.

Table 1 Specification of spiral fibres

Strength	Nominal length	Diameter	Aspect ratio	Coil diameter	Coil pitch
1300 MPa	15 mm	0.56 mm	27	5 mm	10 mm

Table 2 Mixture proportions

Water to cement ratio	Fibre volume fraction	Mix proportion (kg/m^3)					
		Water	Cement	10 mm aggregates	7 mm aggregates	Minus 4 mm aggregates	Sand
0.48	1.0%	205	426	444	306	130	843

Table 3 Material properties under quasi-static loading

Density	Compressive strength	Tensile strength	Young's modulus
2247 kg/m^3	43.25 MPa	2.87 MPa	29.76 GPa

SHPB Test Setup

The dynamic splitting tensile tests were conducted using SHPB test system. The schematic view of the SHPB apparatus is shown in Fig. 2. The incident and transmitted pressure bars have the same dimension of Ø75-2000 mm. Strain gauges are attached at midpoints of pressure bars. The bars are made of stainless steel with elastic modulus 200 GPa, density 7800 kg/m3, and Poison's ratio 0.3. A tapered impact ram was used to impact and generate half-sine loading wave form so that the violent wave oscillation and dispersion in SHPB tests can be eliminated (Lok et al. 2002). The specimen was diametrically sandwiched between pressure bars.

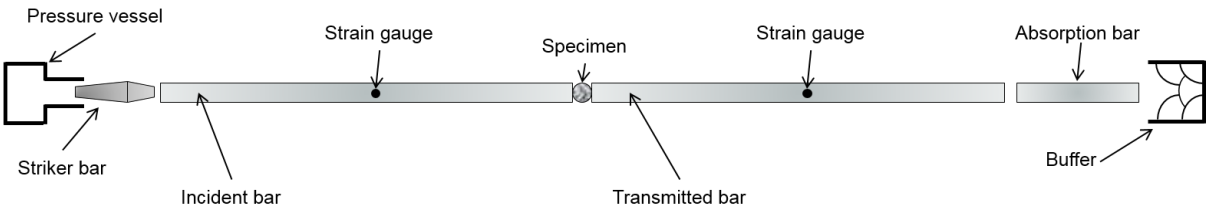

Figure 2 SHPB test setup

In SHPB tests with the assumption that the peak dynamic stress f_{td} of the splitting cylinder is proportional to the peak transmitted stress σ_T, it has (Tedesco et al. 1993)

$$f_{td} = \frac{2P_T}{\pi LD} \tag{1}$$

in which

$$P_T = \pi R^2 \sigma_T \tag{2}$$

is the transmitted force, and R is the radius of the SHPB pressure bar.
Accordingly, the loading rate $\dot{\sigma}$ and the strain rate $\dot{\varepsilon}$ in the specimen can be estimated from the equations

$$\dot{\sigma} = \frac{f_{td}}{t} \tag{3}$$

and

$$\dot{\varepsilon} = \frac{\dot{\sigma}}{E} \tag{4}$$

where t is the time lag between the start of the transmitted stress wave and the maximum transmitted stress, and E is the Young's modulus of the specimen.

Test results

13 SFRC specimens with 1% spiral fibres were tested under dynamic loads with strain rate ranges from 2.75 to 11 1/s. Fig. 3 gives typical stress histories recorded in SHPB test and damaged specimen after test. Fig. 4 summarises the obtained dynamic increase factors (DIF) which is defined as ratio of dynamic to static strength.

NUMERICAL STUDY

Material Model

The plasticity concrete model developed by Malvar et al (1997) is used to model mortar matrix in the simulation. This model uses three shear failure surfaces with the consideration of damage and strain rate effects. The strain rate effect on the material strength is described by the DIF. In the simulation, the compressive DIF relations for mortar matrix are adopted from (Hao and Hao 2011). The tensile DIFs for mortar matrix are adopted from (Malvar and Crawford 1998). The compressive and tensile DIFs of mortar matrix are given below.

$$CDIF = 0.0419\left(\log \dot{\varepsilon}_d\right) + 1.2165 \quad \text{for} \quad \dot{\varepsilon}_d \le 30s^{-1} \tag{5}$$

$$CDIF = 0.8988\left(\log \dot{\varepsilon}_d\right)^2 - 2.8255\left(\log \dot{\varepsilon}_d\right) + 3.4907 \quad \text{for} \quad 30s^{-1} \le \dot{\varepsilon}_d \le 1000s^{-1} \tag{6}$$

$$TDIF = \left(\dot{\varepsilon}_d / \dot{\varepsilon}_{ts}\right)^{\delta} \quad \text{for} \quad \dot{\varepsilon}_d \le 1s^{-1} \tag{7}$$

$$TDIF = \beta\left(\dot{\varepsilon}_d / \dot{\varepsilon}_{ts}\right)^{1/3} \quad \text{for} \quad \dot{\varepsilon}_d > 1s^{-1} \tag{8}$$

where δ=1/(1+8f_{cs}/f_{c0}), logβ=6δ-2, f_{cs} is the static compressive strength and f_{c0}=10MPa, $\dot{\varepsilon}_{ts} = 10^{-6}s^{-1}$.

The coarse aggregates in the present study are modelled by PSEUDO_TENSOR model (Mat_16). The DIFs of coarse aggregates used in the present study are obtained from (Hao and Hao 2013) and given below.

$$CDIF = 0.0187\left(\log \dot{\varepsilon}_d\right) + 1.2919 \quad \text{for} \quad 1s^{-1} \le \dot{\varepsilon}_d \le 220s^{-1} \tag{9}$$

$$CDIF = 1.8547\left(\log \dot{\varepsilon}_d\right)^2 - 7.9014\left(\log \dot{\varepsilon}_d\right) + 9.6674 \quad \text{for} \quad 220s^{-1} \le \dot{\varepsilon}_d \le 1000s^{-1} \tag{10}$$

$$TDIF = 0.0598\left(\log \dot{\varepsilon}_d\right) + 1.3588 \quad \text{for} \quad 10^{-6}s^{-1} \le \dot{\varepsilon}_d \le 0.1s^{-1} \tag{11}$$

$$TDIF = 0.5605\left(\log \dot{\varepsilon}_d\right)^2 + 1.3871\left(\log \dot{\varepsilon}_d\right) + 2.1256 \quad \text{for} \quad 0.1s^{-1} \le \dot{\varepsilon}_d \le 50s^{-1} \tag{12}$$

Because there are only very limited test data available, the tensile DIF is set to have a constant value when strain rate exceeds 50 1/s to avoid overestimation of aggregate strength.

The steel fibres are modelled by PIECEWISE_LINEAR_PLASTICITY material model (Mat_24) from the LS-DYNA database.

The pressure bars remain elastic in SHPB tests. Therefore they are modelled by the isotropic ELASTIC MATERIAL (Mat_1) in LS-DYNA. The parameters of the materials are listed in Table 4.

Table 4 Material parameters in numerical simulation

Material	Model in LS-DYNA	Input parameter	Value
Mortar matrix	MAT_72R3	Density	2200 kg/m^3
		Unconfined compressive strength	35 MPa
		Poisson's ratio	0.18
Coarse aggregate	MAT_16	Density	2750 kg/m^3
		Unconfined compressive strength	160 MPa
		Poisson's ratio	0.20
Steel fibre	MAT_24	Density	7800 kg/m^3
		Young's modulus	200 GPa
		Poisson's ratio	0.3
		Yield stress	1300 MPa
Pressure bar	MAT_1	Density	7800 kg/m^3
		Young's modulus	200 GPa
		Poisson's ratio	0.3

The components, i.e. coarse aggregates, spiral fibres and mortar matrix, are assumed to have perfect bonding in the mesoscale model. Erosion technique is adopted in the numerical simulation. An erosion criteria depending on the maximum principle strain of 0.2 is used for mortar matrix, aggregates and spiral fibres.

Mesoscale Numerical Model for SFRC

In the present study, mortar matrix, coarse aggregates and spiral fibres in the mesoscale model of SFRC specimen are distinctively simulated with the respective material properties. To simplify the model, coarse aggregates are assumed to have circular shape with random size and distribution. SFRC specimen is modelled with a 2D plane stress assumption (Hao et al. 2008). It is assumed that the fibre quantity and distribution are the same in every unit length along the specimen. The aggregate particle size distribution is assumed to follow the modified Fuller's curve proposed by Walraven (1981) for 2D modelling as below.

$$P\left(D < D_0\right) = P_k \begin{pmatrix} 1.065 D_0^{0.5} D_{\max}^{-0.5} - 0.053 D_0^{4} D_{\max}^{-4} - 0.012 D_0^{6} D_{\max}^{-6} \\ -0.0045 D_0^{8} D_{\max}^{-8} - 0.0025 D_0^{10} D_{\max}^{-10} \end{pmatrix} \tag{13}$$

where P is the cumulative percentage of aggregates passing a sieve with aperture diameter D, D_{max} is the maximum size of aggregate particle. The maximum diameter of aggregate particle is set to be 10 mm, then the aggregates are divided into four ranges with diameters of 2-4, 4-6, 6-8 and 8-10 mm, respectively.

Shell elements are used in the numerical model. The SFRC specimen in simulation has diameter of 75 mm with a unit thickness of 1 mm. The lengths of pressure bars are both 2000 mm. The striker bar and absorption bar are neglected in the numerical model. Instead, time-dependent nodal force is adopted as the boundary condition input at the end of the incident bar. The spiral fibres and coarse aggregates of different diameter ranges are generated with random location and orientation, with the avoidance of overlapping among fibres, aggregates and specimen boundaries (Chen et al. 2015). Fig. 5 gives an example of the developed SFRC specimen.

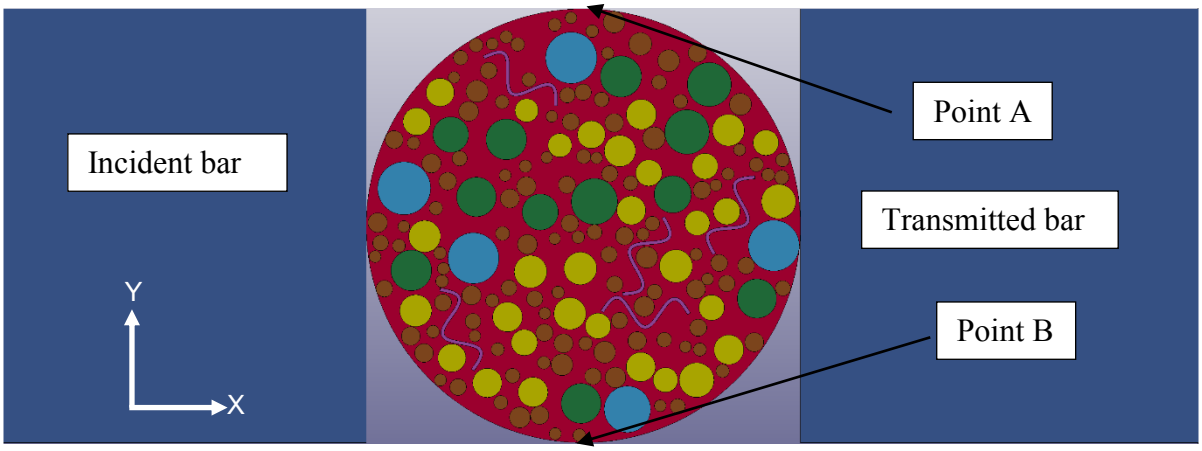

Figure 5 An example of generated mesoscale model of SFRC specimen

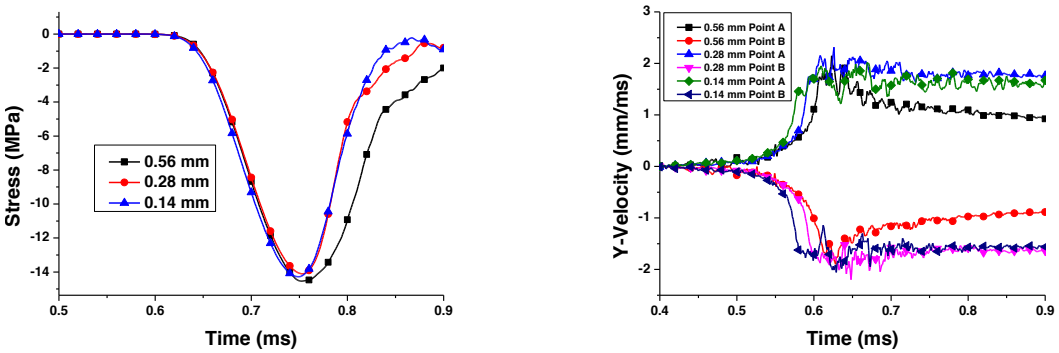
Mesh Convergence

To find the optimal mesh size that gives accurate numerical simulation results with efficient use of computational time, mesh convergence tests are carried out. The mesh sizes of 0.14 mm, 0.28 mm and 0.56 mm are considered in the mesh convergence tests. The incident stress wave in mesh convergence tests has the same shape of that in Fig. 3a, but a slightly lower peak of 55 MPa. According to Eqs. 1 and 2, the dynamic splitting tensile strengths are directly related to the transmitted stress wave. Therefore the simulated transmitted stress waves are compared. Moreover, the crack opening velocity of the tested specimen in dynamic splitting tensile tests is an important parameter to evaluate the crack control capability of the material. In numerical simulation, the Y velocity histories of the nodes with the maximum absolute Y coordinates, Points A and B as indicated in Fig. 5, are recorded to track the crack opening velocity. The numerically simulated crack opening velocities with different mesh sizes are also compared in mesh sensitivity analysis. The comparison of transmitted stress wave and crack opening velocity with different mesh sizes are illustrated in Figs. 6a and 6b, respectively. As shown, numerical simulation using mesh size of 0.28 mm gives very similar results compared to that with 0.14 mm mesh whereas the analysis using mesh size of 0.56 mm gives apparently different prediction of transmitted stress and crack opening velocities. Considering the accuracy and the efficiency in simulation, the finite element model with mesh size of 0.28 mm is used in this study.



(a) Transmitted stress (b) Crack opening velocity

Figure 6 Comparison of results from simulations using different mesh sizes

Comparison of Experimental and Numerical Results

The incident stress wave in Fig. 3a is used in the simulation to validate the developed numerical model. The comparison of stress histories from test and simulation is given in Fig. 7. It can be seen that the results from the test and numerical simulation match well. The numerical simulation gives reliable prediction of the responses, especially accurate peak transmitted stress as it is directly related to the splitting tensile strength, of SFRC specimen under dynamic splitting tension in SHPB tests.

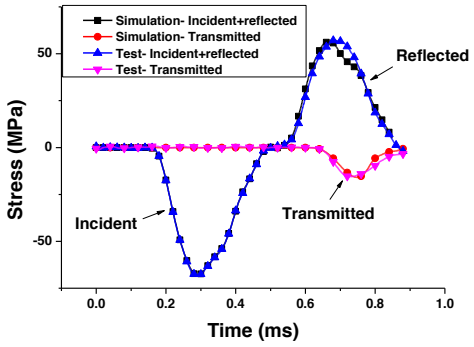


Figure 7 Comparison of stress histories obtained from test and numerical simulation

Parametric Simulations

To investigate the influence of volume fraction of spiral steel fibres on the DIF of SFRC materials, specimens with 1%, 2% and 3% spiral fibres are developed as shown in Fig. 8, and parametric simulations are carried out. The input stress waves in parametric simulations have the same duration but different peak stresses so that the strengths of SFRC specimens with different volume fractions of spiral fibres under different strain rates can be obtained.

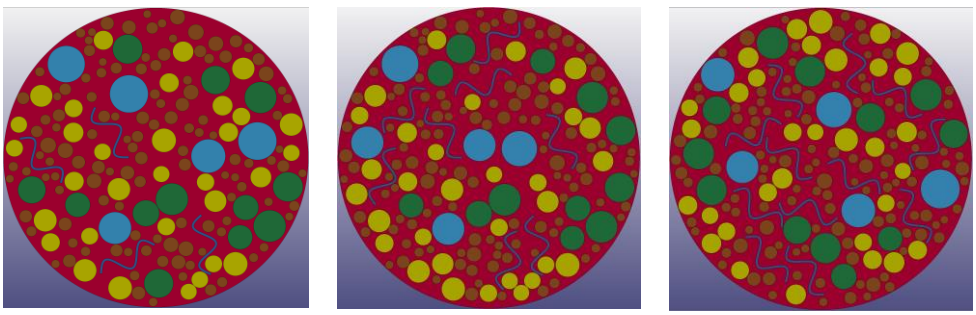

Figure 8 Specimens with 1%, 2% and 3% volume fractions of spiral fibres

Fig. 9 gives the obtained DIFs from simulations considering different volume fractions of spiral fibres. It can be seen that the DIFs of spiral fibre reinforced concrete specimens are sensitive to strain rate. This is because 1) the strength of concrete matrix is dependent on strain rate (Hao et al. 2013), and 2) the loading rate influences the pull-behaviour of steel fibres from concrete matrix (Banthia and Trottier 1991, Kim et al. 2009). Moreover, it is found that DIFs are dependent on the volume fraction of spiral fibres. This is because of the contribution to the specimen strength from individual fibres. The more fibres in the concrete mixture, the higher splitting tensile strengths the specimen will gain.

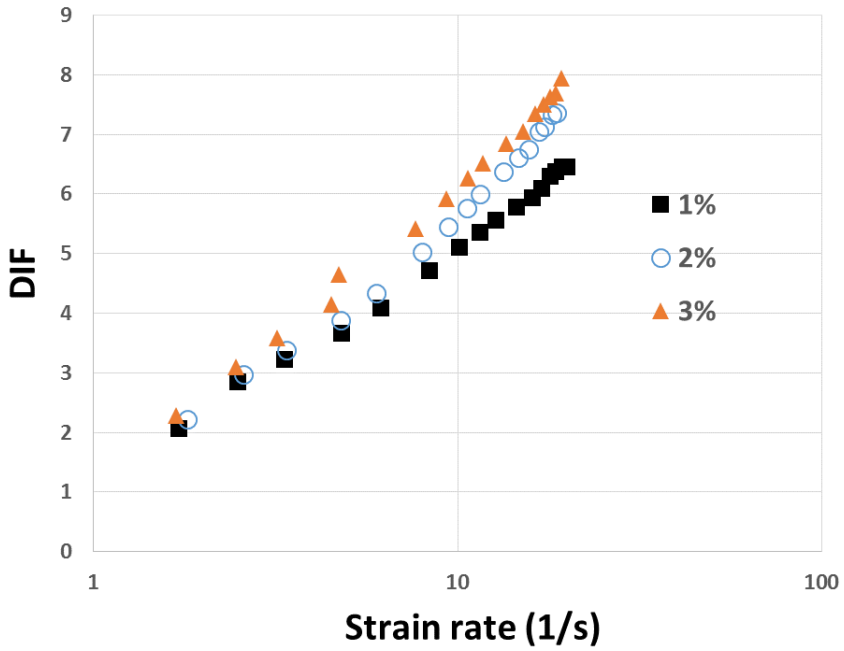

Figure 9 Comparison of DIFs from numerical tests

DISCUSSIONS AND CONCLUDING REMAKRS

Previous studies have indicated the superiority of using spiral steel fibres to reinforce concrete material and improve the ductility, crack control capability, impact load resistance and energy absorption capacity. A series of dynamic splitting tensile tests by means of SHPB are described and results presented in this study. A mesoscale model with distinctive consideration of mortar matrix, coarse aggregates and spiral fibres is developed and numerical simulations are carried out using 2D plane stress model. Mesh sensitivity analysis indicated that 0.28 mm mesh is able to yield satisfactory simulation results while assuring efficient computational effort. The numerical model is demonstrated to be able to accurately predict the behaviour of SFRC specimen in SHPB splitting tensile tests. SFRC specimens with 1-3% spiral fibres are considered in the parametric simulations. It is found that the DIFs of SFRC material are dependent on both the strain rate and fibre content.

It should be noted that different distributions of coarse aggregates and spiral fibres inevitably influence the simulation results to a certain extent. Besides, simulations in the present study are carried out with 2D plane stress model. Future studies with intensive numerical simulations with 3D mesoscale model considering randomly distributed coarse aggregates and fibres will be carried out to study the influences of random fibre and aggregate distributions on the SFRC material properties.

ABSTRACT

With the climate change, more and more extreme wind events such as cyclone take place around Australia and the world, which cause tremendous loss and damage. The wind speed has been reported constantly increasing with the climate change, which imposes more threats to building environments. The building envelopes are vulnerable to the windborne debris impact in a form of creating an opening in wall, roof, door, windows and screens, which leads to internal pressure increase and results in roof lifting up. The capacity requirements of wall or roof panels to resist windborne debris impact in cyclonic regions has been substantially increased in the 2011 Australian Wind Loading Code (AS/NZS 1170.2:2011) as compared to its previous version. The performance of commonly used structural panels in Australian Building Industry under the increased design wind speed needs be evaluated. Intensive laboratory tests and intensive numerical simulations on performances of typical structural panels subjected to windborne debris impacts have been carried out. This paper presents the results of one panel type, i.e., corrugated panel. The vulnerability curves of the corrugated panel with respect to the debris mass and impact speed are simulated. These results can be used in probabilistic loss estimations of structural panels in extreme wind events.

KEYWORDS

Fragility curve, structural panel, windborne debris impact

INTRODUCTION

In Australia, tropical cyclone is considered one of the major natural hazards, especially in Northern regions of Western Australia and Queensland. With the climate change, the wind speed has been increasing in Australia and the extreme wind events occur more frequently than before, which cause devastating losses. The post-storm investigations found that strong wind events generated enormous amount of windborne debris and the windborne debris impact was highlighted as a major cause of damage to building envelope components such as wall, window and roof (Minor and Behr 1994). Strong wind might blow up the debris from damaged structures, roof tiles, rafter and timber shank, which might penetrate the building envelope, imposing threats to people inside the building. It might also create an opening on the building envelope, and the opening would increase the pressure differentials outside and inside the building, which makes the envelope more vulnerable to collapse or lift-up. Therefore, the windborne debris is considered as a crucial factor to the performance of the building envelope in strong wind events.

The performance of structural panels subjected to windborne debris impact is greatly affected by various uncertainties including random variations in parameters of the panel and windborne debris. The windborne debris impact fragility curves of building envelope components are developed to provide probabilistic description of the impact resistance capacity of panels. Fernandez et al. (2010) presented an experimental investigation of the performance of metal shutter systems designed to protect windows from windborne debris such as roof tiles. It was found that the deflection of the metal panel window protection system was highly sensitive to impact location and also to debris type and impact orientation. Borges et al. (2009) simulated the interaction of contact of windborne debris traveling at a specific velocity against the metal shutters. The permanent and maximum deformations and stresses were evaluated to determine the most detrimental behavior of the storm shutter assembly by means of parametric studies. Herbin and Barbato (2012) derived the fragility curves corresponding to different damage measures for aluminium storm shutters subjected to windborne debris impact. Monte Carlo simulation (MCS) was used in combination with the finite element method in the analysis. It was found that the projectile kinetic energy at impact is a sufficient intensity measure for building envelope components with ductile behavior subjected to windborne debris impact, and the performance of storm panels in terms of penetration of windborne debris is critically dependent on the details of the panels' installation.

To obtain the fragility curves of the structural panels to windborne debris impact, intensive testing or numerical simulations are needed for probabilistic statistics. With the development of computer technology, numerical simulations are effective and reliable to simulate experimental testing with the advantages of saving time and cost. In the previous study (Chen et al. 2014; Chen and Hao 2014), laboratory tests on structural panels were conducted to simulate the windborne debris impact by using a pneumatic cannon testing system. The test data were used to calibrate the accuracy of the numerical model developed in finite element code LS-DYNA. The calibrated numerical model can then be used to conduct intensive numerical simulations to obtain the vulnerability curves of the structural panels to windborne debris impact. The numerical simulations are conducted to assess if the structural panel fails or services the windborne debris impact with randomly generated impact location, impact angle, debris mass, panel boundary conditions, and material properties. Latin Hypercube Sampling method (LHS) is used to accelerate the simulation convergence. The statistical results are graphed to produce the fragility curves with respect to the impact velocity. Owing to the page limit, this paper only presents the generated fragility curves for the corrugated panel, which is commonly used in Australian building industry. The proposed fragility curves can be used in probabilistic loss predictions of corrugated structural panels in strong wind events.

METHODOLOGY

The fragility curves of corrugated structural panels subjected to windborne debris impacts can be developed by using stochastic finite element method (SFEM) (Liu 2008). SFEM is a hybrid method which combines finite element simulations with the probabilistic methods such as Monte Carlo simulation (MCS), Latin Hypercube Sampling method (LHS), Rosenblueth point estimate method, perturbation method, Neumann expansion, Taylor expansion, or reliability-based methods etc. (Ghanem 2008). Monte Carlo simulation (MCS) is the most widely used means for uncertainty analysis. It is straightforward to use and can give reliable estimations of statistical parameters. However, it is extremely time consuming and needs a large amount of computational effort to get the converged estimation. Latin Hypercube Sampling (LHS) is one variant of standard Monet Carlo method. It was developed to address the need for uncertainty assessment. The random variable distributions, consisting of all the uncertain parameters, are divided into an equal ordered number of segments, with each interval representing an equal probability (Wyss and Jorgensen 1998). One variable with normally distributed Probability Density function (PDF) and the other one with uniformly distributed PDF can be divided into five segments each of probability 1/5. Once the segments have been determined, a value within each segment is randomly chosen for all variables, and each value is used exactly once and in a random permutation with each of the other variables (Wyss and Jorgensen 1998). The method is used in applications which involve numerical simulations to reduce the number of simulations required to produce a result with minimal bias. Generally, LHS requires fewer samples than direct Monte Carlo sampling for similar accuracy, which will be demonstrated in the convergence test.

In this study, the methodology used is based on the combination of deterministic finite element analysis using LS-DYNA and Latin Hypercube Sampling method (LHS), which is applied to study the probability of the response by accounting for various uncertainties and random variations of the panel and debris parameters. The accuracy and reliability of using LHS method is verified by using Monte Carlo simulation results.

NUMERICAL SIMULATION

Numerical Models

A numerical model was developed and calibrated by using commercial software LS-DYNA in the previous study (Chen et al. 2014). The tested corrugated panels had dimension of 1200*762 mm and was subjected to a 4kg wooden projectile impact at different locations and velocities by using pneumatic cannon. The finite element model of the tested corrugated panel is depicted in Figure 1.

The Belytschko-Tsay shell element with mesh size of 4mm is utilized to model the corrugated panel. The elastic-plastic material model *MAT PLASTIC KINEMATIC is adopted to model cold rolled stainless steel. The strain rate effect is taken into account by using the Cowper-Symonds model. The steel material properties such as Density, Young's modulus, Yield stress, Poisson's ratio and Hardening parameter are given as 7.85g/cm^3, 220GPa, 550MPa, 0.3 and 1, respectively. The 4kg hardwood projectile is modeled as solid element with linear elastic material model *MAT RIGID. The contact between the projectile and the specimen is defined by using *CONTACT ERODING SURFACE TO SURFACE with segment based contact option (i.e. SOFT=2).

SBOPT=3 & DEPTH=5, which undertake edge-to-edge checking (LSTC 2010). The model was proven yielded reliable predictions of responses of corrugated panels subjected to windborne debris impacts.

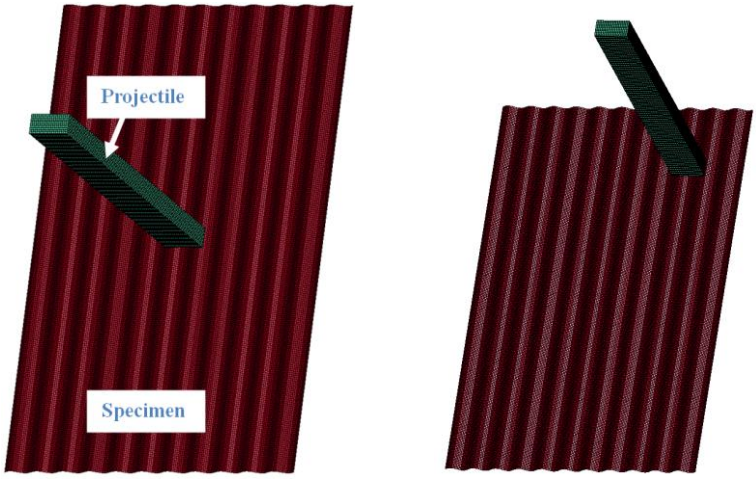

Figure 1 Numerical models (L) Impact at centre; (R) Impact at boundary

Parameters Considered

With the calibrated numerical model, parameters considered in the simulations to develop the fragility curves of corrugated panels include geometry of debris, debris mass, boundary conditions, impact angle, impact location and material properties of the panel, in particular the yield strength and Young's Modulus. All parameters are modeled as statistically independent random variables.

Debris geometry (rod; sheet; compact)

When built a model for describing the damage that might be put on to buildings by windborne debris, Wills et al.(2002) classified windborne debris into three types: compact-like (3D), plate-like (2D) and rod-like (1D) according to their shapes and dimensions. Lin et al. (2007) gave the examples for compact-like (e.g. roof gravels), plate-like (e.g. plywood, roof tile and roof shingle) and rod-like debris (e.g. timber shank). The classification has been accepted in many literatures that study the motion and effects of windborne debris. In addition, shingle was found among the most common source of debris in cyclones (Gao and Fatt 2013). Roofing tiles were observed to be the major windborne debris in Hurricane Andrew (1992). However, a projectile of 2 by 4 inches timber is still recommended as representative debris due to the difficulties to define a representative roof tile in modelling the windborne debris (Lin 2005). Numerical simulation results, which are not shown here owing to page limit, indicate that the panel is most vulnerable to rod-type debris impact among the three debris geometries. Since rod geometry is also the only, besides small steel ball which was found not critical to structural panels, debris geometry specified in the Australian Wind Loading code for assessing the safety of structural panels, in the present study, only rod type debris geometry is considered.

Debris mass (1 kg ~ 6 kg)

The windborne debris can be categorized as light-weight, medium-weight and heavy-weight according to their damage performance (Wright-Patterson Air Force Base, Ohio1976). Light-weight debris includes roof gravel, sheet metal panel and tree branches. Medium-weight debris includes timber planks and posts. Heavy debris includes poles, storage tanks and even automobiles. Minor (1994) identified the most prevalent windborne debris as small debris (such as roof gravel) and large debris (such as framing timbers). As specified in the Australian and American Standard (AS/NZS 2011; FEMA 2008; Florida Building Code 2010; ASTM2009), 4kg rod-type projectile with cross section of 2 by 4 inches has been widely used in design and testing of product qualification. It has been also used in the previous laboratory testing and the numerical model calibration. To create the fragility curves with random debris impacting, the rod-type debris mass varied between 1kg and 6kg (i.e. 1kg, 2kg, 4kg and 6kg) are initially considered. The projectile's lengths are changed accordingly. In this study, the debris mass is considered as a deterministic parameter, and fragility curves corresponding to the different debris masses are generated.

Boundary conditions (pinned or fixed)

The boundary condition is considered as pinned or fixed around the perimeter of the panel. It is also considered as deterministic with the fragility curves corresponding to each boundary condition independently generated.

Impact angle (0 ~ 90 degree; uniform distribution)

The impact angles are considered randomly varying in the range of 0 ~ 90 degree with a uniform distribution. The projectile is rotated about both the X and Z axes, i.e., in each simulation, two random angles are generated and used.

Impact location (region 1~9; uniform distribution)

The X and Y coordinates of the projectile impact location, defined as the impact location of the geometric center of the section of projectile, are modelled as uniformly distributed random variables. The impact location has been split into 36 regions, with 4 major regions and 9 sub-regions each, as shown in Figure 2. The debris impact location is randomly picked among the 36 sub-regions. For each region, the centre of the debris impacts the centre of each of the sub-regions. Since the panel is symmetrical, random impact regions can be shifted to one major region. For example, the effects of debris impacting region 1 would be the same as impacting regions 11, 21 and 31, which greatly simplify the simulation.

1	2	3	33	32	31
4	5	6	36	35	34
7	8	9	39	38	37
17	18	19	29	28	27
14	15	16	26	25	24
11	12	13	23	22	21

Figure 2 Diagram of regions of the panel

Material properties (yield strength and Young's Modulus; normal distribution)

The Young's modulus and yield strength of corrugated panel are considered as normally distributed random variables, while the Poisson's ratio and other mechanical properties are modeled as deterministic quantities. Due to the lack of statistical information regarding the material properties, the probability distribution and variance are selected based on the engineering judgment as shown in Table 1. They are assumed statistically independent of each other.

Table 1 Statistical characterization of material parameters

Zincalume AZ150 G550	Units	Mean	COV	Distribution
Density	Kg/m^3	7850	-	Deterministic
Poisson's Ratio	-	0.3	-	Deterministic
Young's Modulus	GPa	220	10	Normal
Yield Strength	MPa	550	10	Normal

Note: COV (coefficient of variance)

Convergence test

To verify the Latin Hypercube Sampling (LHS) method, a total of 120 stochastic FE simulations have been conducted by using the Monte Carlo (MC) method, followed by a number of 72 simulations by using the LHS method under the same conditions. As shown in Figure 3, the LHS method yielded a result of P (Failure) equal to 82% and the MC method yielded a result of P (Failure) equal to 79% and both approaches converged. Although LHS yielded a slightly different failure probability, it required less number of simulations, which

greatly saves computational time. Therefore, the LHS method is used to develop the fragility curves in the present study.

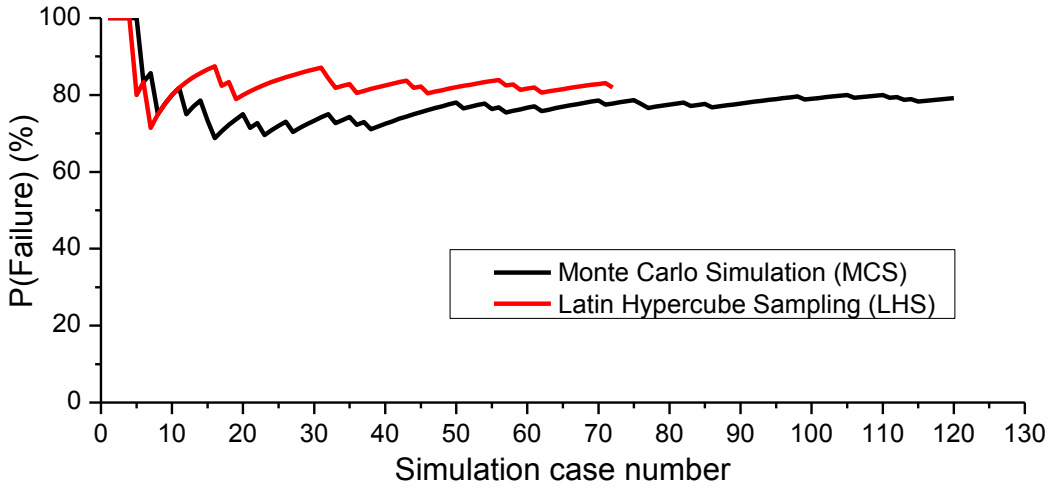

Figure 3 Convergence test results for MCS and LHS method

RESULTS AND DISCUSSIONS

During the intensive numerical simulations, two types of failure modes are observed, including debris penetrating the panel at center and torn failure at the boundary as shown in Figure 4. Intensive simulations have been conducted for corrugated panels with two boundary conditions subjected to impacts of debris of mass 1 kg, 2 kg, 4 kg and 6 kg at different impacting velocities. The simulation results are assessed based on either the panel failing or surviving, i.e., no opening is created, the impact. The convergence of each data point is checked to ensure the validity of the numerical data.

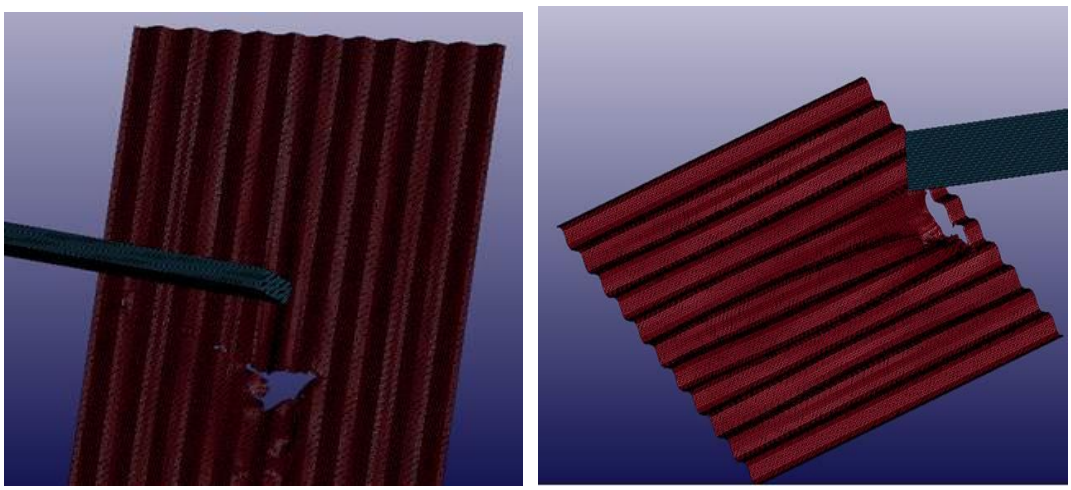

Figure 4 (L) Penetration failure at centre; (R) Torn failure at boundary

Figure 5 shows four fragility curves, each of which corresponds to different masses of rod type debris impacting a fixed panel. Figure 6 shows four fragility curves, each of which indicates the probability of failure of pinned corrugated panel subjected to impacts of debris with different masses. Since the largest possible impact velocity is about 44 m/s as defined in Australian Wind Loading code for region D with a 10,000 years return period (AS/NZS 2011), the simulations stopped at 45 m/s even 100% failure is not reached. As shown in Figure 5, the failure probability is about 84% and 95% when the fixed panel is subjected to the 1kg and 2 kg projectile impact at 45 m/s, respectively.

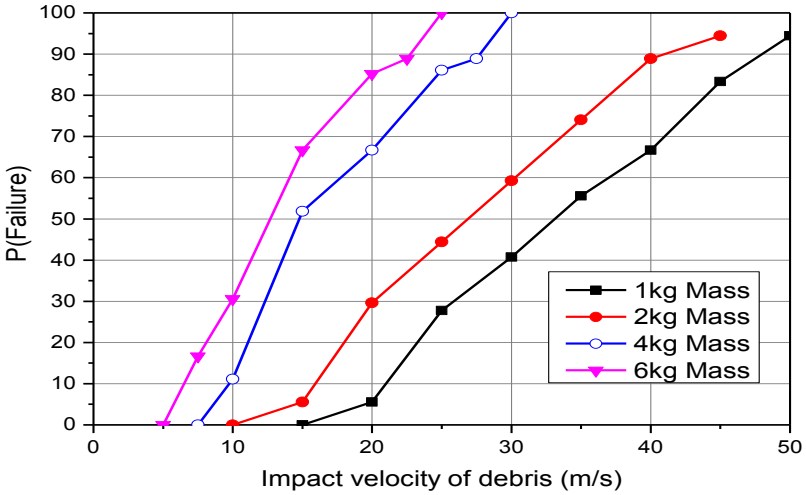

Figure 6 Fragility curve for a pinned panel subjected debris impact

CONCLUSIONS

This paper presents the development of fragility curves of corrugated structural panels subjected to windborne debris impacts. Finite element method together with Latin Hypercube Sampling (LHS) is used to perform intensive numerical simulations to construct the fragility curves of corrugated panels with either fixed or pinned boundary conditions subjected to impacts of debris of different masses with different velocities. Debris impact location, impact angle, as well as the panel material strength and elastic modulus are considered as random in the simulations. The results demonstrate that

1) The probability of failure increases with the debris mass and impact velocity as expected;
2) The impact location is a significant factor that affects the survivability of the panel. The panel is more vulnerable when impacted at locations closer to its boundary than at its center;
3) The fixed-boundary panel is more vulnerable than the panel with pinned boundary;

The fragility curves developed in this study can be used in the reliability analysis of corrugated panels subjected to windborne debris impact.

ABSTRACT

This paper presents an overview of how designers could undertake a displacement-based seismic assessment of rectangular reinforced concrete (RC) walls in accordance with Australian codes and standards. RC detailing in Australia generally results in a limited ductile RC structure and as such will be the focus of this paper. The various seismic performance objectives set out by Australian codes and standards are summarised herein. The paper will outline how a non-linear static pushover analysis could be performed in accordance with the Australian concrete structures standard to determine the force-displacement response curve of a rectangular wall. Mean stress-strain curves representing the actual performance of reinforcement and concrete are presented. The method presented for determining the force-displacement response curve is validated against large scale laboratory test results with very good correlation shown. The paper concludes with a parametric study of rectangular walls looking at how the overstrength and displacement ductility vary with changes in the axial load ratio, effective height, concrete strength and vertical reinforcement ratio.

KEYWORDS

Displacement-based design, reinforced concrete walls, RC walls.

INTRODUCTION

In the 90's there was extensive examination of the then current seismic design philosophy. Limitations and faults with force-based seismic design procedures were identified, and researchers and designers began considering and exploring new alternatives. Priestley (1993) authored a paper titled *Myths and Fallacies in Earthquake Engineering – Conflicts Between Design Reality* which identified and drew widespread attention to many of the problematic aspects of force-based seismic design. In the late 90's research into displacement-based seismic design began to start gaining serious momentum. *Direct Displacement-Based Seismic Design of Concrete Buildings*, written by Priestley and Kowalsky (2000), outlined the direct displacement-based design (DDBD) procedure for buildings and represented the first milestone in a gradual and not yet complete shift towards displacement-based seismic design. That paper was a precursor for the well-known text, *Displacement-Based Seismic Design of Structures* (Priestley, Calvi and Kowalsky 2007), which is internationally considered the authority on the subject matter.

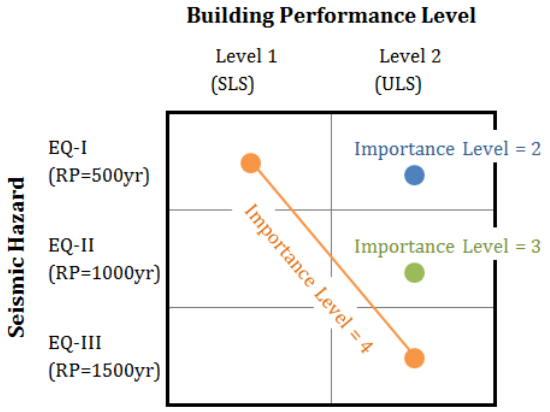
While there has been much work and research in developing displacement-based seismic design procedures, currently earthquake loading standards are still largely written around force-based seismic design procedures. The most recent version of the Australian earthquake loading code, AS 1170.4 (Standards Australia 2007) included a clause allowing designers to use displacement-based assessment procedures in Australia in the form of a non-linear static pushover analysis. AS 1170.4 does not however provide any guidance to the designer wishing to use this approach. The commentary to AS 1170.4 (Wilson and Lam 2007) provides designers with further explanation, in that it says this method of analysis can be used to either (a) determine the overstrength and displacement ductility values of the structure to be used in a force-based analysis or (b) assess the performance of the structure using the 'capacity spectrum method'. The first option allows for structure specific overstrength and ductility values to be assessed as opposed to using the default values given by the code. This overcomes one of the major criticisms of force-based analysis in that it is assumed all structures of a similar basic structural form and level of detailing possess the same level of overstrength and ductility (Priestley 2013; Priestley et al. 2007). The second option allows for the structure to be assessed using the capacity spectrum method, outlined in detail by Wilson and Lam (2007), where the earthquake performance of a structure is assessed by overlaying its capacity curve on an acceleration-displacement response spectrum (ADRS).

AIMS AND OBJECTIVES

This paper will present a procedure design engineers could use to assess the earthquake compliance of reinforcement concrete (RC) buildings in Australia using a displacement-based design approach; while complying with all relevant Australian codes and standards. The performance levels of structures required at different limit state loading scenarios in the relevant codes of practice are discussed, followed by an examination of the information required to perform non-linear analyses of RC walls in accordance with the Australian concrete structures standard, AS 3600 (Standards Australia 2009). A procedure will then be presented for undertaking a non-linear static pushover analysis without the need of a specialised finite element (FE) package. The focus of this paper will be limited ductile RC walls as they form the primary elements of the lateral load resisting system in the majority of low, mid and high-rise structures built in Australia.

CODE PERFORMANCE LEVELS

The Building Code of Australia (BCA) (Australian Building Codes Board 2014) outlines the earthquake loading requirements for buildings constructed in Australia. The BCA stipulates a return period of earthquake actions which buildings must be designed for based on their importance level. Buildings are assigned an importance level from 1 to 4 depending on their intended use: importance level 2 is for normal buildings; importance level 3 is for buildings that may contain large numbers of people; and importance level 4 is for buildings that are required for post-disaster recovery or may contain hazardous materials. In addition to the requirements of the BCA, AS 1170.4 requires importance level 4 buildings to undergo a special study to demonstrate they remain serviceable after an importance level 2 equivalent event. The intent of the latter, while it is not explicitly written in AS 1170.4, is that the building is operational following the event, with limited non-structural damage permitted; unlike a serviceability wind event where no damage, either structural or non-structural, should occur. Figure 1 outlines the earthquake performance criteria required by the BCA and AS 1170.4. Importance level 1 buildings are not discussed here because very few buildings or structures fall into this category.



Seismic hazard	Return period	Probability of exceedance
EQ-I	500 years	9.5% in 50 years 18% in 100 years
EQ-II	1000 years	4.9% in 50 years 9.5% in 100 years
EQ-III	1500 years	3.3% in 50 years 6.5% in 100 years

Figure 1 Australian earthquake performance criteria – design level earthquakes.

There are no documents that explicitly outline inter-storey drift limits for buildings in Australia at different performance levels. Although some standards do contain clauses stating an inter-storey drift limit for a specific level of performance. AS 1170.4 requires an inter-storey drift limit of 1.5 per cent for the ultimate limit state (ULS) performance of buildings. The commentary to the Australian concrete structures standard, AS 3600 Supp1 (Standards Australia 2014) says the inter-storey drift limit of concrete buildings under serviceability limit state (SLS) conditions should be 0.2 per cent. The latter recommendation however is only appropriate for wind loading where the SLS event is typically a 1 in 25 year return period event. For an earthquake SLS event (i.e. for importance level 4 buildings) an appropriate inter-storey drift limit would be 0.4 to 0.5 per cent. The inter-storey drift limits are summarised in Table 1.

AS 3600 specifies material strain limits for RC structures. It provides strain limits for ultimate limit state performance but does not provide any guidance for serviceability limit state performance. It stipulates that the ultimate compressive strain limit of concrete should be 0.003 when using the 'rectangular stress block' assumption. For advanced methods of analysis taking into account material stress-strain relationships AS 3600's only requirement for compressive strain limits is that "the strain in the compressive reinforcement does not exceed 0.003". No tensile strain limits are specified and hence tensile reinforcement strain limits can be taken as the ultimate strain of the reinforcement (ε_{su}). The strain limits are summarised in Table 2.

Table 1 Australian earthquake performance criteria – inter-storey drift limits.

Standard	Serviceability limit state (SLS)	Ultimate limit state (ULS)
AS 1170.4	–	1.5 %
AS 3600 Supp1	0.2 %	–
Recommendation by the authors for the seismic performance of importance level 4 buildings	0.4 to 0.5 %	1.5 %

Table 2 Australian earthquake performance criteria – AS 3600 material strain limits.

Material limit	Serviceability limit state (SLS)	Ultimate limit state (ULS)
Concrete	–	–
Compressive reinforcement	–	0.003
Tensile reinforcement	–	ε_{su}

While AS 3600 does not place a strain limit on the tensile reinforcement, the reinforcement in walls subject to cyclic lateral load is generally unable to develop its ultimate tensile strain without low cycle fatigue or local buckling failures occurring prior. Sullivan, Priestley and Calvi (2012) recommend Eq. 1 for the tensile limit of reinforcement under ULS equivalent loading. Priestley et al. (2007) stipulates that for vertical reinforcement to achieve the tensile strains expressed by Eq. 1 without the bars buckling they need to be restrained by ligatures at a maximum spacing of $s = (3 + 6(f_{su}/f_{sy}))d_b$, where d_b is the bar diameter of the vertical reinforcement.

$$\varepsilon_{s.uls} = \max[0.6\varepsilon_{su}; 0.05] \quad (1)$$

RC walls constructed in Australia typically have non-ductile detailing without confinement reinforcement (i.e. ligatures). Typical detailing consists of a mat of equal sized and spaced vertical and horizontal bars each face with extra 'U' bars at the ends of walls and around openings. The authors are currently undertaking experimental testing to better understand the maximum strain the vertical reinforcement in limited ductile RC walls can undergo prior to bar buckling occurring. The current testing suggests reinforcement strains can exceed 3 per cent prior to the onset of this behaviour. For the moment a tensile strain limit of 0.03 is being recommended.

MEAN STRESS-STRAIN CURVES

AS 3600 requires all non-linear analysis methods to use "mean values of all relevant material properties" and AS 3600 Supp1 further states that for "non-linear and other refined methods of analysis, actual stress-strain curves, using mean rather than characteristic values, should be used". AS 3600 provides guidance to what the mean in-situ strength of concrete is but no guidance is provided to what a suitable mean stress-strain response curve of reinforcement is. Menegon et al. (2015) have recently undertaken a study to determine the mean properties of reinforcement complying with AS/NZS 4671 (Standards Australia and Standards New Zealand 2001). Bilinear stress-strain curves were recommended for the expected (i.e. mean) response of D500L, D500N and D500E reinforcement. These curves were based off the tensile test results of over 6,000 rebar samples obtained from an independent materials testing laboratory that is contracted by industry suppliers to test and ensure code compliance of their rebar. The values for constructing the bilinear stress-strain curves are summarised in Table 3. The bilinear stress-strain curve for D500N reinforcement – the typical and most commonly used grade of reinforcement in Australia – that is recommended for use in non-linear analyses is shown in Figure 2.

Table 3 Mean properties of reinforcement (Menegon et al. 2015).

Grade	Yield stress (f_{sy})	Ultimate stress (f_{su})	Ultimate strain (ε_{su})
D500L	585 MPa	620 MPa	3.3 %
D500N	550 MPa	660 MPa	9.5 %
D500E	530 MPa	660 MPa	13 %

Menegon et al. (2015) also provide a discussion as to what the long term in-situ strength of concrete is. With reference to Neville (1996), they recommended there is no long term strength gain of in-situ concrete. This is in contrast to continuously moist cylinder samples which continue to strengthen somewhat indefinitely. The mean in-situ strength of concrete (f_{cmi}) is taken to be 90 per cent of the mean strength of concrete (f_{cm}) as per the recommendations in AS 3600 and AS 3600 Supp1 (Eq. 2). AS 3600 Supp1 recommends a modified version of the Thorenfeldt, Tomaszewicz and Jensen (1987) model for the unconfined stress-strain response of normal and high strength concretes. It has been modified to suit Australian concretes and is shown in Eq. 3. The modified Thorenfeldt et al. (1987) model is shown in Figure 2 for standard grades of concrete used in RC walls.

$$f_{cm} = (1.2875 - 0.001875 f_c')f_c' \tag{2}$$

$$f_c = f_{cmi}\left[\frac{n(\varepsilon_c/\varepsilon_{co})}{n-1+(\varepsilon_c/\varepsilon_{co})^{nk}}\right] \tag{3}$$

Where: ε_c is the concrete strain; ε_{co} is the concrete strain corresponding to the maximum compressive stress and is taken as $4.11 f_{cmi}^{0.75}/E_c$; $n = E_c/(E_c - E_{sec})$; E_c is the modulus of elasticity specified by AS 3600, i.e. 30100, 32800, 34800 and 37400 for N32, N40, N50 and S65 concrete grades respectively; E_{sec} is the secant modulus of elasticity and is equal to f_{cmi}/ε_{co}; When $\varepsilon_c \le \varepsilon_{co}$, $k = 1$ and when $\varepsilon_c > \varepsilon_{co}$, $k = 0.67 + \varepsilon_{co}/62 \ge 1.0$.

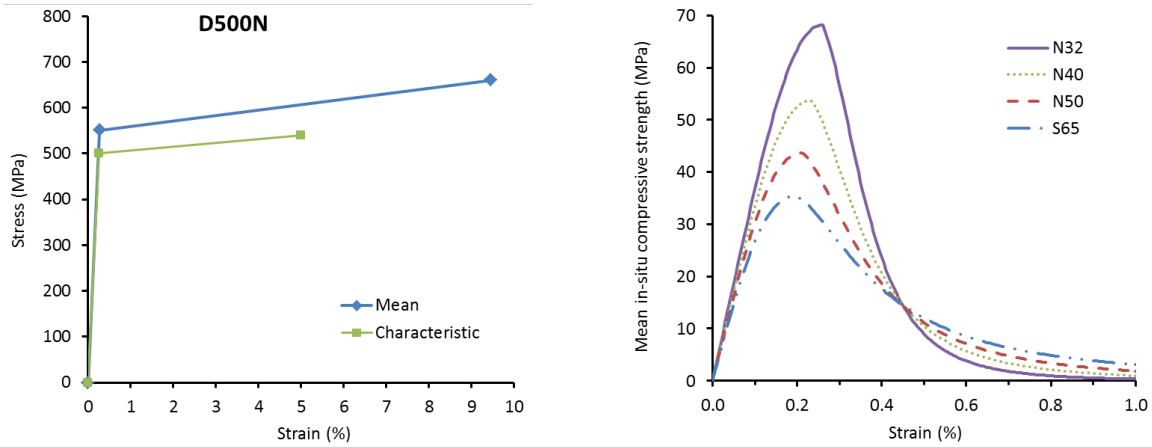


Figure 2 LEFT: Mean and characteristic stress-strain curves of D500N reinforcement. RIGHT: Mean in-situ unconfined stress-strain curves for standard grades of concrete used in RC walls.

NON-LINEAR STATIC PUSHOVER ANALYSIS

The capacity curve (i.e. force-displacement response) of a limited ductile RC wall can be determined by firstly undertaking a moment-curvature analysis of the section. The force-displacement response is then calculated from the moment-curvature response based on the height of the wall and the concept of a plastic hinge, where over a plastic hinge length (L_P) a uniform curvature distribution equal to the maximum curvature of the wall is assumed (refer Figure 3). The process explained herein is for slender RC walls that are dominated by flexural actions, i.e. the overall height to length ratio is greater than two to three.

Lam, Wilson and Lumantarna (2011) presented a method for determining the moment-curvature response of a section using Microsoft Excel spreadsheets. This approach enables designers to determine the complex non-linear behaviour of cracked RC members without the need for any specialised software packages (e.g. Response-2000 (Bentz and Collins 2001)). The material stress-strain relationships presented in the previous section are recommended for undertaking moment-curvature analyses on RC structures built in Australia. The non-linear moment-curvature response of the section can be simplified to an approximate bilinear response curve. This is done by projecting a line from the origin through the point of the response curve corresponding to the notional yield curvature (ϕ_y') and up to the point corresponding to the yield curvature (ϕ_y) of the section. The corresponding moment value at this location is the nominal moment capacity (M_n). A straight line is then projected from this point to the point corresponding to the ultimate curvature (ϕ_u) of the section (refer Figure 4).

With reference to AS 3600, where applicable, and Priestley et al. (2007) the following criteria is being recommended. The notional yield curvature (ϕ_y') is taken as the point corresponding to the first yield of the extreme tensile reinforcement (i.e. $\varepsilon_s = \varepsilon_{sy}$) or the maximum compressive stress being reached in the extreme compressive fibre (i.e. $\varepsilon_c = \varepsilon_{co}$), whichever occurs first. The yield curvature (ϕ_y) is taken as the point

corresponding to the strain in the extreme tensile reinforcement reaching 0.015 or the maximum compressive stress of the concrete being reach in the extreme compressive fibre (i.e. $\varepsilon_c = \varepsilon_{co}$), whichever occurs first. The concrete strain limit for the yield curvature and notional yield curvature are taken as the same value because confinement ligatures are not used in RC walls in Australia (typically). The ultimate curvature (ϕ_u) is taken as the point corresponding to the tensile reinforcement reaching 0.03 (as discussed in a previous section) or the strain in the extreme compressive vertical reinforcement reaching 0.003, whichever occurs first. The slope of the elastic branch of the bilinear relationship is equal to $E_c I_{eff}$ and as such the effective second moment of area (I_{eff}) of the wall can be calculated using Eq. 4.

$$I_{eff} = \frac{M_n}{E_c \phi_y} \qquad \text{OR} \qquad I_{eff} = \frac{M_y}{E_c \phi'_y} \tag{4}$$

The bilinear moment-curvature response can be converted to force-displacement using the process and equations proposed by Priestley et al. (2007) shown by Eqs 5 through 8. That is, the yield displacement (Δ_y) is calculated using the maximum yield curvature at the base and assuming a linear curvature distribution up the height of the wall. The ultimate displacement (Δ_u) is calculated using the plastic hinge concept as is illustrated in Figure 3. The plastic hinge length incorporates a strain penetration length (L_{sp}) of the starter bars into the supporting element below the wall. Priestley et al. (2007) provide a detailed explanation to why integrating the actual curvature distribution of an RC wall (i.e. using first principles of structural mechanics) does not produce displacement values that agree well with experimental tests.

$$F = \frac{M}{H_e};\ F_y = \frac{M_y}{H_e};\ F_n = \frac{M_n}{H_e};\ F_{max} = \frac{M_{max}}{H_e} \tag{5}$$

$$\Delta_y = \frac{\phi_y (H_e + L_{sp})^2}{3} \tag{6}$$

$$\Delta_u = \Delta_y + (\phi_u - \phi_y) L_p \left[H_e - \left(\frac{L_p}{2} - L_{sp} \right) \right] \tag{7}$$

$$L_p = k H_e + 0.1 L_w + L_{sp} \tag{8}$$

Where: H_e is the effective height of the wall and can be taken to equal 70 per cent of the overall height of the wall: L_{sp} is the strain penetration and can be taken to equal $0.022 f_{sy} d_b$; L_w is the wall length; and $k = 0.2(f_{su}/f_{sy} - 1) \leq 0.8$. (Priestley et al. 2007).

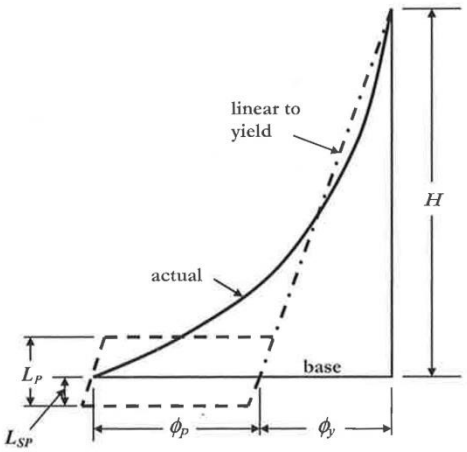

Figure 3 Idealisation of curvature distribution (Priestley et al. 2007).

After constructing a force-displacement response curve, overstrength and ductility factors can be determined. The overstrength factor (Ω) is taken to be the maximum force capacity of the structure (F_{max}) divided by the ultimate force capacity calculated in accordance with AS 3600 ($\phi F_u = \phi M_u / H_e$), i.e. $\Omega = F_{max}/\phi F_u$. Note in this instance ϕ is a capacity reduction factor which is used in ULS design to Australian material standards. AS 1170.4 accounts for the overstrength by the use of the structural performance factor (S_p), where $S_p = 1/\Omega$ (Wilson and Lam 2007). The displacement ductility is determined using Eqs 9 and 10.

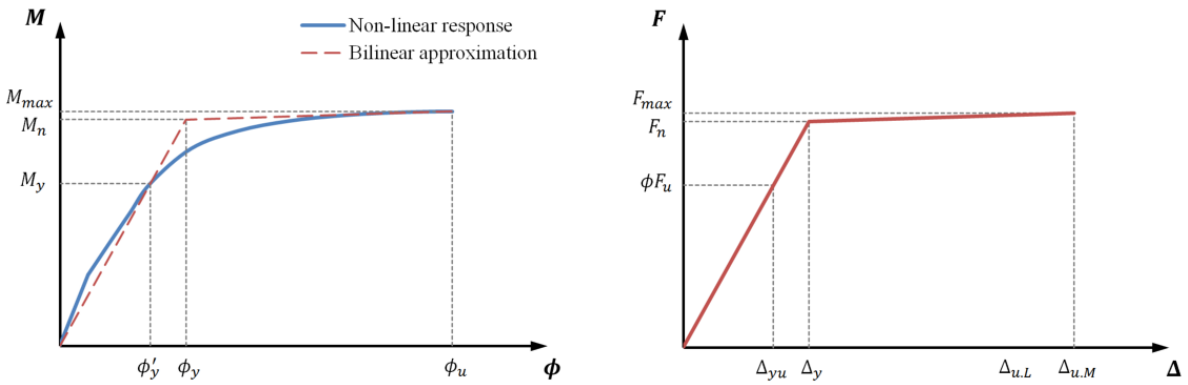

Figure 4 LEFT: Non-linear moment-curvature response with bilinear approximation.
RIGHT: Bilinear force-displacement response

$$\mu_\Delta = \frac{\Delta_u}{\Omega\Delta_{yu}} \tag{9}$$

$$\Delta_{yu} = (\phi F_u)\left(\frac{\Delta_y}{F_n}\right) \tag{10}$$

The effective stiffness of the wall (k_{eff}) can be calculated by dividing the nominal force capacity by the yield displacement, i.e. $k_{eff} = F_n/\Delta_y$.

The process outlined so far yields a bilinear force-displacement response curve for an RC wall. Priestley et al. (2007) also offers another approach to determine a 'refined' force-displacement response curve; expressed by Eqs 11 to 13.

$$\textbf{Cracking:} \quad \Delta_{cr} = \frac{\phi_{cr} H_e^2}{3} \quad \text{and} \quad F_{cr} = \frac{M_{cr}}{H_e} \tag{11}$$

$$\textbf{First yield:} \quad \Delta'_y = \frac{\phi'_y (H_e + L_{sp})^2}{3} \quad \text{and} \quad F_y = \frac{M_y}{H_e} \tag{12}$$

$$\textbf{After yield:} \quad \Delta_{cr} = \Delta'_y \left(\frac{M}{M_y}\right) + \left[\phi - \phi'_y \left(\frac{M}{M_y}\right)\right] L_p \left[H_e - \left(\frac{L_p}{2} - L_{sp}\right)\right] \quad \text{and} \quad F = \frac{M}{H} \tag{13}$$

To assess the accuracy of the outlined approach with the material stress-strain curves suggested (i.e. bilinear model for reinforcement and AS 3600 Supp1 for concrete), a validation against an experimental laboratory test of a large scale RC wall was performed. There has been many experimental laboratory studies undertaken worldwide looking at the in-plane lateral loading behaviour of RC walls. Unfortunately the majority of these studies have either (a) studied the behaviour of ductile RC walls (i.e. walls with confinement reinforcement in the end compressive regions of the walls) or (b) been performed on squat RC walls where shear behaviour dominants the response. Very few studies have looked at the flexure response of slender limited ductile RC walls. Dazio, Beyer and Bachmann (2009) recently undertook an experimental study that included one test wall that almost exactly matched the detailing and construction practices in Australia. The test wall was 2000 mm long, 150 mm thick and had an aspect ratio of approximately 2.3. The reinforcement had similar stress-strain properties to Australian reinforcements and the wall was tested with an axial load ratio of about 4 per cent. The cross section of the test wall is shown in Figure 5.

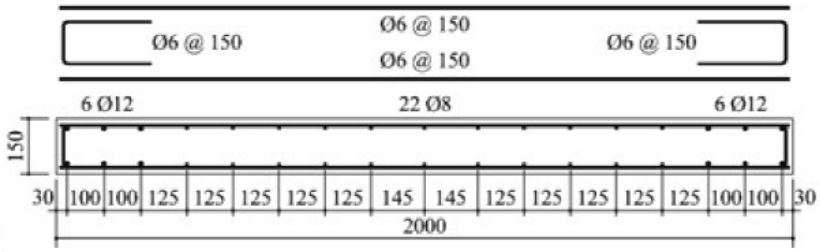

Figure 5 Dazio et al. (2009) test specimen WSH4.

The wall was initially analysed using the 'refined method' proposed by Priestley et al. (2007), as outlined previously, using the AS 3600 Supp1 unconfined concrete stress-strain model. The theoretical curve almost exactly matches the enveloped cyclic behaviour of the wall, about up to the point where the compressive strain in the reinforcement reaches 0.003. After which the theoretical model slightly underestimates the performance, as shown in Figure 6. The analysis was repeated using the classical Mander, Priestley and Park (1988) confined concrete stress-strain model. It was calculated that the 'U' bars at each of the wall would provide a small amount of lateral confinement of 0.5 MPa – calculated in accordance with equations proposed by Mander et al. (1988) for lateral confinement – which results in an increase in compressive strength of approximately 6 per cent. It can be seen in Figure 6 that the predicted response up to the compressive strain limit being reached is almost identical between the models, however following this point the Mander et al. (1988) model more accurately predicts the response of the test wall.

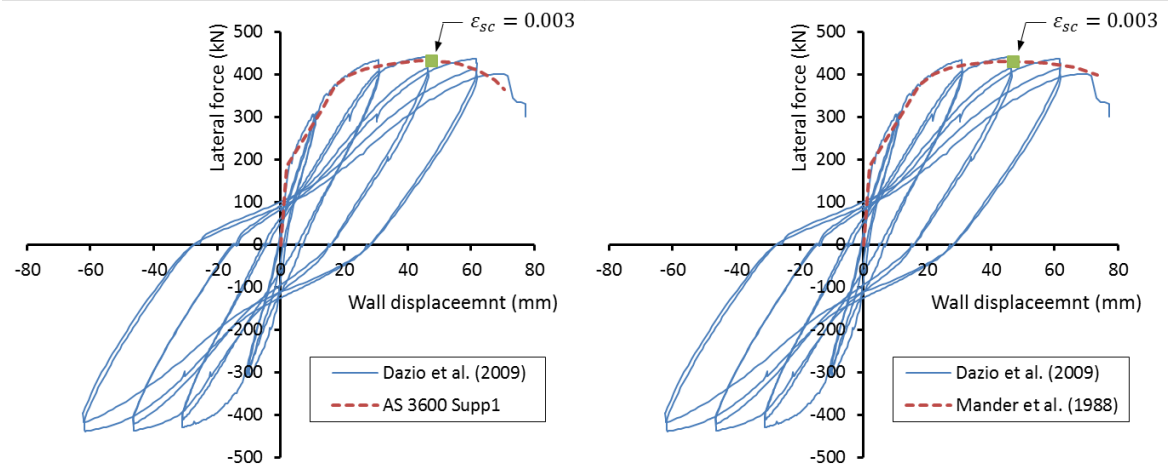

Figure 6 Comparison of the experimental and theoretical force-displacement response for wall specimen WSH4 using (a) the AS 3600 Supp1 unconfined model and (b) the Mander et al. (1988) confined model.

The AS 3600 Supp1 unconfined concrete stress-strain model is being recommended for general use in modelling limited ductile RC walls for a variety of reasons, including:

1. Ultimate response to AS 3600 limits the compressive reinforcement strain to 0.003 and at this level of performance there is no observable difference between the results from the two stress-strain models.
2. While is it extremely common for RC walls in Australia to be detailed with 'U' bars in the end regions of walls, it is not a codified requirement and hence some walls do not have them. This would effectively eliminate the added performance on the post peak branch of the response curve.
3. The AS 3600 Supp1 model yields only slightly more conservative values beyond the compression reinforcement strain limit of 0.003 and so the added complexities of using the confined Mander et al. (1988) model are generally not justified.

SENSITIVITY STUDY

Part of the requirements of undertaking a non-linear analysis to AS 3600 is the designer must allow for variability of material properties. The commentary, AS 3600 Supp1 states that the results of a non-linear analysis should be checked by undertaking a sensitivity study where the designer runs a series of analyses "in which the key input variables are altered systematically". This activity was performed for a typical rectangular wall that was 3000 mm long and 250 mm thick with a concrete grade of N40, axial load ratio of 5 per cent and a vertical reinforcement ratio of 1.1 per cent.

The parameters which were varied included: the yield and ultimate stress of the reinforcement; the ratio of the ultimate to yield stress of the reinforcement; the ultimate strain of the reinforcement; the axial load on the wall; and the in-situ compressive strength of the concrete. An initial analysis was performed using the mean values for all the parameters, as discussed previously. Additional analyses were performed where each of the parameters was changed from the mean value to the lower and upper characteristic values. Except for the axial load on the wall, this was varied by plus or minus 20 per cent. No more than 2 parameters were changed at once. The results of the study can be seen in Figure 7. The ultimate curvature varied from 16 per cent smaller to 20 per cent higher than the mean response reference value and the corresponding moment varied from 7 per cent smaller to 9 per cent higher than the mean response reference value.

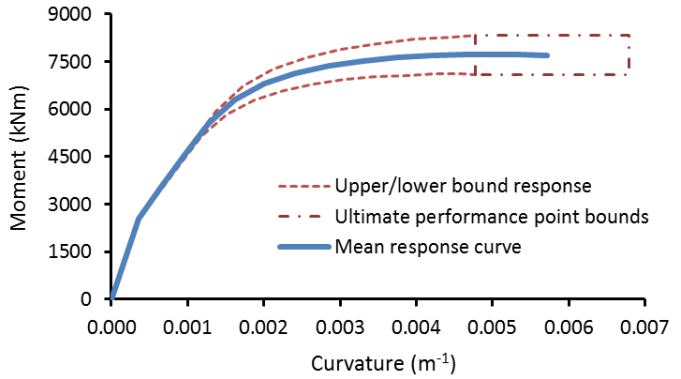

Figure 7 Sensitivity study: moment-curvature results.

It can be seen that for the rectangular wall used in the study changing the individual material properties of either the reinforcement or concrete, or varying the axial load, does not greatly affect the overall performance of the wall. It is important to note that using the criteria proposed in this paper generally results in the ultimate performance of limited ductile rectangular RC walls being governed by the compressive strain limit being developed in the compression reinforcement. As such the ultimate tensile strain of the reinforcement used in the analysis does not affect the performance of the wall; changing the mean ultimate strain (9.5 per cent) to the lower or upper characteristic values of 5.75 and 13.18 per cent respectively had no observable effect on the ultimate curvature. This is in contrast to sections with a large compressive flange (i.e. 'T' sections or box-shaped lift cores) where the tensile strain in the tension reinforcement is generally the limiting criteria. For these sections varying the ultimate strain of the reinforcement can have very dramatic effects on the ultimate displacement and displacement ductility of the section, as shown by Menegon et al. (2015).

PARAMETRIC STUDY

A parametric study using the non-linear static pushover analysis method presented earlier was performed to better understand the overstrength and displacement ductility of limited ductile rectangular RC walls. Initially two walls were considered; one being 3000 mm long and 250 mm thick and the other being 5000 mm long and 250 mm thick. Both walls had an axial load ratio of 5 per cent, an effective height of 25 m, a vertical reinforcement ratio of 1.4 per cent and a concrete grade of N40. After determining the overstrength and displacement ductility of these two baseline walls, each of the four aforementioned parameters were varied and the new overstrength and displacement ductility values were calculated. The results are shown in Figure 8.

It was observed that the displacement ductility generally decreases with an increase in the axial load ratio, effective height or vertical reinforcement ratio of the wall. Increasing the concrete strength seems to slightly increase the ductility; however this increase in ductility has a corresponding slight decrease in overstrength. The only parameter which appears to significantly affect the overstrength is the axial load ratio of the wall and is largely due to the capacity reduction factor used in ULS design to AS 3600, which equals 0.8 when a wall is in pure bending and decreases to 0.6 when the axial load equals the balanced load of the wall.

For limited ductile RC walls AS 1170.4 recommends an overstrength value of 1.3 and a displacement ductility value of 2. The combination of the two parameters (i.e. $\Omega\mu_\Delta$) forms the reduction factor used in force-based seismic analysis and in this cause equals 2.6. The overstrength was generally 5 to 20 per cent higher than the value of 1.3 proposed by AS 1170.4. In contrast, the displacement ductility was calculated to be between approximately 1.2 and 1.6, which is less than the value of 2 proposed by AS 1170.4. This results in the reduction factor (i.e. $\Omega\mu_\Delta$) being constantly less than 2.6. It should be noted here that failure in this instance is typically the AS 3600 compressive reinforcement strain limit being reached, not axial load failure of the wall (i.e. collapse).

The walls with an effective height of 25 m (e.g. a wall in an 8 to 12 storey building) had an ultimate displacement that was always greater than 250 mm (refer Figure 9). The peak displacement demand (PDD) of the AS 1170.4 response spectrum on a 'very soft soil' site (i.e. class E_e) for a typical ULS earthquake (i.e. RP = 500 years) in Melbourne or Sydney is 90 mm. The latest amendment of AS 1170.4 (in press) requires a multiplication factor of 1.5 to the displacement demand when performing displacement-based assessments, resulting in a PDD of 135 mm. This value can then be multiplied by 1.6 to account for any torsional response of asymmetric floor plans (Lumantarna, Lam and Wilson 2013). This results in a 'worst case' displacement demand for an ULS event of 216 mm. Indicating automatic code compliance for all of these walls, despite the displacement ductility being less than the value of 2 given in AS 1170.4.

CONCLUSION

This paper has presented a design procedure practicing structural engineers could potentially use to undertake a displacement-based seismic assessment of rectangular limited ductile RC walls, in accordance with AS 1170.4 and AS 3600. A non-linear static pushover analysis and mean stress-strain curves of concrete and reinforcement have been presented. The analysis procedure has been validated against a large scale experimental laboratory test of a limited ductile RC wall. A preliminary sensitivity study has been presented and indicates that varying the material properties of reinforcement and concrete does not greatly affect the performance of rectangular walls. A parametric study was undertaken to better understand how the overstrength and displacement ductility of these walls vary with respect to axial load ratio, effective height, vertical reinforcement ratio and concrete strength. It was shown the overstrength was always greater than the value of 1.3 given in AS 1170.4, whereas the displacement ductility was much less than the codes value of 2.

ABSTRACT

Concrete structures are exposed to high temperatures during fire. Bothe the mechanical properties and durability after exposed to elevated temperatures are of great importance in terms of the serviceability of buildings. In this project, the effects of elevated temperatures (20, 100, 200, 300, 400, 500 and 600 ℃) on the compressive strength, elastic modulus, fracture energy, water capillary absorption and chloride penetration have been studied. The influence of cooling methods on these properties has been also investigated. The results obtained indicate that when the temperature is below 400 ℃ for concrete A (W/C=0.4) and 300 ℃ for concrete B (W/C=0.5) with natural cooling, the compressive strength did not decrease immediately. But with water splashing cooling, the compressive strength of concrete lost approx. 20 % at 300 degree. The elastic modulus of concrete decreased gradually with the increasing of temperature. And there is no real difference between two types of cooling methods. When the temperature is over 400 degree only, the fracture energy decreased significantly. After exposed to elevated temperatures, concrete absorbed much more water and chloride ions, which bring a high risk for RC structures. This effect shall also be taken into consideration when concrete structures after fire is evaluated.

KEYWORDS
Elevated temperature, concrete, compressive strength, elastic modules, fracture energy, water capillary absorption, chloride penetration

INTRODUCTION

Concrete is used extensively throughout the world. The applications of such concretes are increasing day by day due to their superior structural performance, environmental friendliness, and energy-conserving implications (Mehta 1999). Apart from the usual risk of fire, these concretes are exposed to high temperatures and pressures for considerable periods of time in the abovementioned industries. Although concrete is generally believed to be an excellent fireproofing material, many recent studies have shown extensive damage or even catastrophic failure at high temperatures (Phan 1996). The mechanical properties such as strength, modulus of elasticity and volume stability of concrete are significantly reduced at high temperatures. This may result in undesirable structural failures (Ali *et al*. 2004; Janotka and Nurnbergerova 2005; Sanad *et al.* 2000; Cioni *et al.* 2001; Poon *et al.* 2004; Georgali and Tsakiridis 2005). Most researchers believe that the concrete compressive strength increases at around 200□; at about 400□, it begins to decay and 400~800□ temperature ranges is the major loss of strength which is 400~600□ strength decreases fastest segment (Poon *et al.* 2001; Peng *et al.* 1999; Li *et al.* 2002; Ghan *et al.* 1999).

The repair and reinforcement of concrete structures after fire is generally based on the evaluation of mechanical properties. But in fact, the durability of concrete materials after exposed to elevated temperatures decreases more significantly than that of mechanical properties (Yan *et al.* 2005; Sun *et al.* 2003). In recent years, the deterioration of durability of concrete after elevated temperatures has been concerned by the engineering field. However, the experimental research in this field is rare. Therefore in this project, the effect of elevated temperatures both on the mechanical properties, water capillary absorption and chloride penetration of concrete were studied in particular.

MATERIALS AND METHODS

Materials and Preparation of Test Specimens

The specimens were prepared with two types of concrete. The compositions of the two types of concrete are shown in Table 1. Ordinary Portland cement type 42.5, crushed limestone with a maximum grain size of 25 mm and river sand with a maximum grain size of 5 mm were used. Cubes with the side length of 100 mm and prisms with the dimensions of 100 mm × 100 mm × 515 mm were prepared. All the samples were demolded after 24 hours and then stored in a humid room with RH ≥ 95 % and temperature of 20 ± 2 ℃ until they have reached an age of 28days.

Table 1 Mixture proportion of the concrete (kg/m^3)

	Cement	Sand	Gravel	Water	Superplasticizer
A (W/C=0.4)	380	579.1	1269	152	4.9
B (W/C=0.5)	320	653	1267	160	3.8

Elevated Temperature and Cooling Methods

The specimens were taken out from the curing room after 28 days and placed in a room with temperature of 20 □ and humidity of 50 % for 7 days. After that, the specimens were put in the oven and were heated up to 100, 200, 300, 400, 500, 600, 700 and 800 □, respectively, for three hours. Then the specimens were taken out of the oven to cool them down. The cooling methods include natural cooling in the lab climate and fast cooling by splashing water on the specimens' surfaces. For the two types of cooling methods, it is denoted by '-N' for natural cooling in the air and '-W' for water splashing cooling, respectively, in the following text.

Measurements of Mechanical Properties

After cooling down by natural cooling or water splashing cooling, the compressive strength of specimens exposed to different temperatures were measured. In each case, the compressive strength was the average value of three samples. In the meantime, the relative elastic modulus of concrete specimens before and after exposed to elevated temperature had been measured by ultrasonic method. When the ultrasonic wave encounters defects that exit in concrete due to elevated temperature, the transmission will be slowed down. Therefore, the internal defects of concrete can be evaluated by measuring the velocity of ultrasonic wave in concrete. The dynamic elastic modulus can be then calculated by Eq. 1.

$$E_{\mathrm{d}} = \frac{(1+\upsilon)(1-2\upsilon)\rho V^2}{(1-\upsilon)} = \frac{(1+\upsilon)(1-2\upsilon)\rho L^2}{(1-\upsilon)t^2} \tag{1}$$

Where, E_{d} is the dynamic elastic modulus; V is the velocity of ultrasonic waves; t is the transmission time; L is the transmission distance; ρ is the density of the concrete specimen and υ is the Poisson's ratio.

In addition, the fracture energy of concrete before and after exposed to elevated temperature had been also determined by three-point bending test (RILEM). In this way, the deterioration of concrete specimens due to the elevated temperature can be evaluated.

Water Capillary Absorption and Chloride Penetration

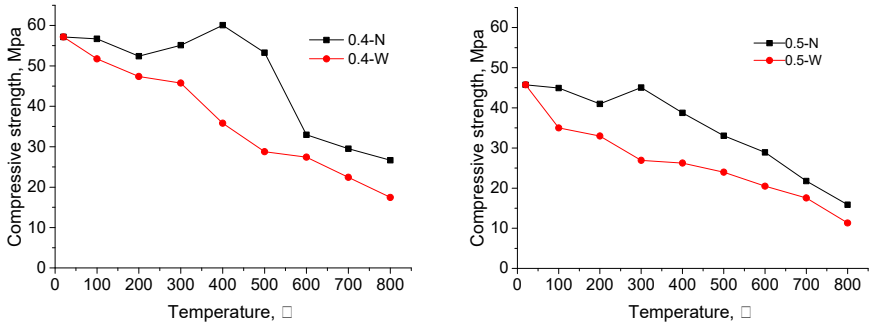
Before and after exposed to elevated temperatures, water capillary absorption of two types of concrete had been also measured. Before the test all surfaces were covered with self adhesive aluminium foils except to the contact surface with water and the opposite surface. After that, the specimens were placed in contact with water to conduct water absorption test. In this way, water will penetrate into the specimens in one dimension. Then the amount of water absorbed at the contact time of up to 7 days had been measured by gravimetric method. For some specimens water was replaced by 3.5 % NaCl solution to investigate the chloride penetration into the concrete after exposed to elevated temperature. At a certain time of chloride penetration, the specimens was taken out and grinded from the contact surface mm by mm. Then the chloride concentration in different tested concrete had been determined by titration method.

RESULTS AND DISCUSSION

Influence of Elevated Temperature on Compressive Strength

The results of compressive strength of the two types of concrete before and after exposed to elevated

temperatures are shown in Figure 1. It can be learned from the results that, in general, both for concrete A and concrete B the compressive strength after water splashing cooling decreased with the increasing of temperature. But when the temperature is below 400 □ for concrete A (W/C=0.4) and 300 □ for concrete B (W/C=0.5) after natural cooling, the compressive strength of concrete did not decrease immediately. This means with natural cooling after exposed to a certain high temperature concrete was not damaged yet. While after that, serious deterioration for the microstructure of concrete was determined. If water was splashed on the surfaces after exposed to high temperature, concrete was more damaged due to the thermal stresses caused by the cold water.

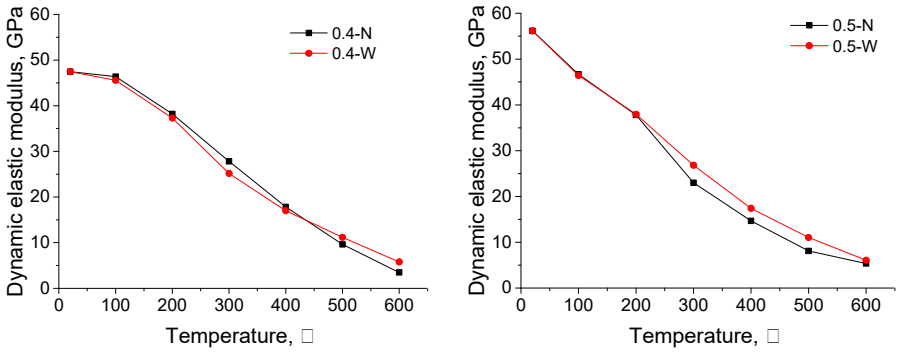


(a) Concrete A (b) Concrete B

Figure 1 The compressive strength of concrete after exposed to elevated temperature

Influence of Elevated Temperature on Elastic Modulus

The elastic modulus of concrete after exposed to elevated temperature has been determined. The results after natural cooling and water splashing cooling are shown in Figure 2. It can be learned that after exposed to elevated temperature micro cracks were formed in concrete and ultrasonic sound would need more time to transmit. Therefore, the elastic modulus was decreased gradually with the increasing of temperature both for concrete with natural and water cooling. But it seems there is no pronounced difference between two types of cooling methods. And water cement ratio is not sensitive either.

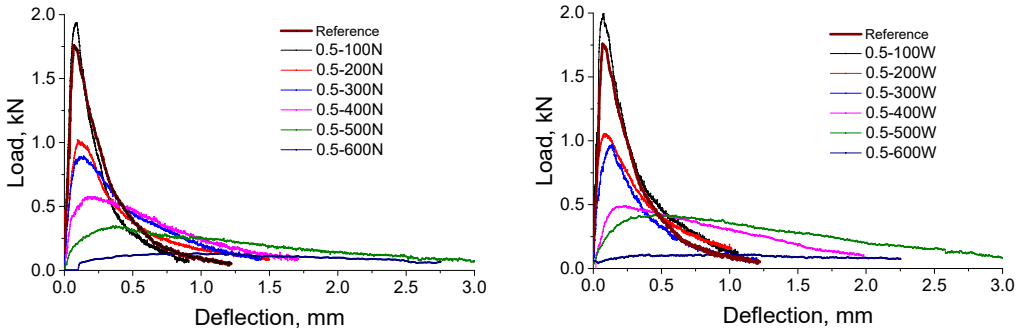


(a) Concrete A (b) Concrete B

Figure 2 The relative elastic modulus of the two types of concrete after exposed to elevated temperature

Influence of Elevated Temperature on Fracture Energy

Three points bending test has been performed to investigate the influence of elevated temperature on fracture energy. The load-deflection curves of the concrete after exposed to different temperatures are shown in Figure 3. The results indicate that with increasing of temperature, the load capacity decreased, but the maximum deflection get increased. With different cooling methods, the load-deflection curves show no much difference. The fracture energy of concrete has been further calculated by means of the program Consoft. The results are listed in Table 2. It can be learned that below 400 degree, the fracture energy calculated from the load-deflection curves does not decrease generally. Only after the temperature is over 400 degree, the fracture energy decreased significantly.



(a) Natural cooling (b) Water splashing cooling

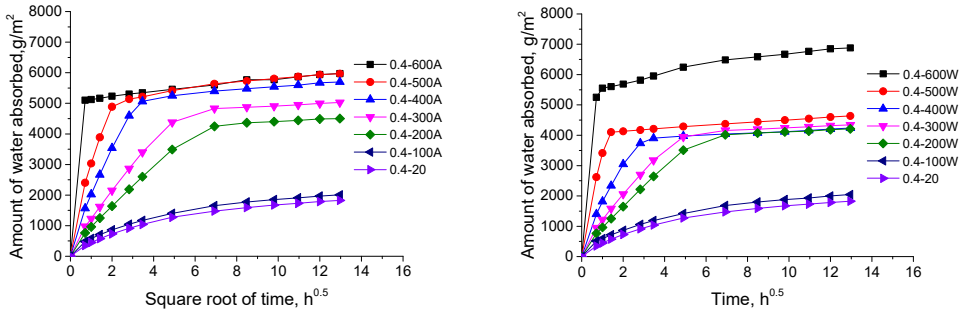
Figure 3 The load-deflection curves of concrete B after exposed to elevated temperature and (a) natural cooling and (b) water splashing cooling

Table 2 Fracture energy of concrete after elevated temperature (N/m)

Temp. □ / Cooling methods	20	100	200	300	400	500	600
Natural cooling	115.4	136.62	118.57	107.51	114.04	64.674	42.48
Water cooling	115.4	105.68	106.8	102.56	112.11	64.9	33.742

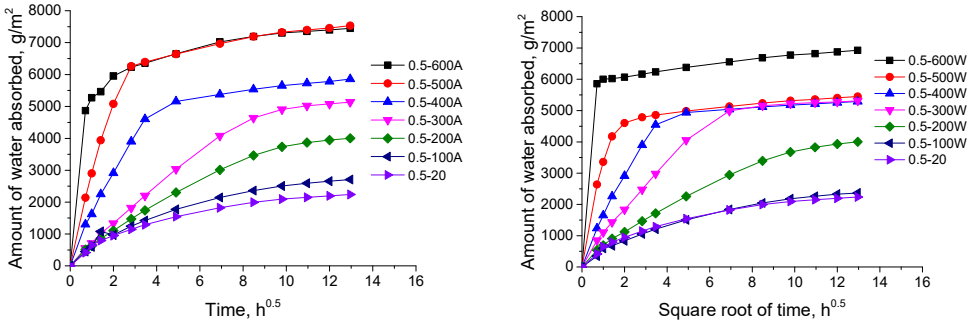
Influence of Elevated Temperature on Water Capillary Absorption

Numerous studies (Zhao *et al.* 1996; Khatri *et al.* 1997; Wang and Li 2003) show that water transportation play an important role in most of deterioration mechanisms of reinforced concrete structures. In this project, water absorption test has been performed in order to study the influence of elevated temperature on this property. The amounts of water absorbed at different absorption time had been measured. The results are shown in Figures 4 and 5 for concrete A and B, respectively. It can be seen from the results that both for concrete A and B, with the increasing of temperature, the amount of water absorbed increased. This means more capillary pores were formed under high temperatures. The slope of the beginning of the curves is considered to be the rate of water absorption, which is also called the coefficient of water capillary absorption. The results are further shown in Figure 6. It can be learned that the coefficient of water capillary absorption increased rapidly.



(a) Natural cooling (b) Water splashing cooling

Figure 4 The amount of water absorbed of concrete A at different time after exposed to elevated temperature and (a) natural cooling and (b) water splashing cooling



(a) Natural cooling (b) Water splashing cooling

Figure 5 The amount of water absorbed of concrete B at different time after exposed to elevated temperature and

(a) natural cooling and (b) water splashing cooling

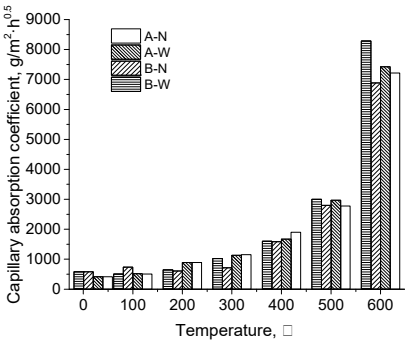


Figure 6 The coefficient of water capillary absorption of concrete after exposed to elevated temperatures

The maximum amount of water absorbed is usually considered to be the water absorption capacity. These results are further shown in Figure 7. With higher water cement ratio, concrete has more capillary pores and thus has higher water capacity. After exposed to elevated temperature, the porosity of concrete was also increased and has much higher water absorption capacity. For instance, the water absorption capacity of concrete A was increased from about 2000 g/m^2 at 20 degree up to approximately 7500 g/m2 at 600 degree.

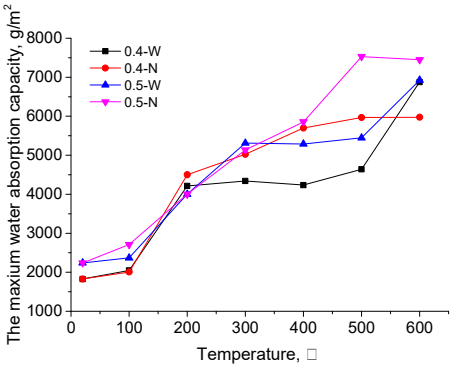

Figure 7 The water absorption capacity of concrete A and B after exposed to elevated temperatures

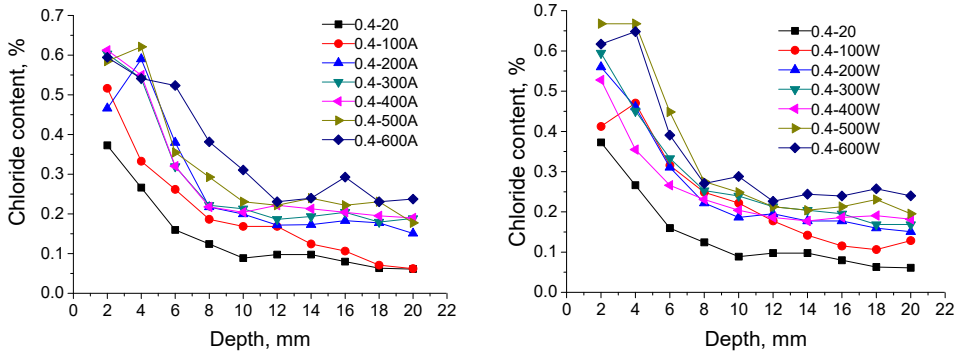
Influence of Elevated Temperature on Chloride Penetration

After exposed to elevated temperatures, concrete has been put in contact with 3.5 % NaCl solution for 7 days. After that the chloride concentration related to the mass of concrete were measured by titration method. The results are shown in Figure 8. This indicates again that after exposed to elevated temperature, the microstructure system of concrete was damaged and therefore more salt solution penetrated into concrete.



(a) Natural cooling (b) Water splashing cooling

Figure 8 Chloride profiles in concrete A after exposed to elevated temperatures and after (a) natural cooling and (b) water splashing cooling

CONCLUSIONS

- When the temperature is below 400 □ for concrete A (W/C=0.4) and 300 □ for concrete B (W/C=0.5) after natural cooling, the compressive strength did not decrease immediately. But in the case of water splashing cooling, the compressive strength of concrete lost already approx. 20 %. The elastic modulus

of concrete decreased gradually with the increasing of temperature. But there is no real difference with two types of cooling methods.

- With the increasing of temperature, the load capacity of concrete under three point bending decreased, but the maximum deflection get increased. With different cooling methods, the load-deflection curves show no much difference. Below 400 degree, the fracture energy does not decrease generally. When the temperature is over 400 degree only, the fracture energy decreased significantly.
- This project also studied the influence of elevated temperature on water and chloride penetration into concrete, which is relevant to the durability of concrete. After exposed to elevated temperatures, concrete absorbed much more water and chloride ions, which bring a high risk for RC structures. This effect shall also be taken into consideration when concrete is reused after fire accidents.

ABSTRACT

To predict the cracking time properly is a major indication to evaluate the service life of corroded reinforced concrete (RC) structures. Based on the assumption of uniform corrosion of steel reinforced bar, a model to predict the time from initiation to corrosion cracking is proposed. Finally, the data presented in the published literatures are picked up for the comparison between the proposed model and Maaddawy's model. The results illustrate that the proposed model is in good agreement with the test results and better than the model suggested by Maaddawy.

KEYWORDS

Concrete, reinforcement corrosion, cover cracking, cracking time, prediction model.

INTRODUCTION

The corrosion of reinforcement in the aggressive environment which results in the deterioration of reinforced concrete (RC) structures has been and will continue to be one of the most predominant factors which limit the service life of RC structures. Steel reinforced bar embedded in concrete is normally considered to be passive as the steel-concrete interface formed a microscopically thin layer of iron oxide of γ-$Fe_2O_3 \cdot H_2O$, due to the high alkalinity environment (pH ranges from 12.5 to 13) of the concrete pore solution[1]. When reinforcement is attacked by chloride ions or/and carbon dioxide, the passivation layer around the steel disappears and corrosion occurs. The formed rust products have 3 to 8 times the volume of the original steel[2] and can be expressed as $m \cdot Fe(OH)_2\, n \cdot Fe(OH)_3\, p \cdot H_2O$, where the values of m, n and p vary considerably, depending on conditions such as pH of the solution, the oxygen supply and moisture content[3]. The volume expansion of corrosion products generates internal stress in the concrete which leads to the cracking of concrete and the spalling of the cover. Forecasting the cracking time properly is an important indication to evaluate the service life of corrosion RC structures. The presence of first corrosion crack is normally considered to be the end of functional service life and the structures require rehabilitation[4, 5]. So there is a need to develop a corrosion-induced cracking model to predict the service life of existing structures.

In1980, K. Tuutti[4] proposed a model to predict the service life of reinforced concrete structures shown in Figure 1. Based on this model, the deterioration of reinforced concrete can be divided into two distinct period: 1) Initiation period, T_0, which represents the period required for Cl^- or/and CO_2 to ingress into the interface between steel and activate corrosion; 2) Propagation period, T_{cr}, which represents the time that rust products accumulation gradually which result in the cracks occur on structures and cause the failure of structures finally.

However, R.E. Weyers[5] reported that not all corrosion products contribute to the expansive pressure on the concrete. A portion of rust may fill the voids and pores in the interfacial transition zone (ITZ), while some rust products migrate away from the interface between steel and concrete. Moreover, the researchers[6, 7] found that using the model suggested by K. Tuutti to predict the cracking time of samples or structures from laboratory and field may underestimate the time to corrosion cracking. Therefore, the researchers[5, 8, 9] modified the model and considered that the corrosion process of RC structures can be classified into three period roughly. As showed in Figure 2, the modified model[10-12] divided the propagation period in the K. Tuutti's model into two different periods: 1) Rust expansion period, T_{free}, which represents the time required for corrosion products to fill the voids and pores in the ITZ; 2) Cracking period, T_{stress}, which represents the period that the expansive pressure occurs after the corrosion products having filled the porous zone and results in the cracks of structures. The

model presumed that before the internal tensile stresses outweigh the tensile strength of concrete, the pressure increases linearly as the volume of the rust. But it needs to be kept in mind that the assumption is valid before the cracks appear, after that the distribution of pressure is non-uniform.

Based on the Fick's second law, the researchers proposed a number of models[13-16] to predict the initiation period. For the last two periods, many models were suggested to forecast the cracking time of RC structures. These models can be mainly divided into three categories: empirical models[17-23], analytical models[3, 12, 24, 25] and numerical models[26-29]. A corrosion-induced cracking model to forecast the last two periods is proposed here. Then the data provided in the published literatures are picked up for the comparison between the proposed model and Maaddawy's model.

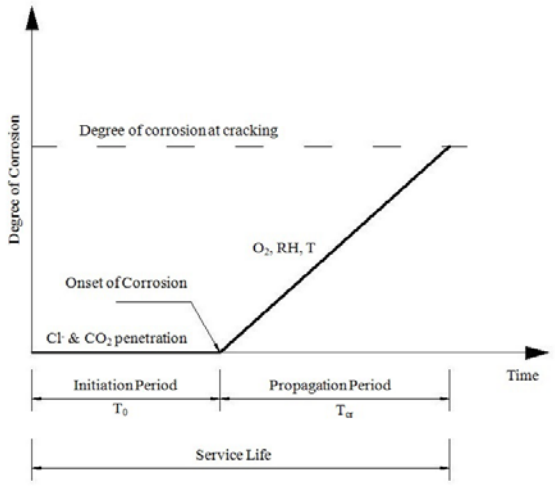

Figure 1 Service life model for corroded structures[4]

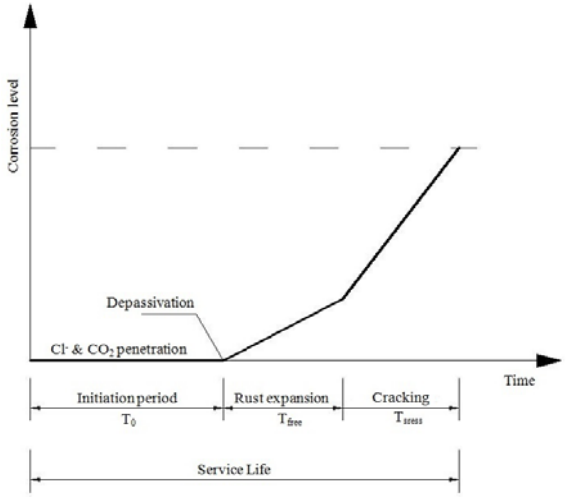

Figure 2 Modified service life model [10-12]

CORROSION-INDUCED CRACKING MODEL

Basic Assumptions

In order to develop the model of the corrosion cracking, 7 basic assumptions are made: 1)Corrosion products are formed uniformly around the steel reinforcing bar which leads to a uniform expansive stresses around the steel bar. The assumption is commonly used and widely accepted in modeling the volume expansion which caused by corrosion[3, 17, 24, 25, 30]. 2)There exists a porous zone around the steel-concrete interface and the corrosion products need to fill the zone firstly before they start to induce internal pressure on the concrete[3, 24, 30]. The zone volume is usually in relation to the surface of steel reinforcing bar, water cement ratio, degree of hydration and the compactness of concrete. The layer normally varies from 10 to 20μm[31]. 3)Only the stresses and the strains which resulting from the corrosion expansive pressure are considered. While other effects[3, 17, 24, 25, 30], such as dynamic loading and wetting-drying cycle, are eliminated here. 4)The stresses along the bar-axis are negligible[3, 24, 25, 30, 32]. 5)Concrete is a brittle isotropic linear elastic material[3, 24, 25]. 6)The concrete surrounding the bar is treated as a thick-walled cylinder and the thickness of the wall equal the thinnest concrete cover[3, 24, 30, 32]. The concrete ring is assumed to crack when the tensile stress in the circumferential direction at every part of the ring has reached the tensile strength of concrete[3, 13, 24, 25, 33, 34]. 7)During the process of the crack front, a portion of corrosion products shall be accommodated with the corrosion radial cracks[32].

Parameters of the Model

Mass loss of steel

A uniform layer of corrosion products would create uniform expansive stresses at the steel-concrete interface which results in a uniform radial displacement (δ_c) at the surface of the rust layer. As the existence of a porous zone around the interface surface between steel and concrete, the corrosion products need to first fill the zone before their expansion starts to create pressure on the surrounding concrete. According to the knowledge of elasticity mechanics[35], the formula of internal radial pressure(P_{cor}) and concrete displacement (δ_c) can be expressed as follows:

$$\delta_c = \frac{R_0}{E_{ef}}\left[\frac{(R_0+C)^2+R_0^2}{(R_0+C)^2-R_0^2}+\nu_c\right]P_{cor} \tag{1}$$

Where v_c is the Poisson's ratio of the concrete, which varies from 0.18 to 0.2； c is the wall thickness equal to the thinnest concrete cover; $R_0=D/2+\delta_0$, D is the diameter of the steel reinforcing bar; δ_0 is the thickness of the porous zone; E_{ef} is the effective elastic modulus of the concrete, given by:

$$E_{ce} = E_c/(1+\phi) \tag{2}$$

Where E_c is the elastic modulus of the concrete; ϕ is the creep coefficient of concrete [17, 24, 36], which falls in the range of 0-3[30]. For short-term accelerated corrosion, ϕ is 0;For long-term natural corrosion, ϕ is 2.35[37].

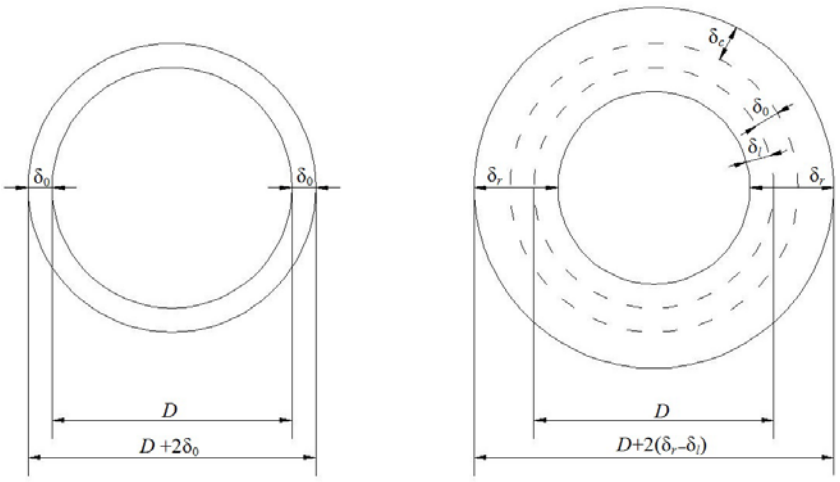

Figure 3 Change in steel diameter induced by corrosion

As shown in Figure 3, the increased volume can be expressed as follows:

$$\frac{M_r}{\rho_r}-\frac{M_{loss}}{\rho_s} = \frac{\pi}{4}\left\{\left[D+2(\delta_r-\delta_l)\right]^2-D^2\right\} \tag{3}$$

Where M_r is the weight of steel reinforcing bar (g); M_{loss} is the weight loss of consumed steel (g); ρ_r is the mass density of the rust (g/cm^3); ρ_s is the mass density of the steel (g/cm^3); δ_l is the thickness of steel lost; δ_r is the thickness of rust. The thickness of rust, δ_r, is given by:

$$\delta_r = \delta_l+\delta_0+\delta_c \tag{4}$$

Combining Eqs.(4) and (3), Eq.(3) can be rewritten as follows:

$$\frac{M_r}{\rho_r}-\frac{M_{loss}}{\rho_s} = \frac{\pi}{4}\left[4D(\delta_0+\delta_c)+4(\delta_0+\delta_c)^2\right] \tag{5}$$

As $(\delta_0+\delta_c)^2<<D$, the term $4(\delta_0+\delta_c)^2$, can be neglected. Therefore, Eq.(5) can be changed as follows:

$$\frac{M_r}{\rho_r}-\frac{M_{loss}}{\rho_s} = \pi D(\delta_0+\delta_c) \tag{6}$$

Some researchers [3, 25, 26] have given the relationship between M_r and M_{loss} as follows:

$$M_{loss} = \gamma M_r \tag{7}$$

Where γ is the ratio of molecular mass of steel to molecular mass of rust which ranges from 0.523 to 0.622[38]. When the rust product is $Fe(OH)_2$, γ is 0.523 and when rust product is $Fe(OH)_3$, γ is 0.622. Here only take an average value 0.573 for simplicity.

Besides, the researchers[3, 26] suggest an expression between mass density of rust (ρ_r) and the mass density of the steel (ρ_s) as follows:

$$\rho_r = 0.5\rho_s \tag{8}$$

Taken the unit length L equals 1cm. Put Eqs. (1), (7) and (8) into Eq.(6) the formula for the mass loss of steel (M_{loss}) can be obtained as follows:

$$M_{loss} = \pi D\left(\frac{2}{\gamma}-1\right)\rho_s\left\{\delta_0 + \frac{R_0}{E_{ef}}\left[\frac{(R_0+C)^2+R_0^2}{(R_0+C)^2-R_0^2}+\nu_c\right]P_{cor}\right\}\cdot 10^{-2} \tag{9}$$

Critical pressure

The cracks produced by expansion pressure coming to the surface of concrete is considered as the failure. For the thin-walled cylinder model of cover concrete, the tensile stress is usually assumed to be uniform. Thus, the critical pressure P_{cr} can be expressed as follows, where f_{ct} is the tensile strength of concrete.

$$P_{cr} = \frac{2Cf_{ct}}{D} \tag{10}$$

While Zhao and Jin[39] considered the aspect that the tensile stress in the concrete is non-uniform actually and given the expression of the critical pressure P_{cr} at failure as follows:

$$P_{cr} = 0.6\left(0.5+\frac{C}{D}\right)f_{ct} \tag{11}$$

Tepfers[40] has studied the use of elastic, plastic and partly cracked thick-walled cylinder models to predict the load at which bars fail in a pullout test. The results illustrated that the partly cracked elastic case was found to give a lower bound to the cover cracking load and the plastic case gave an upper bound. So Tepfers suggests taking the average of the partly cracked elastic case (Eq.10) and plastic case (Eq.11). Hence the same is proposed here, the critical pressure P_{cr} can be expressed as:

$$P_{cr} = 0.3\left(0.5+4.33\frac{C}{D}\right)f_{ct} \tag{12}$$

Time of corrosion cracking

Faraday's law has been taken by numerous researchers[10, 18, 41-43] to estimate the weight loss of steel at different applied current density levels. Therefore, Faraday's law will be also obtained here to depict the corrosion amount.

$$M_{loss} = \frac{MI_{corr}}{zF}t \tag{13}$$

Where M_{loss} is the weight loss of consumed steel (g); M is the atomic mass of Fe ion, M=56 g/mol; z is the ionic charge, with the value of 2.5 (Fe^{2+}, z=2; Fe^{3+}, z=3) [10, 32]; F is Faraday's constant, F=96500 C/mol; t is the corrosion time (s).

The corrosion current density i_{corr} is identified as the corrosion current per unit steel surface. If the unit length L equals 1cm and the unit of diameter D is mm, the relationship between I_{corr}(A) and i_{corr}(μA/cm^2) can be expressed as follows, where t_{ini} is the time of initial corrosion and D_e is the reduced diameter of steel bar after corrosion, D_e=D-2δ_{cr}.

$$I_{corr} = \begin{cases} 10^{-7}\cdot\pi\cdot D\cdot i_{corr} & (t = t_{ini}) \\ 10^{-7}\cdot\pi\cdot D_e\cdot i_{corr} & (t > t_{ini}) \end{cases} \tag{14}$$

Based on the data in the literatures, there exists a relationship between the amount of rust to cause cracking and the ratio of C/D. So the data[38, 41, 44, 45] is picked up for curve fitting and the result is given in Figure 4.

Inspection of Figure 4 shows that a reasonable relationship between the amount of rust to cause cracking and the ratio of C/D. Therefore, the following relationship can be used to calculate the amount of corrosion required to induce cracking, where Δ_{cr} is the steel section loss required for corrosion-induced cracking (%).

$$\Delta_{cr} = 1.148e^{\frac{C}{4.81D}} - 0.7 \tag{15}$$

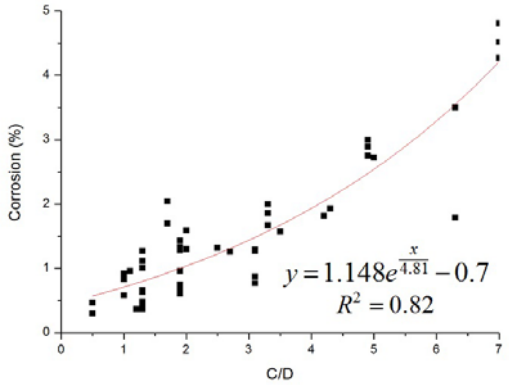

Figure 4 Relationship between bar weight loss and *C/D* ratio

Then Δ_{cr} is converted into the steel radius loss as follows:

$$\delta_{cr} = \frac{D}{2} - \sqrt{\frac{D^2}{4}\left(1 - \frac{\Delta_{cr}}{100}\right)} = \frac{D}{2}\left[1 - \sqrt{1 - \frac{\Delta_{cr}}{100}}\right] \approx \frac{D\Delta_{cr}}{400} = \frac{D}{400}\left(1.148e^{\frac{C}{4.81D}} - 0.7\right) \approx 0.00287De^{\frac{C}{4.81D}} \tag{16}$$

Combining Eqs.(16) and (14), the critical current is then given by:

$$I_{corr} = 10^{-7} \cdot \pi \cdot D\left(1 - 0.00574e^{\frac{C}{4.81D}}\right) \cdot i_{corr} \tag{17}$$

Substitute Eqs.(9), (12), (17) and parameters γ=0.573, ρ_s=7.85 g/cm^3 into Eq.(13), then the corrosion time (h), which ignores the ingress of corrosion products into cracks, can be expressed as follows:

$$t_1 = \frac{377204.7 \cdot \left\{\delta_0 + 0.3\left(0.5 + 4.33\frac{C}{D}\right) f_{ct} \cdot \frac{R_0}{E_{cf}}\left[\frac{(R_0 + C)^2 + R_0^2}{(R_0 + C)^2 - R_0^2} + \nu_c\right]\right\}}{\left(1 - 0.00574e^{\frac{C}{4.81D}}\right) \cdot i_{corr}} \tag{18}$$

Model modification

The researches usually consider that as the corrosion products occur quickly and result in the pressure increases sharply in the short-term accelerated tests. The cover will crack before the open cracks are filled with corrosion products completely. Therefore, some researchers[30, 36] assume that during the process of crack front, no corrosion products will penetrate into the cracks. It is too categorical for this assumption. Even in the accelerated tests, there still a portion of corrosion may be filled into the cracks before the cover cracks. Lu and Liu[46] obtained an expression for the time which corrosion products penetrate into cracks as follows:

$$t_2 = k\frac{C}{D}t_1 \tag{19}$$

Where k is a modified coefficient. Based on the results of Lu and Jin[12], For short-term accelerated corrosion, k varies from 0.1 to 0.3; For long-term natural corrosion, k varies from 0.7 to 0.8.

Combining Eqs. (18) and (19), the total time (t_{cr}(h)), which considering the rust penetration into cracks, from corrosion initiation to full cracking of cover can be expressed as:

$$t_{cr} = t_1 + t_2 = \left(1 + k\frac{C}{D}\right) \cdot t_1 = \frac{377204.7 \cdot \left(1 + k\frac{C}{D}\right) \cdot \left\{\delta_0 + 0.3\left(0.5 + 4.33\frac{C}{D}\right) f_{ct} \cdot \frac{R_0}{E_{cf}}\left[\frac{(R_0 + C)^2 + R_0^2}{(R_0 + C)^2 - R_0^2} + \nu_c\right]\right\}}{\left(1 - 0.00574e^{\frac{C}{4.81D}}\right) \cdot i_{corr}} \tag{20}$$

MODEL VERIFICATION

In order to validate the accuracy of the proposed model, some experimental results published in literatures are selected to compared with our model. Besides, comparison between Maaddawy's Model and the presented model is also made simultaneously. The parameters in the model are given here: ν_c=0.2; for short-term accelerated test,k=0.3; for long-term natural corrosion, k=0.75. The results are listed in Table 1.

	16	70	1.79	3.3	27	3.54	3.49~4.53	0.97~1.19

a.Calculated value based on $f_{ct} = 0.94\sqrt{f_c'}$ or $E_c = 4500\sqrt{f_c'}$,where f_c' is the compressive strength of concrete.

b. Except Liu's test, the unit for time is hour.

As can be seen from Table 1, the test times almost fall within the predicted times and the presented model is more suitable for predicting cracking time for both short-term accelerated tests and long-term natural conditions when compared with the model proposed by Maaddawy. The accuracy is more obvious for long-term natural tests. However, there still some results are slightly higher than the upper limit predicted by the presented model. The reason may contribute to the time which observed from initiation to crack is little higher. Another reason can be ascribed to the calculation error which occurs during the process of using the formulae list above.

MODEL SIMPLIFIED

The model list above , see Eq. (20), is complex. Therefore, the model have to be simplified. As showed in Figure 4, the relationship between the amount of rust to cause cracking and the ratio of C/D can also fitting as a linear relation (Figure 5). And the results listed in Table 2 illustrate that the simplified model can also predict the corrosion-induced cracking time well. It shows that the simplified model is also suitable for predicting the cracking time.

Figure 5 shows that a good relationship between the amount of rust to cause cracking and the ratio of C/D can be obtained. So the formula can be rewritten as :

$$\delta_{cr} = 0.00275C \tag{21}$$

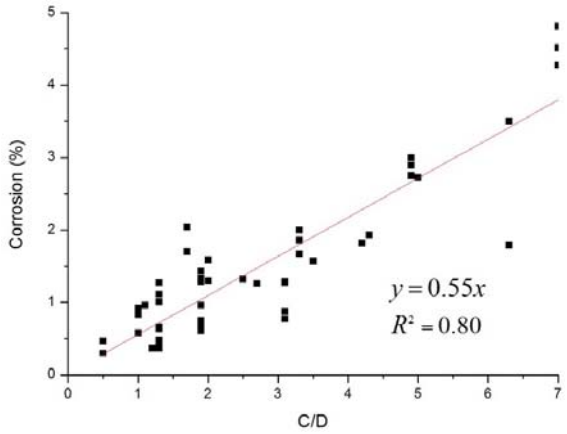

Figure 5 Linear relationship between bar weight loss and *C/D* ratio

The simplified formula for corrosion-induced cracking time t_{cr}(h) can be expressed as :

$$t_{cr} = \frac{377204.7 \cdot \left(1 + k\frac{C}{D}\right) \cdot \left\{\delta_0 + 0.3\left(0.5 + 4.33\frac{C}{D}\right) f_{ct} \cdot \frac{R_0}{E_{cf}}\left[\frac{(R_0 + C)^2 + R_0^2}{(R_0 + C) - R_0^2} + \nu_c\right]\right\}}{\left(1 - 0.0055\frac{C}{D}\right) \cdot i_{corr}} \tag{22}$$

Using Eq.(22) to predict experimental results published in literatures again. The results are given in Table 2.

CONCLUSIONS

A uniform corrosion-induced cracking model is proposed. On one hand, the model ignored the influence of rust products to the interface. On the other hand, the condition of corrosion products came into the cracks were considered and did some optimization for short-term accelerated tests and long-term natural tests. By comparison with Maaddawy's model, it could be found that the developed model is more suitable in forecasting the corrosion-induced cracking time.

ABSTRACT

Damage is inevitable in the reinforced concrete (RC) structures under various mechanical loads, which has a significant effect on the chloride diffusion. To predict the service life of RC structures in marine environment, it is essential to clarify the impact of damage extent on the chloride transport in concrete. For this objective, uniaxial compression tests were conducted on the concrete specimens to create various extents of damage. The ultrasound velocity and the residual strain was measured to characterize the evolution of damage. Afterward, a non-steady state migration method was employed to evaluate the diffusivity of sound and damaged concretes. On the basis of damage mechanics, the damage variables were quantified by the increase of residual strain and the degradation of ultrasound velocity. A linear relationship can be used to correlate the residual strain based damage with the ultrasound velocity based damage. The chloride diffusivity relates well with the damage extent in concrete. An exponential function can be employed to correlate the relative increase of chloride diffusivity with the damage extent.

Chloride transport, residual strain, ultrasonic sound, damage variable, compressive load

INTRODUCTION

Chloride-induced steel corrosion is a major durability issue of reinforced concrete structures in the marine environment, which is directly influenced by the chloride diffusion property of the cover concrete. It has been well known that the ingress of chloride ions into concrete is primarily dominated by the porosity and the connectivity of the pores of the concrete. In addition to the material quality itself, the diffusivity of concrete is also influenced by other factors such as the ambient temperature, the further hydration capacity of concrete, and the subjected loads. Especially, under the mechanical loads, the microstructure of concrete varies greatly due to the stress-induced damage, which will in turn affect the chloride diffusivity in the concrete (Hoseini et al., 2009). Therefore, it is utmost important to evaluate the chloride transportation in concrete with regard to the evolution of damage.

Over the past decades, the chloride diffusivity of concrete has been extensively studied, and recent studies have

proven that the chloride diffusivity is stress dependent. Under compressive loads, the chloride ingression was affected by a threshold stress level (Samaha and Hover, 1992; Lim et al., 2000; Saito et al., 1995; Wang et al. 2011; Djerbi et al., 2013). Under flexural or tensile loads, the chloride diffusivity increased with the increase of tensile stress applied to the concrete (Wang et al., 2011; Hoseini et al., 2009; Li et al. 2014). To predict the service life of concrete structures, the relationship between the mechanical loads and the transport properties of concrete has been under investigation on the basis of experimental results. In most cases, the stress level was selected to relate the mechanical stress with the chloride diffusivity (Wang et al. 2011; Li et al. 2014). Although a good correlation between the applied stresses and the diffusion property has been illustrated, a same stress level may generate different damage or cracking extent for different kind of concrete. Another widely accepted variable was the crack opening displacement (Ismail et al., 2008; Audenaert et al., 2009; Jang et al., 2011; Akhavan et al., 2012). For the cracked concrete, this parameter relate well with the chloride diffusivity, however it can't cover the entire damage level or the cracking extent. Moreover, the stress level or the crack opening displacement itself can't explain the controversy in the literature. As is well known, the deterioration of mechanical properties link well with the damage indicator. Thereby, there should be a good correlation between the damage indicator and the degradation of concrete durability. However, reliable quantification has not yet been established up to now.

Therefore, the aim of this paper is to propose a link between the chloride diffusivity and the damage indicator. As the evolution of damage can be represented by the residual deformation and the ultrasonic propagation velocity in concrete, this study firstly quantify the damage indicator using these variables, and then identify the relationship between the chloride diffusivity and the damage indicators.

EXPERIMENTAL PROGRAM

Materials

The Portland cement used in the mix was 42.5 ordinary type produced in Hangzhou complying with the Chinese National Standard. The fine aggregate used was a local river sand, and the coarse aggregate was a locally available crushed gravel with the maximum size of 20 mm. The concrete was mixed using tape water and the mix proportions are listed in Table 1. The cubic compressive strengths of concretes were tested after 28 and 56 days curing, and the average measured values were 25.3 and 28.1 MPa respectively.

Table 1 Mix proportions of the concrete

Quantity (kg/m^3)				Water/cement ratio	Cubic compressive strength (MPa)	
Cement	Sand	Coarse aggregate	Water		28 d	56 d
430	559	1118	185	0.43	25.3	28.1

Specimens

Cubic specimens with the dimensions 200 mm × 200 mm × 200 mm were cast in the wood molds and compacted with a mechanical vibrator. Twenty-four hours after the casting, all of the specimens were de-molded and then cured in a room at a temperature of 20°C and with 95% relative humidity to 56 days. Eight different levels of uniaxial compressive loads (30%, 40%, 50%, 60%, 70%, 75%, 80% and 85% of the compressive strength of the concrete) were applied to the cubic specimens to generate various level damage in the concrete.

To minimize the end effect and avoid the local crushing, the top and bottom surfaces was smoothly polished and leveled with some refine sands before loading. After unloading, concrete cores with a diameter of 100 mm and a height of 200 mm were drilled from the cubic solids. Then, two concrete discs with 50 mm in thickness were cut off from the central part of the cylinders using a diamond blade saw. To identify the damage extent on the chloride transport, the concrete cores were taken along the *y* directions (as shown in Fig.1). To maintain the integrity of the test specimens, the lateral curve surface of the discs were wrapped with plastic film and coated with epoxy resin. The preparation process of damaged specimen is schematically presented in Fig.1.

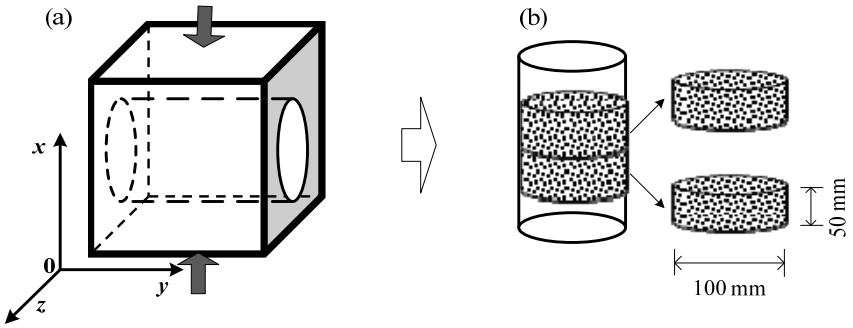

Fig. 1 specimens with different level of damage: (a) damage generation and core sampling, (b) discs for chloride diffusion test

Simulation of chloride penetration

The non-steady state migration method was adopted to evaluate the chloride penetration in concrete (Tang and Nilsson, 1992), following NT BUILD 492 (1999), in which an electrical field was used to migrate the chloride ions into concrete. Prior to the migration test, the concrete cores were cleaned using a ultrasonic washing apparatus and then were vacuum saturated with a saturated $Ca(OH)_2$ solution. Afterwards an external electrical potential of 30±0.2 V was applied across the specimen, forcing the chloride ions from the 10% NaCl solution to penetrate into the concrete. After the test, the concrete cores were coated by epoxy to keep the integrity of specimen. Then, the coated cores were sawed into slices perpendicular to the x direction, and a 0.1 mol/L $AgNO_3$ solution was sprayed on each sections. Finally, the chloride penetration depth was measured on each part at 10 points from the visible white silver chloride precipitation.

The non-steady state chloride migration coefficient D_{RCM} can be calculated by following equation (NT BUILD 492, 1999):

$$D_{RCM}=\frac{RT}{ZFE}\frac{x_d-\alpha\sqrt{x_d}}{t} \tag{1}$$

in which $E=\frac{U-2}{L}$ and $\alpha=2\sqrt{\frac{RT}{ZFE}}erf^{-1}\left(1-\frac{2C_d}{C_0}\right)$.

where D_{RCM} is the non-steady state chloride migration coefficient, m^2/s; R is the gas constant, R=8.314 J/(K mol); Z is the absolute value of ion valence, Z=1 for chloride ion; F is the Faraday constant, F=9.648×10^4 J/(V mol); U is the absolute value of the applied voltage, V; T is the average value of the initial and final temperatures in the anolyte solution, K; L is the thickness of the specimen, m; x_d is the average value of the penetration depths, m; t is the test duration, s; C_d is the chloride concentration at which the color changes, C_d =0.07 N for Portland

cement concrete; C_0 is the chloride concentration in the catholyte solution.

DAMAGE QUANTIFICATION

Damage, as an indicator of concrete degradation, can be determined by a number of methods. To measure the damage caused by uniaxial compressive loads, some non-destructive measurements were employed in this study, including the ultrasonic wave propagation and the residual deformation.

Residual Strain Based Damage

As a basic parameter, the material strain is often measured in the test, which can be divided into reversible part and residual part (Loo, 1992):

$$\varepsilon_{ij} = \varepsilon_{ij}^{e} + \varepsilon_{ij}^{r} \tag{2}$$

where ε_{ij}^{e} is the reversible strain; ε_{ij}^{r} is the residual strain. Immediately measured after unloading, the reversible strain is the elastic part in the deformation measurement, and the residual strain includes the plastic strain and the damage strain due to the matrix cracking. While the residual strain is obtained after a while after unloading, the residual strain consists of the unrecoverable plastic strain and the damage strain, which represents the damage in concrete. The residual strains were recorded 30 minutes after unloading in this test. The typical results are shown in the Fig.2.

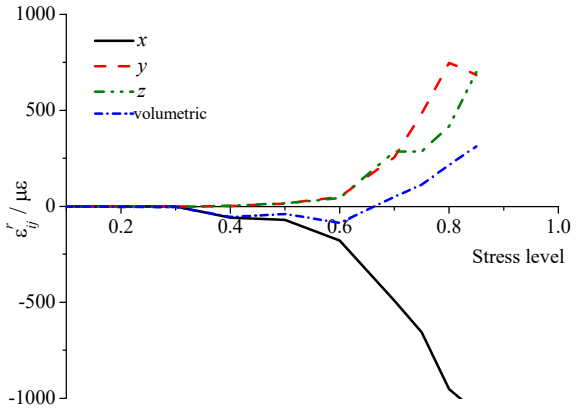

Fig. 2 Residual strains of concrete under uniaxial compressive loads

According to the damage mechanics, damage in the material can be characterized by a loss of stiffness or a reduction of the secant modulus (Mazars and Pijaudier-Cabot, 1989). Based on this, the stress-strain relationship can be given by:

$$\sigma = E\varepsilon \tag{3}$$

A damage parameter d can be defined as:

$$d = 1 - \frac{E}{E_0} \tag{4}$$

where E_0 is the initial elastic modulus of undamaged concrete, and is E the secant modulus of damaged concrete. From above relationships, the damage parameter d_r based on the residual strain can be approximately expressed as:

$$d_r = \frac{\varepsilon_{ij}^r}{\varepsilon_{ij}} \tag{5}$$

The damage values in the test were obtained from Eq.(5) and displayed in Fig.3.

As can be seen from Fig.3, the axial and lateral residual strains approach to zero at lower compressive loads ($\leqslant$ 40% of the compressive strength), meaning that the microcracks in RAC is not propagated. Correspondingly, the damage at this stage is close to zero as illustrated in Fig.3. Thereafter, with the increase of compressive stresses, all of the axial and lateral residual strains increase gradually. It indicates that more and more microcracks develop and coalesce (Mehta and Monteiro, 2006). When the applied compressive load exceeds 60% of the compressive strength, the crack system becomes unstable and macrocracks occurred in the concrete. At this stage, most of the marcocracks can't be recovered after unloading, resulting in rapid increases of residual strains and damage values, as shown in Fig.2 and Fig.3.

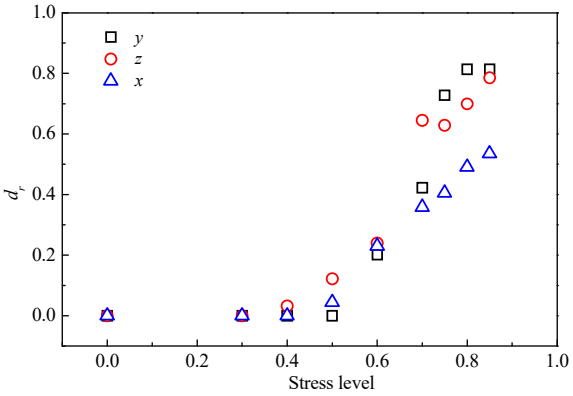

Fig.3 Evolution of damage based on residual strain.

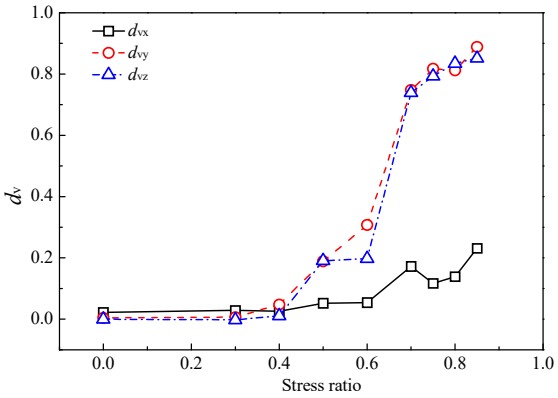

Fig.4 Evolution of damage based on ultrasound velocity

Ultrasonic Wave Based Damage

As the fact that the ultrasound velocity can be reduced by the internal damage, a non-destructive detection method based on the ultrasonic wave has been applied to evaluate the damage in concrete materials. According to the detection principle, the velocity of ultrasonic wave V can be expressed as (Selleck et al., 1998):

$$V^2 = \frac{E}{\rho} \frac{1-\mu}{(1-2\mu)(1+\mu)} \tag{6}$$

in which E is the elastic modulus of concrete (N/m2), μ is the Poisson's ratio, and ρ the mass density (kg/m3). Submitting Eq.(6) to Eq.(4), the damage parameter d_v can obtained as:

$$d_v = 1 - \frac{V^2}{V_0^2} \tag{7}$$

where V and V_0 are the velocities of ultrasonic waves in damaged and undamaged concretes. The damage values determined from the measured velocity are presented in Fig.4. It is clear that the damage increases with the level of applied load beyond 40% of the compressive strength. The sudden increase of damage as shown in Fig.4 also put in evidence that some macro cracks have been formed in the specimen when the applied load exceeds 60% of the compressive strength.

RELATIOSHIP BETWEEN CHLORIDE DIFFUSIVITY AND DAMAGE

The chloride diffusion coefficients of sound and damaged concretes were tested and displayed in Fig.5. The relative chloride diffusion coefficient of damaged concrete D/D_0 is defined as the ratio between the diffusion coefficient of damaged concrete D and the diffusion coefficient of sound concrete D_0. It appears that there is no remarkable increase in the chloride diffusion when the concrete is subjected to a stress level below 40% of the compressive strength. No obvious cracks were observed on the concrete surface below this stress level in the test. As shown in Fig.3 and Fig.4, the damage values are close to zero correspondingly at this stage. At the stress levels below 60% of the compressive strength, the effect of microcracks on the chloride penetration is less pronounced after the concrete is unloaded due to their smallest crack widths. However, the chloride ions penetrated rapidly into the concrete when the applied compressive load exceeds 60% of the compressive strength, due to the occurrence of macrocracks in the concrete. Although the applied load had been removed from the concrete in the chloride test, the macrocracks can't be entirely closed. As a result, the unrecoverable marocracks facilitated the transport of fluids and chloride ions. Therefore, for macrocracked concrete, the influence of damage extent on the chloride transport should be highlighted.

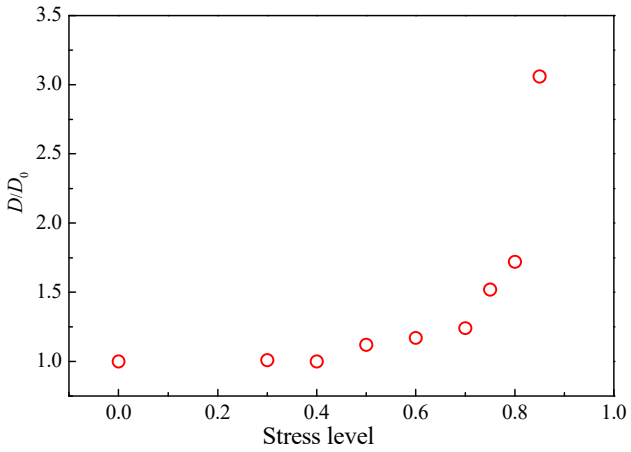

Fig.5 Relative chloride diffusion coefficients D/D_0 of concrete under different compressive stress levels

It has been generally accepted that most of the cracks propagate along the loading direction for the concrete subjected to uniaxial compressive loading. In terms of the lateral strain, it can be assumed that the increase in transverse strain beyond the linear elastic level can be attributed totally to the cracks' formation (Loo, 1992). Furthermore, crack width has been reported to influence significantly the permeability of concrete in the literature (Aldea et al., 1999; Djerbi et al., 2008). According to the test method illustrated in Fig.6, the concrete disks were sawed into slices for chloride diffusivity test perpendicular to the x direction. Therefore, the variables measured parallel to the z direction can be used to characterize the damage extent in the specimen. As shown in Figs. 3 and 4, a same trend is displayed for the damage variables of d_r and d_v, indicating that there is a good correlation between them. Figure 7 displays the relationship between these two variables, and a linear function can be adopted to describe their correlations.

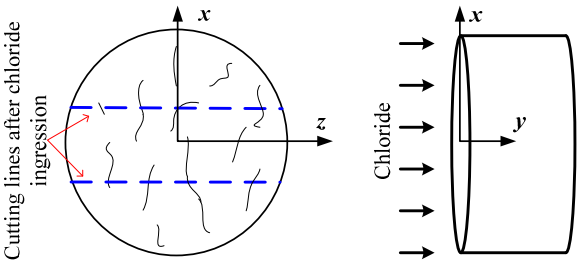

Fig. 6 Slices for chloride diffusion coefficient test

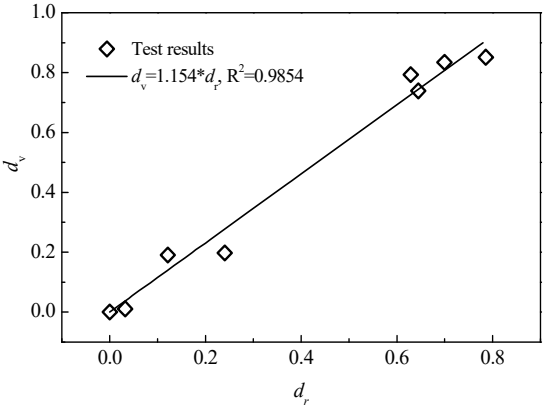

Fig.7 Correlation between the damage variables of d_r and d_v

The increase in relative chloride diffusivity D/D_0 with the damage variable d_r is shown in Fig. 8. It is clear that the larger damage the larger chloride diffusivity is. As illustrated in Fig. 8, the relative chloride diffusivity increases slightly below a damage value of 0.2. However, it increases dramatically beyond the damage extent of 0.6 due to the formation of macrocracks. For example, a threefold increase in chloride migration coefficient is observed in cracked concrete corresponding to a damage level of 0.78. An exponential function as follows can be obtained to correlate the relative increase of chloride diffusivity with the evolution of damage:

$$\frac{D}{D_0} = 0.014 \times e^{\left(\frac{d_r}{0.102}\right)} + 0.986 \tag{8}$$

On the basis of Eq.(8) and the relationship between d_r and d_v, the impact of damage on the chloride transport can be predicted for the reinforced concrete structures subjected to compressive stress fields. However, it is noted that this relation is established on the range of d<0.8. For the main crack- or fracture-dominated concrete, further studies should be given to clarify the correlation between the damage extent and the chloride diffusivity. Otherwise, the impact of damage on the chloride diffusivity may be underestimated in this case.

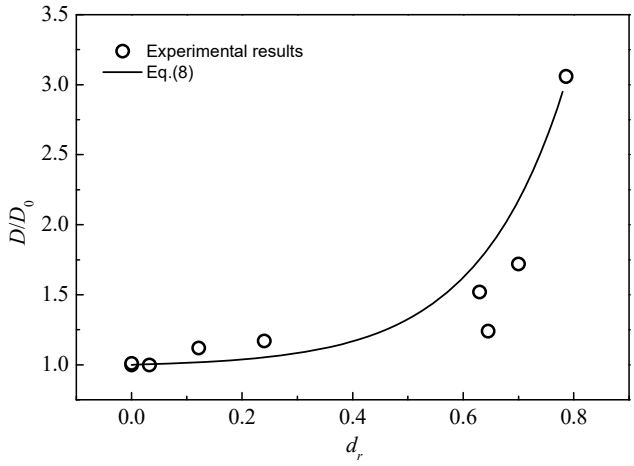

Fig. 9 Correlation between the relative chloride diffusivity D/D_0 of and the damage variables of d_r

CONCLUSIONS

The damage in concrete subjected to a uniaxial compressive load can be quantified by the increase of residual strain and the reduction of ultrasonic velocity on the basis of damage mechanics. The evolutions of damage variables relate with the existence state and the development of microcracks system in concrete under different compressive stress level. There is a linear relationship between the residual strain based damage and the ultrasonic velocity based damage variables.

The damage has an important impact on the chloride diffusivity of concrete. The chloride diffusivity increases slightly below a lower damage value of 0.2, and increases dramatically beyond the damage extent of 0.6 due to the formation of macrocracks. Compared with the chloride diffusion coefficient of sound concrete, a threefold increase is observed in cracked concrete corresponding to a damage level of 0.78. An exponential function can be obtained to correlate the relative increase of chloride diffusivity with the evolution of damage.

ABSTRACT

Triethylenetetramine (TETA), as a corrosion inhibitor for steel in aqueous media was introduced into chloride-contaminated concrete specimens by using a novel method called bidirectional electromigration rehabilitation (BIEM). An electric field was applied between embedded steel cathodes and external anodes to inject the corrosion inhibitor from external electrolytes into the concrete and at the same time to extract the chloride ions from the concrete cover zone.After the treatment, the specimens were drilled to determine the concentration profiles of the corrosion inhibitor, chloride and hydroxyl ions within the concrete. Effects of variations in the applied current density, duration of electrolysis, water/cement ratio, initial chloride content and surface carbonation on the concentration profiles of the proposed ions were determined. Electrochemical chloride extraction (ECE) in which saturated $Ca(OH)_2$ solution was used as an external electrolyte was applied as control experiments. As is expected, chloride content decreased and alkalinity increased after the treatment. Also, the concentration of the inhibitor injected around the embedded steel bars was adequate to provide corrosion protection. The results can provide a direction in designing the BIEM process.

INTRODUCTION

Reinforcement corrosion is one of the main causes for the deterioration of concrete structures (P. T. Miyagawa 1991; K. Mehta and R. W. Burrows 2001). The reinforcing steel in concrete structures exposed in the marine environment or suffering de-icing salt may corrode when the chloride concentration around the steel bar reaches the threshold value, leading to the performance degradation or even early structural failure (Djerbi, Bonnet and Khelidj 2008; Song *et al.* 2010). It is important to protect the steel from corrosion in order to extend the service lives of the chloride contaminated reinforced concrete structures.

In recent years, electrochemical methods have been widely applied in rehabilitation for existing reinforced concrete structures (Martínez *et al.* 2009). Among those electrochemical rehabilitation techniques and

electrochemical chloride extraction (ECE) are most widely studied and used in repairing chloride-contaminated structures. The drawback of these methods, however, is that, firstly, the treatment cannot remove all chlorides in the concrete; secondly, the treatment itself does not provide a permanent solution as chloride ions could come back again after the treatment ceases (Fajardo *et al.* 2006; Miranda *et al.* 2006; Yeih *et al.* 2006). In order to protect the reinforcing steel from corrosion in addition to the removal of chlorides, suggestions have been made to use corrosion inhibitors that can be applied on the surface of concrete cover (Miranda *et al.* 2006). These kinds of inhibitors are mostly based on particular amines and alkanolamines or their compounds, which are claimed to be capable of diffusing considerable distances through concrete by capillarity when applied on the surfaces of the structures (Morris and Vázquez 2002; Morris *et al.* 2003). Although these corrosion inhibitors proved to be effective in preventing reinforcement from corrosion within concrete structures (Nmai 2004; Ormellese *et al.* 2011), it should be emphasized that the surface-applied inhibitors can hardly penetrate to the depth of embedded steel reinforcement, reaching adequate concentrations to provide corrosion protection when the concrete cover is too thick or the concrete compaction is too high (Montemor *et al.* 2003; Bolzoni *et al.* 2006). Then the possibility of using electrical fields to accelerate their ingress in concrete has been explored. Since 2005, Sawada, et al. (Sawada *et al.* 2005; Sawada *et al.* 2007; Kubo *et al.* 2008) have succeed in promoting the injection of corrosion inhibitors into carbonated concrete specimens, significantly reducing the corrosion rates of steel bars.

The present authors (Zhang 2012; Zhang *et al.* 2013) have preliminarily explored this kind of method and proposed the remedial technique of bidirectional electromigration rehabilitation (BIEM) through which chloride ions are successively removed along with the injection of inhibitors into the ordinary reinforced concrete specimens. Triethylenetetramine (TETA) was used which is an amined-based corrosion inhibitor for the electrochemical process considering the anticorrosion effectiveness, electrochemical migration capabilities and environmental friendliness. It is known that the effectiveness of electrochemical treatment is influenced by many elements such as circulated charge and specimen type (Li and Page 2000). Nevertheless it is still unclear which conditions are necessary to cause significantly enhanced rates of field-induced injection of the corrosion inhibitor and extraction of chloride ions through various types of concrete. Therefore it is difficult to apply the technique appropriately in field situation.

To obtain a deeper understanding of the bidirectional electromigration rehabilitation, experiments are undertaken with concrete specimens mixed with chloride salt. The concentration profiles of chloride ions, hydroxyl ions and corrosion inhibitor in the concrete cover were measured before and after the electrochemical process was applied. Influence of some key factors on the electrolysis procedure such as current density, treatment duration, water/cement ratio, initial chloride content, surface carbonation were investigated. The effects of the bidirectional electromigration rehabilitation and electrochemical chloride extraction were also compared. It is hoped that this investigation would provide some guidance for practical application of this remedial technique.

TECHNICAL PRINCIPLE

The technical principal of BIEM was illustrated in Fig 1. The electrical field is applied between the embedded steel as cathode and the external anode immersed in the electrolyte contacting to the surface of the concrete specimen. Under the electric field action, the cationic species of corrosion inhibitor would migrate into the concrete cover to the cathode while chloride ions in the concrete would migrate out of concrete to the anode (Zhang 2012). The corrosion inhibitor would form a protective film around the embedded steel bars. It can isolate the corrosive substances such as chloride and oxygen when its concentration reaches to an adequate value

(Nmai 2004). Moreover, alkalinity of the pore solutions close to the embedded steel bars would be enhanced as a result of the generation of hydroxyl ions at the cathod, which favours the steel repassivation. \

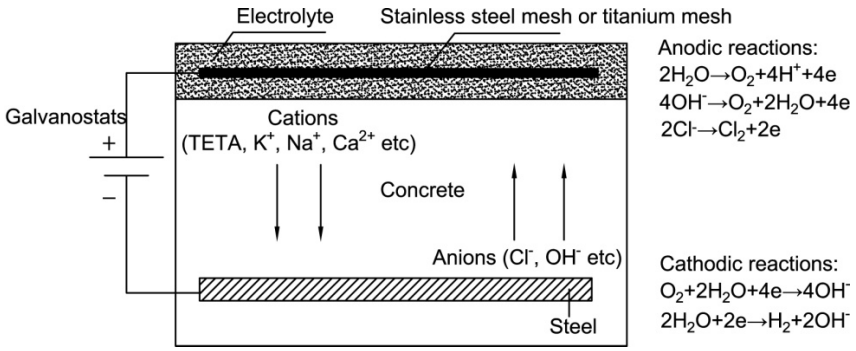

Fig. 1 Schematic of technical principal of BIEM

As described above, the selection of appropriate corrosion inhibitors is the key to the success of the electrochemical treatment. The corrosion inhibitor suitable for BIEM should provide enough corrosion protection under the condition of chloride ions. It should also exist predominantly as cationic species in aqueous media under certain condition. The amine or alkanolamine based corrosion inhibitor would be a good choice if these requirements are taken into consideration (Sawada *et al.* 2005; Sawada *et al.* 2007; Kubo *et al.* 2008; Zhang 2012). The degree of hydrolysis of the organic corrosion inhibitors is governed by their dissociation constants (pK_a) and the solution pH (Sawada *et al.* 2005). When the solution pH is equal to pK_a, the amount of cationic species is equal to that of molecule species. As the pH value decreases, the number of cationic species goes up and that of molecule species goes down. As the pH value increases, the situation goes contrarily. Since pH value of the pore solution in concrete is generally larger than 12.5, the corrosion inhibitor of large pK_a should be chosen to accelerate its injection into concrete.

EXPERIMENT PROGRAMME

Specimen Preparation

Ordinary Portland cement (OPC) mixed with NaCl was used to make the concrete specimens. The mix proportion of the concrete is shown in Table 1. Specimens of dimensions 150×150×300mm were cast with two mild steel bars, which were 12mm in diameter at intervals of 50mm and cover depths of 40mm from one face (see Fig. 2). The specimens were demoulded 24h after casting and cured for a minimum period of 3 months to ensure that the cement was properly hydrated. The end surfaces of the steel bar were connected with electric wire and masked with epoxy resin.

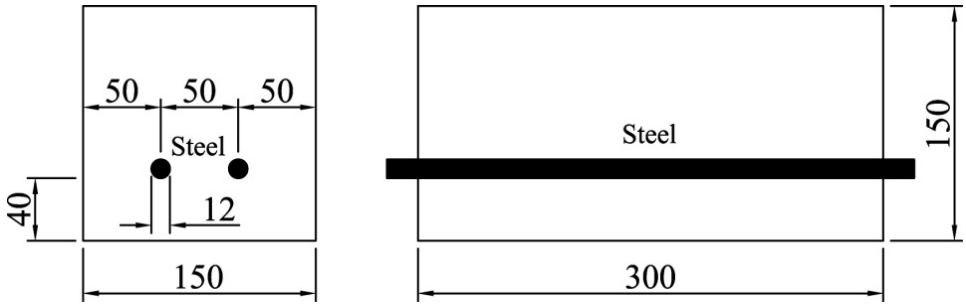

Fig. 2 Schematic of the reinforced concrete specimen (dimensions are in mm)

Treatment of specimens

The types of specimens and their treatment methods are shown in Table 2.The specimens were subjected to electrolysis by means of the experimental arrangement illustrated in Fig. 3. The bottom surfaces of the specimens were immersed in the external electrolyte containing TETA (1mol/L) to a depth of 1mm. Side surfaces of those specimens were sealed with wax to prevent ions exchange. The pH of the electrolyte was controlled to about 10 by phosphoric acid (Zhang 2012). The anodes used in the experiment were made of Type 316 stainless steel mesh while the cathodes used were the embedded steel bars in the specimens. The circuit was then completed and current densities were galvanostatically controlled at 1, 3 or 5A/m^2 of the steel cathode surface area. The periods of the treatment are betwee 7 and 30 days for different specimens. Saturated $Ca(OH)_2$ solution was used as the electrolyte for those specimens subjected to ECE. The pH value of the electrolytes was monitored and if it went down to 7 the electrolytes were renewed. All chemicals used were of analytical-reagent grade with the exception of TETA which was >95% pure.

Penetration Profiles of Corrosion Inhibitors, Chloride and Hydroxyl Ions

The specimens were dried in shade after the treatments. Concrete powders were taken out every 5mm along the migration path from different parts of treated surfaces by means of a 10mm drill in diameter. The drilling position was shown in Figure. 4. The powder less than 0.075mm in size was taken through a sieve to determine the content of organic corrosion inhibitor which had penetrated into the concrete blocks. A 20mg sample was weighed and wrapped for each sample to measure the corrosion inhibitor content by means of a Thermo Finnigan Flash 1112 EA organic element analyzer. The residual powder under 0.3mm in diameter was used to determine the Cl^- and OH^- concentration by titration. A 5g sample was mixed with 100ml deionized water and was stored for 24h, then the supernatant liquor being used for titration. The Mettler-Toledo T50A atomatic ptentiometric titrator was applied in the experiment. The titrant for Cl^- titration was 0.01mol/L $AgNO_3$ solution and that for OH^- titration was 0.04mol/L HCl solution. The electrode for Cl^- titration was Plug & Play combined silver ring electrode with ceramic frit for argentometric titrations and that for OH^- titration was Plug & Play combined pH electrode with ceramic frit for direct pH measurements and acid/base titrations in aqueous solutions.

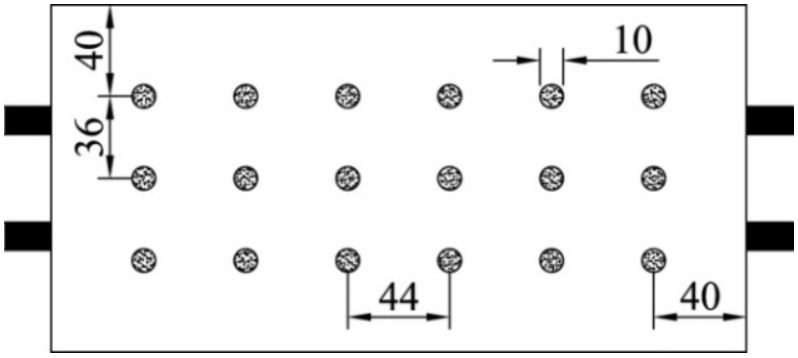

Fig. 4 Schematic of the drilling position on the treated surface (dimensions are in mm).

RESULTS AND DISCUSSION

Concentration profiles of chloride ions, hydroxyl ions and corrosion inhibitor in the concrete cover and the value of OH^-/Cl^- and $TETA/Cl^-$ determine the probability of steel corrosion largely and thus are important in evaluating the effectiveness of the electrochemical remedial techniques. Therefore they were measured in the experiment with given current density, treatment duration, water/cement ratio (w/c), mixed chloride content or surface carbonation as control parameters. Moreover, the effects of ECE and BIEM were also compared particularly.

Influence of Current Density

As illustrated in Figure. 5(a)-(c), the concentration profiles of Cl^- , OH^-, TETA change with current densities applied. In this group of specimens, Type 1 concrete with 3% NaCl was used and the treatment time is 15 days.

The residual Cl^- concentration in the specimens decreases with the increase of current density. Obviously, the increase of current density could intensify the effectiveness of chloride extraction as the circuit charge increased. However, the residual Cl^- in outermost layer was even higher than that in untreated specimens when the current density is less than $3A/m^2$, which means that the electric field applied was not enough to drive the Cl^- out completely resulting in the accumulation of Cl^- in the outer layer of the specimens. The removal efficiency of Cl^- was defined as the ratio of the difference between the initial Cl^- concentration and the residual Cl^- concentration to the value of the initial Cl^- concentration in the vicinity of the embedded steel and this efficiency was used in this paper to evaluate the effect of chloride extraction of the electrochemical process. As indicated in Fig 5(a), the removal efficiency of Cl^- increased from 21% to 65% and finally to 78% as the current density changed from 1A m^2 to $3A/m^2$ and then to $5A/m^2$. This implies that when the current density increases to a certain level, it is more difficult to increase the extraction effectiveness of Cl^- by means of rising current density.

Change of the water-soluble OH^- concentration accords with the alkalinity change in the concrete. The alkalinity around the steel suggested its possibility of further corrosion in some extent. As shown in Fig. 5(b), the alkalinity drops from inside to outside owing to the CO_2 and H_2O in the atmosphere. The alkalinity of the concrete cover was increased with progress of the treatment due to the OH^- generated by the cathodic reaction and the increase rises as the enhancement of current density. Under the applied electric field with current density of $1A/m^2$ the OH^- concentration rose up to 21% but the alkalinity of outer layer concrete has little increased. Nevertheless when the current density increased to $3A/m^2$ and $5A/m^2$, the alkalinity of outer layer concrete increased more obviously. As a result, the possibility of steel corrosion would be reduced and the resistant ability for the structure to carbonation would be improved.

The migration of the corrosion inhibitor was also affected by the current density as described in Fig. 5(c). Within the first 20mm from the embedded steel bars the concentration of TETA kept almost the same in a relatively low range, but it increased a lot in the outer 20mm layer. The concentration of TETA in the specimens also increased with the increase of current density. It is known that the organic corrosion inhibitors act ineffective in preventing steel from corrosion when their concentrations are too low (Eydelnant *et al.* 1993). Only as the concentration of the inhibitors is no lower than that of chloride ions in pore solution, the corrosion inhibitors can provide adequate protection for the reinforcement (Elsener *et al.* 1999). As shown in Fig. 5(c) when the current density increased from $1A/m^2$ to $3A/m^2$, the concentration of inhibitors penetrated to the surface of the steel increased by

176%. However, this increase was only 16% when the current density varied from 3A/m^2 to 5A/m^2 while the increase of the inhibitor concentration close to the treated surface exhibited more.

The relationship between the ratios of different constituents and current density is shown in Fig. 5(d). The minimum ratio of the concentration of corrosion inhibitor to that of the chloride ions when the inhibitor is able to provide effective protection for reinforcement is defined as the effective value of the corrosion inhibitor. As discussed above, the effective value was believed to be 1 in most cases (Elsener *et al.* 1999). As shown in Fig. 5(d), when the current density reached 3A/m^2, (TETA)/Cl^- exceeded 1. OH^-/Cl^- near the steel also increased with the increase of the current density contributing to more effective corrosion protection for the reinforcement (Mammoliti *et al.* 1996; Castellote *et al.* 2000). It follows that the increase of current density played positive role in the increase of the concentration of TETA and OH^- and the decrease of Cl^-, but the effect was limited. It is significant to set proper current density accordingly.

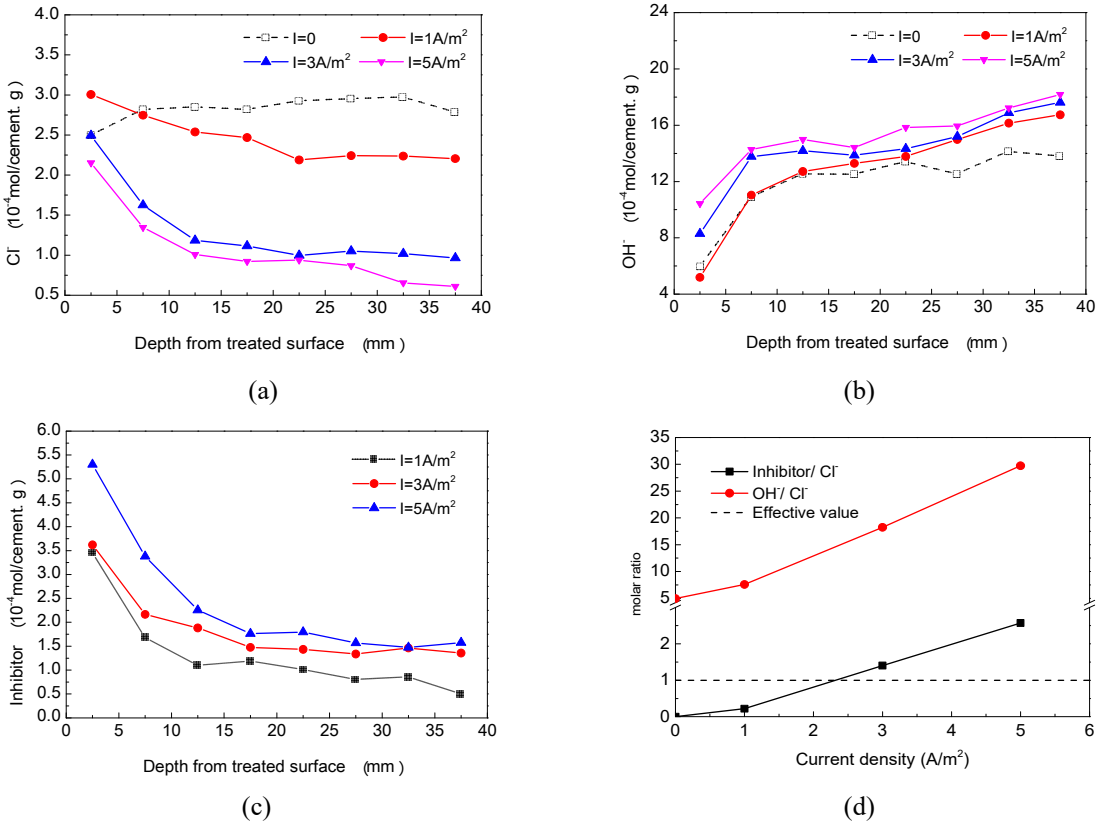

Fig. 5 Concentration profiles/ ratios in specimens after BIEM for different current densities. (a) Concentration profiles of Cl^-. (b) Concentration profiles of OH^-. (c) Concentration profiles of inhibitor. (d) Ratios of proposed constituents close to the steel reinforcement.

Influence of Treatment Duration

The concentrations of Cl^- , OH^-, TETA were plotted with the variation of treatment time in Fig. 6(a)-(c). Type 1 concrete with 3% NaCl was used and the current density was kept at 3 A/m^2.

The residual Cl^- distributed relatively uniformly in the range of 20mm in front of the embedded steel bars and increased gradually to the treated surface (Fig. 6(a)). As the treatment duration prolonged, more Cl^- were extracted. In the layer close to the steel bars, 38% of Cl^- were removed after 7 days. When the treatment time

increased to 15 days and 30 days, the percentage of Cl^- removed reached to 65% and 85% respectively. The concentration of Cl^- in the outermost layer exceeded the initial concentration by 35% after 7 days' treatment because the Cl^- migrated to the anode under the influence of applied electrical field. In that case, the concentration difference of Cl^- between the inner part and the outer part of specimen was enhanced, leading to the acceleration of counter-migration of Cl^- to the reinforcement after the treatment (Chatterji 1995).

The distribution tendency of OH^- in the concrete cover zone remains almost the same after BIEM with a little decrease in the concentration difference (Figure. 6(b)). The alkalinity increased with the treatment time increasing. The increase of water-soluble OH^- around the steel was 14% after 7days and 28% after 15days. And after 30 days, the increase reached 35%. It implies that as the treatment duration prolonged, the increase of alkalinity slowed down.

The concentration of corrosion inhibitor in concrete cover zone increased along with the treatment time (Figure. 6(c)). In the layer close to the surface, the concentration of TETA kept increasing with the progress of the treatment. However, in the vicinity of the embedded steel bars, the story of the concentration enhancement was different. The concentration of TETA close to the reinforcement increased by 44% from 7 days to 15 days through the electrolysis procedure while it increased by only 20% from 15 days to 30 days. This was attributed to the fact that the OH^- continuously generated through the cathodic reaction increased the concrete alkalinity. As a result, the cationic species of TETA in concrete pore solution was reduced with the raise of pH, making it more difficult for the corrosion inhibitor to migrate into the concrete cover zone (Sawada *et al.* 2005).

The relationship between the ratios of different constituents and current density is shown in Fig. 6(d). After the specimen was treated for 15 days, the value of (TETA)/Cl^- exceeded 1, suggesting active effectiveness in preventing steel from corrosion. The ratio of OH^- to Cl^- also increased with the increase of treatment time, which was favoured in the repassivation of the corroded steel bars.

(c) (d)

Fig. 6 Concentration profiles/ ratios in specimens after BIEM for different treatment durations. (a) Concentration profiles of Cl^-. (b) Concentration profiles of OH^-. (c) Concentration profiles of inhibitor. (d) Ratios of proposed constituents close to the steel reinforcement.

Influence of Water/cement Ratio

The concentration profiles of Cl-, OH- and TETA in specimens of different water/cement ratios are shown in Fig. 7(a)-(c). In this group, concrete of Type 1, 2 and 3 was used. The mixed ratio of NaCl was 3% for each type. The current density exerted was $3A/m^2$ and the treatment lasted for 15 days.

As illustrated in Fig. 7(a), the residual concentration of Cl^- decreased as the water/cement ratio increased. With a higher w/c ratio, the concrete was always having a lager porosity and lower compactness. As a result, the resistance to the migration of Cl^- migration was reduced and then the diffusion coefficient of Cl^- increased (Costa and Appleton 1999). However, residual concentration of Cl^- in the outermost layer did not change much as the w/c changed.

The overall concentration of OH^- increased with w/c. The initial OH^- concentration for the concrete with higher w/c was higher. Therefore when the w/c decreased from 0.48 to 0.43, the concentration of OH^- increased inconspicuously. Yet the increase of OH^- was relatively obvious when the w/c decreased from 0.54 to 0.48.

As indicated in Fig. 7(c), the concentration of TETA in front of the steel bars enhanced with the increase of w/c. Nevertheless in the outermost layer close to the surface, the concentration kept almost the same for different w/c. As mentioned above, the concrete with higher w/c had lower compactness and alkalinity, leading to a higher concentration of cationic TETA in the pore solution. Hence the efficiency of TETA migration was higher in those concrete with higher w/c.

The ratios of different constitutes in the concrete cover were illustrated in Fig. 7(d). When w/c was greater than 0.48, the ratio of TETA to Cl^- was larger than the effective value. However, as w/c was equal to 0.43 the ratio of TETA to Cl^- was less than the effective value, in which the current density and treatment time should be extended accordingly. The water/cement ratio had little effect on the ratio of OH^- and Cl^- in the process of BIEM.

(c) (d)

Fig. 7 Concentration profiles/ ratios in specimens after BIEM for different water/cement ratios. (a) Concentration profiles of Cl^-. (b) Concentration profiles of OH^-. (c) Concentration profiles of inhibitor. (d) Ratios of proposed constituents close to the steel reinforcement.

Influence of Initial Chloride Content

For those specimens mixed with different initial quantities of NaCl, the concentration profiles of Cl^-, OH^- and TETA after BIEM were shown in Fig. 8(a)-(c). Type 1 concrete was used to manufacture these specimens but with NaCl mixed at three different contents, corresponding to 1%, 3% and 5%. For this group, the circuits were galvanostatically controlled at $3A/m^2$ for a period of 15 days.

As illustrated in Fig. 8(a), the extraction efficiency of chlorides in concrete increased with the initial chloride concentration. For the specimens with 1% NaCl mixed, the proportion of extracted chlorides in front of the steel bars was about 44%. And for those with 3% NaCl, the proportion was only 65%. When the mixed ratio of NaCl was increased to 5%, the proportion reached to 78%. It follows that the efficiency of BIEM would be higher for those structures heavier polluted by chloride.

The concentration of OH^- in concrete cover kept increasing from outside to inside after the treatment (Fig. 8(b)). The overall concentration of OH^- was lower in the specimen mixed with 3% NaCl. However, the alkalinity of the specimen mixed with 5% NaCl was highest barely for that near the embedded steel bars.

As shown in Fig. 8(c), there was no obvious relationship between the migration of TETA and initial NaCl mixed content. It implies that the initial chloride content of the concrete had little influence on the efficiency of TETA ingression.

After the electrochemical process, the value of OH^-/Cl^- and $TETA/Cl^-$ was relatively higher in the specimen with 1% NaCl. The low initial concentration of Cl^- might be the main reason. It suggests that the bidirectional electromigration rehabilitation may have better effect on those concrete structures with less chloride. There was little difference of these two ratios between the specimens with 3% and 5% NaCl. Nevertheless, the process proved to play an active role in preventing the reinforcement from corrosion since the ratios of corrosion inhibitors to chloride ions all exceeded 1 in all cases.

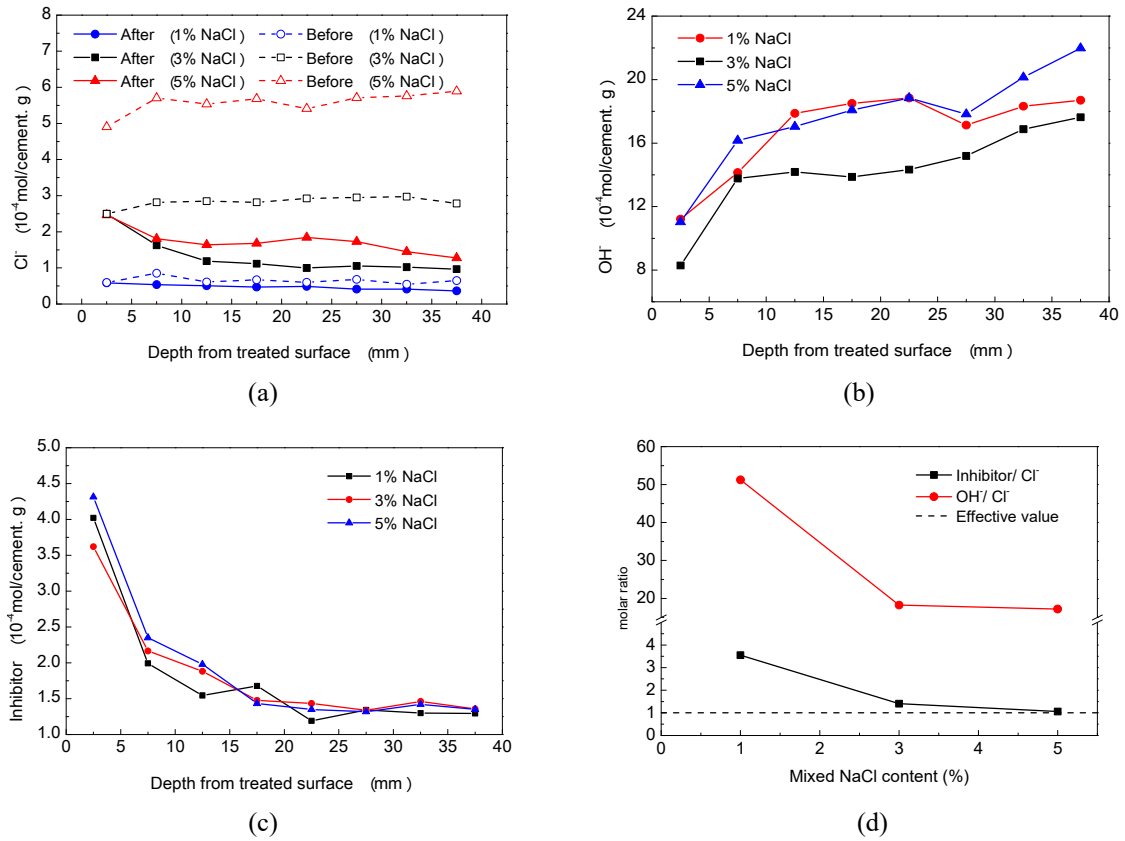

Fig. 8 Concentration profiles/ ratios in specimens after BIEM for different mixed NaCl contents. (a) Concentration profiles of Cl^-. (b) Concentration profiles of OH^-. (c) Concentration profiles of inhibitor. (d) Ratios of proposed constituents close to the steel reinforcement.

Influence of Different Electrolysis

The residual concentration profiles of Cl^- and OH^- after BIEM and ECE were all illustrated in Fig. 9(a) and Fig. 9(b). The specimens in this group were cast with Type 1 concrete with 3% NaCl. Current density applied in the experiment was 3 A/m^2.

As indicated in Fig. 9(a), the residual chloride ion distributions were different after two processes of BIEM and ECE. The overall concentration of Cl^- in the whole concrete cover was reduced evenly. By contrast, the residual concentration of Cl^- in the outer layer of the specimens was relatively higher than in the inner layer after BIEM. One of the possible explanations is that many cationic TETA species accumulated in the outer layers of the specimens where the cations united with chloride ions. That led to the difficulty in extraction of Cl^- thoroughly. After 7 days' treatment, residual Cl^- concentrations around the steel after BIEM and ECE were approximately equal. When the treatment duration extended to 15 days and 30 days, the effect of BIEM was better than ECE in removal of Cl^-. It suggests that BIEM had higher efficiency on removal of Cl^- close to the steel than ECE. For better effect of Cl^- extraction in the overall concrete cover zone, especially in outer layer, a process of short-time ECE after BIEM might be a good supplement.

It is reflected in Fig. 9(b) that the distribution trend of alkalinity in the specimens after ECE was almost in accordance with that after BIEM. Yet the level of the concentration enhancement of water-soluble hydroxyl after ECE was a little higher than that after BIEM. BIEM had a better effect than equal-time ECE on increasing the

ratio of OH^- to Cl^- , as illustrated in Fig. 9(c).

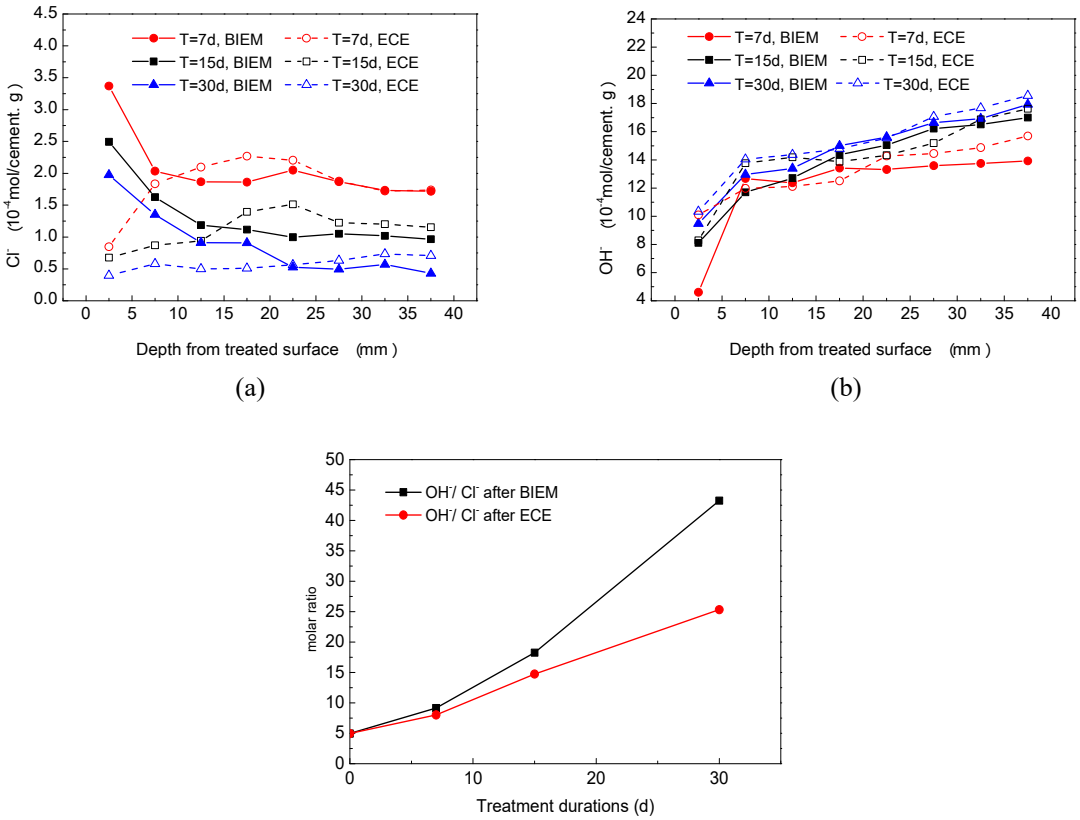

Fig. 9 Concentration profiles/ ratios in specimens after treatments of different kinds (BIEM and ECE). (a) Concentration profiles of Cl-. (b) Concentration profiles of OH-. (c) Ratios of proposed constituents close to the steel reinforcement.

Influence of Surface Carbonation

The carbonation depth of the specimens experienced pre-carbonation was 13.7mm in average measured by the phenolphthalein test. The carbonated and non-carbonated specimens were all subjected to ECE and BIEM at current density of $3A/m^2$ for a period of 15 days. The concentrations of Cl^-, OH^- and TETA in the concrete cover after treatment were plotted in Fig. 10(a)-(c).

The distribution trends of residual concentration of Cl- in the surface carbonated specimen decreased from outside to inside according with that in non-carbonated specimen. In the 20mm close to the embedded steel bars, the residual Cl^- concentration was a little higher in carbonated specimen than in non-carbonated specimen after BIEM. For ECE, however, the Cl^- extraction efficiency was much higher in carbonated specimen than in non-carbonated specimen. In general, the effect of ECE was a little better than BIEM on the removal of chloride ions within the concrete cover zone.

Influenced by CO_2 and H_2O, the alkalinity of concrete in the 15mm near to the treated surface decreased sharply. The increase of OH^- after BIEM was more substantial in surface carbonated specimen, especially the first 15mm close to the treated surface. It appears to be a little different between carbonated and non-carbonated specimens in increase of alkalinity after ECE. The BIEM-caused increase of alkalinity was lager in the surface carbonated

specimen than in non-carbonated specimen.

The efficiency of TETA migration was much better for carbonated specimen than those non-carbonated, especially in outer part close to the concrete surface which had been carbonated. In the layer close to the reinforcement, the concentration of inhibitors in surface carbonated specimen was 33% higher than that in non-carbonated specimen. This phenomenon was attributed to the decrease in alkalinity close to the concrete surface, leading to a rise in number of cationic TETA species. Therefore the migrating ability of TETA was improved. Yet the inner part of the specimen had not been influenced by carbonation so the increase of TETA was limited.

As shown in Fig. 10(d), the values of TETA/Cl^- and OH^-/Cl^- were both higher in the surface carbonated specimen than in non-carbonated specimen. Actually the number of specimens in this experiment was not large enough to get more reliable patterns and conclusions.

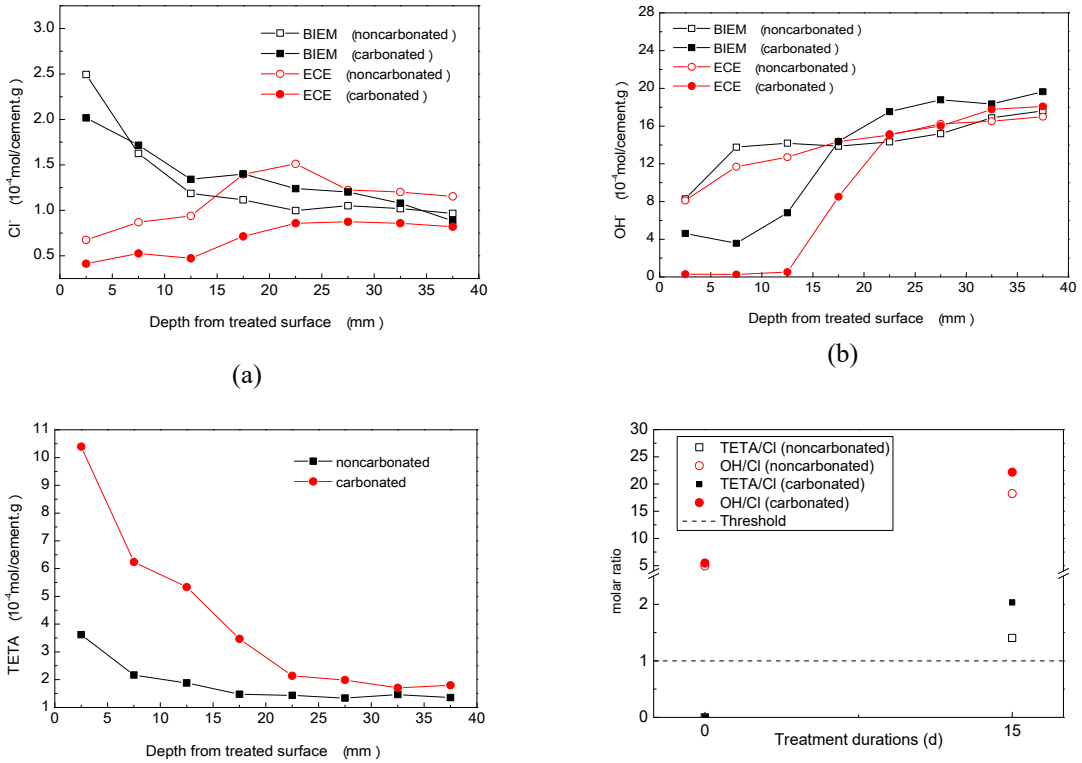

Fig. 10 Concentration profiles/ ratios in specimens after BIEM for different surfaces (carbonated or non-carbonated). (a) Concentration profiles of Cl^-. (b) Concentration profiles of OH^-. (c) Concentration profiles of TETA. (d) Ratios of proposed constituents in front of the steel reinforcement.

CONCLUSIONS

The main conclusions of this investigation may be summarized as follows:

Specimens of ordinary concrete were subjected to bidirectional electromigration rehabilitation (BIEM) and the concentration profiles of Cl^-, OH^- and corrosion inhibitor were determined in the experiment. The results showed that TETA acted as corrosion inhibitor was capable of being effectively injected into both carbonated

and non-carbonated concrete of the sort investigated by means of the relatively short-term electrochemical treatment of BIEM. The concentration of inhibitor around the embedded steel reinforcement was adequate to provide corrosion protection. At the same time, the ratio of OH^- to Cl^- was raised a lot owing to the fact that the concentration of chloride ions decreased and that of hydroxyl ions was increased in the concrete cover, which favoured the repassivation of reinforcement.

(1) The electricity parameters should be taken into account in design of the electrochemical process. The efficiencies of Cl^- extraction, OH^- enhancement and TETA migration increased as the current density and/or the treatment time increased in the process of BIEM. A low current density or a short treatment duration helped little in the rehabilitation while too high current density or too long treatment were unnecessary. It is significant to choose appropriate electricity parameters according to the actual situation and the goal of rehabilitation.

(2) The quality of the concrete also affected the electrical treatment to some degree. The efficiencies of Cl^- extraction, OH^- enhancement and TETA migration decreased as the w/c of specimens decreased. A lower w/c means denser internal structure of concrete and higher alkalinity, which was unfavorable for the transfer of certain particles in the electrochemical process. It implies that different electricity parameters should be chosen according to different w/c.

(3) Another key factor for the electrochemical process was the initial chloride content in the specimens. The specimens containing more chloride owed higher proficiency in Cl^- extraction through BIEM. The alkalinity increased most in specimens mixed with 3% NaCl and in specimens mixed with 1% and 5% NaCl, the alkalinity increases were lower comparatively. The initial content of chloride in specimens had little influence on the migration of TETA.

(4) There existed significant difference between BIEM and ECE in the changes of Cl^- and OH^- concentration. The residual concentration of Cl^- in outer layer of specimen was higher than that in inner layer after BIEM. Nevertheless the distribution of Cl^- was more uniform in the specimen after ECE. The alkalinity increases in the overall concrete cover zone after the two kinds of remedial techniques differed little. Yet for the alkalinity enhancement near the steel bars, ECE proved to be a little bit better.

(5) The chloride contaminated concrete structures in need of rehabilitation in the practical condition are usually carbonated to a certain depth. The migration efficiency of corrosion inhibitor in carbonated concrete was higher than that of non-carbonated one.

ABSTRACT

In service life, concrete can be damaged either by mechanical or environmental loads or by combined ones. These damages will strongly influence water movement in concrete which could later lead to more serious deteriorations. This paper applies neutron radiography to investigate the influence of frost damage on water penetration into concrete. In addition, the improvement of frost resistance by addition of air entrainment was investigated. The results indicate that it is possible to visualize penetration of water into the porous structure of concrete by neutron radiography. Further evaluation of the test data allows determining time-dependent moisture profiles quantitatively with high resolution. After concrete is damaged by freeze-thaw cycles water penetration into ordinary concrete is accelerated. It can be shown that frost damage is not equally distributed in specimens exposed to freeze-thaw cycles. Thermal gradients lead to more serious damage near the surface. The beneficial effect of air entrainment on frost resistance has been demonstrated. After 50 freeze-thaw cycles, air entrained concrete showed no measurable increase in water absorption. But layers near the surface of concrete absorbed slightly more water after 200 freeze-thaw cycles although the dynamic elastic modulus remained constant. Results presented in this paper help us to better understand mechanisms of frost damage of concrete.

Freeze-thaw cycles, concrete, water penetration, air entrainment, thermal gradient, moisture distribution, neutron radiography.

INTRODUCTION

Cracks are always preferential paths for water flow. Cracks may be caused by mechanical load or by thermal and hygral gradients or by local swelling processes. Many authors have studied the influence of cracks on penetration of water and aggressive compounds into cement-based materials in the past (see for example, Jacobsen et al. 1996; Aldea et al. 1999; Win et al. 2004; Kato et al. 2005; Yang et al. 2006; Wang et al. 2008; Kanematsu et al. 2009; Picandet et al. 2009). Jacobsen et al. (1996) studied the effect of freeze-thaw cycles on chloride transport into concrete and they found that internal cracking increased the chloride penetration rate by a factor of 2.5 to 8 when compared with undamaged specimens. Yang et al. (2006) studied water transport in concrete damaged both by tensile loading and frost cycles and reported that the presence of freeze-thaw damage increased both the initial sorptivity and total water absorption of concrete.

It is obvious that if one uses material properties measured on undamaged concrete in prediction models the performance of a structure in aggressive environment may be overestimated. There is an urgent need to modify existing prediction models in such a way that they can take into account mass transport properties modified by damage due to mechanical or environmental loads. But necessary experimental data to feed this new generation of models are scarce. By means of neutron radiography it is possible to visualize and quantify water penetration into concrete. Up to now, this technique has been successfully applied already to study water movement in different porous building materials such as concrete, mortar, stone, and bricks by several researchers (see for example: Pleinert et al. 1998; Lehmann et al. 2002; Hassanein et al. 2006; Cnudde et al. 2008; Abd et al. 2009; Zhang et al. 2010).

The main aim of this paper is to investigate the influence of freeze-thaw cycles on water penetration into

concrete. To which extend is capillary water absorption increased by damage induced by frost action? From the raw data obtained by neutron radiography time-dependent spatial water distributions in concrete during water penetration can be determined in a quantitative way. Frost damage usually is assumed to be equally distributed in the volume. It should be possible to observe additional damage near the surface due to hygral gradients during cooling. All results obtained will be presented and discussed.

MATERIALS AND METHODS

Materials and Preparation of Test Specimens

Prismatic specimens with the following dimensions were prepared with two types of concrete, both with water cement ratio of 0.6: 100 mm × 100 mm × 400 mm. Ordinary Portland cement type 42.5, local crushed aggregates with a maximum diameter of 20 mm and density of 2620 kg/m3, river sand with a maximum grain size of 5 mm and density of 2610 kg /m3, all from Qingdao area, were used. Part of the specimens was produced with the addition of 0.017 % of an air entraining agent related to the mass of cement into the fresh concrete to improve its frost resistance. The exact compositions of the two types of concrete C and CA used in this project, and their air content and compressive strength at an age of 28 days are given in Table 1.

Table 1: Composition, air content and compressive strength of two types of concrete used in this project.

Concrete Type	Cement (kg/m^3)	Sand (kg/m^3)	Gravel (kg/m^3)	Water (kg/m^3)	Air entraining agent (g/m^3)	Air content (%)	28-day compressive strength (MPa)
C	300	699	1191	180	—	2.0	32.2
CA	300	699	1191	180	51	5.2	28.9

All concrete specimens were demoulded after one day and then stored in a moist curing room at a temperature of 20 ± 3 ℃ and relative humidity higher than 95 % until an age of 24 days. At that time all specimens were taken out of the curing room and further stored in water for another four days. At an age of 28 days, specimens were then ready for the following frost test.

Freeze-thaw Cycles

After curing concrete specimens were exposed to freeze-thaw cycles following a Chinese standard method (2010). In this case one freeze-thaw cycle lasts for about three hours. The temperature at the centre of specimens varied between -17 ± 2 ℃ and 5 ± 2 ℃. On concrete samples without addition of air entraining agent (Concrete C), the dynamic elastic modulus has been measured after 10 and 25 freeze-thaw cycles. On concrete samples prepared with addition of air entraining agent (Concrete CA), the dynamic elastic modulus has been measured after 10, 50, 100, 150, 200, 250 and 300 freeze-thaw cycles. In the following, specimens which had suffered freeze-thaw cycles are identified by the appropriate concrete type followed by the number of frost cycles, as for instance, the concrete with air entrainment exposed to 200 freeze-thaw cycles will be designated “CA-200”. As can be expected concrete made with air entraining agent has a significantly improved frost resistance. Change of the related dynamic elastic modulus of both types of concrete, without and with air entraining agent, as function of number of frost cycles is shown in Figure 1.

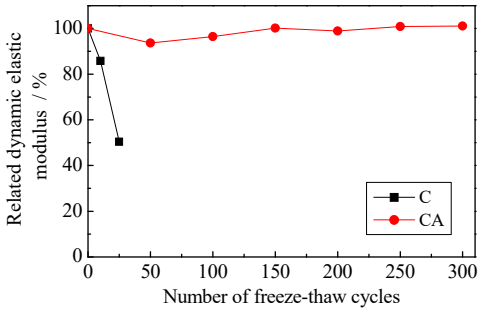

Figure 1 Related dynamic elastic modulus of two types of concrete C and CA as function of the number of freeze-thaw cycles

After exposure to a certain number of freeze-thaw cycles, selected specimens were taken out of the frost testing machine and cut in parts for water penetration tests. First a centre cube with dimensions with an edge length of 100 mm was cut off. Then two opposite layers with a thickness of 25 mm each were cut off the cube. Finally the remaining block which had the following dimensions: 100 mm × 50 mm × 100 mm has been separated into five thin slices with a thickness of approximately 20 mm. The cutting scheme is shown schematically in Figure 2. Slices from the surface were designated as “-1”, the intermediate slices with “-2” and the centre slice with “-3”.

The test sample were then dried in a ventilated oven at 50 ℃ for four days until constant weight was achieved. Then four surfaces were covered with self-adhesive aluminum foil. Two opposite surfaces with the dimensions 20 mm × 100 mm remained free for the capillary absorption test. After the first image had been taken by means of neutron radiography in the dry state of the specimens the aluminum container was filled with water. At this moment water started to penetrate into the frost damaged concrete. Neutron images were then taken at regular intervals following the process of water penetration into the samples. The obtained raw data were later evaluated by means of appropriate computer programs in order to determine time-dependent water distributions quantitatively.

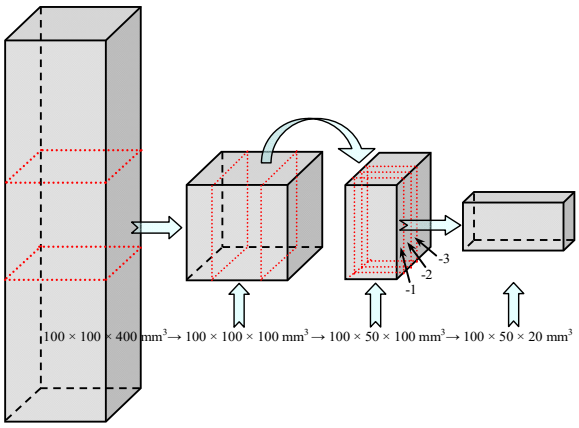

Figure 2 Schematic representation for cutting specimens

Neutron Radiography

All tests of neutron radiography were performed at the thermal neutron radiographic facility called NEUTRA of Paul Scherrer Institute (PSI) in Switzerland (Lehmann et al. 2002). The basic set-up of neutron radiography is shown in Figure 3. After the reservoir was filled with water neutron images were serially taken every twenty seconds for up to four hours. In order to visualize more clearly the process of water penetration into concrete, differential images from any time related to the initial time were then processed. For the quantitative evaluation of the digitized neutron radiographs, a software program was utilized. More details about quantitative calculation of water content in porous materials can be found in references (Pleinert et al. 1998; Hassanein et al. 2006; Abd et al. 2009; Zhang et al. 2009).

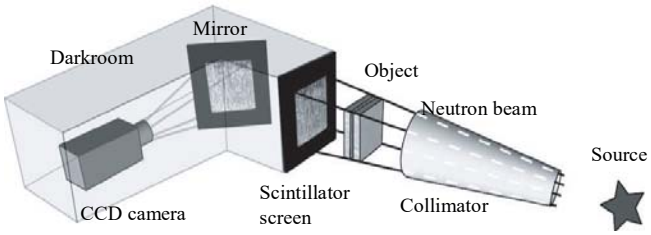

Figure 3 Basic set-up of neutron radiography

RESULTS AND DISCUSSION

Water Penetration into Concrete without Air Entrainment after Frost Damaged

Neutron images of water penetration into concrete without air entrainment and without frost action are shown in Figure 4. It can be seen immediately that by means of neutron radiography we can follow qualitatively the process of water penetration into porous cement-based materials. After a contact time of about five minutes the penetrating water front becomes visible. Then this irregular front gradually moves deeper into concrete with increasing contact time. The aggregates of the composite material are marked with the lighter areas as they do hardly absorb water. The water moves around the aggregates in the porous cement-based matrix. The time-dependent moisture profile along a vertical axis in the marked rectangular area as shown in Figure 3 can be analyzed quantitatively. Obtained results are also shown in Figure 4.

After exposure of the initial concrete prisms to 10 freeze-thaw cycles, concrete slices were cut off at different distances from the surface of the damaged specimens as described above. The process of water penetration into

these samples was then measured. A few selected neutron images are shown in Figure 5 for the three different slices. It can be seen that in comparison with results shown in Figure 4 water penetrates deeper into the frost damaged concrete at the same time of contact. Quite obviously freeze-thaw damage increased the rate of water absorption into concrete. This has been observed by Yang et al. (2006) before. The corresponding water distribution profiles in different layers from the surface to centre of concrete were calculated and the resulting profiles are shown in Figure 5. It can be clearly seen that the closer a sample was positioned to the concrete surface, the deeper water penetrates. This is a clear indication that there exists a damage gradient. And damage decreases with increasing distance from the surface.

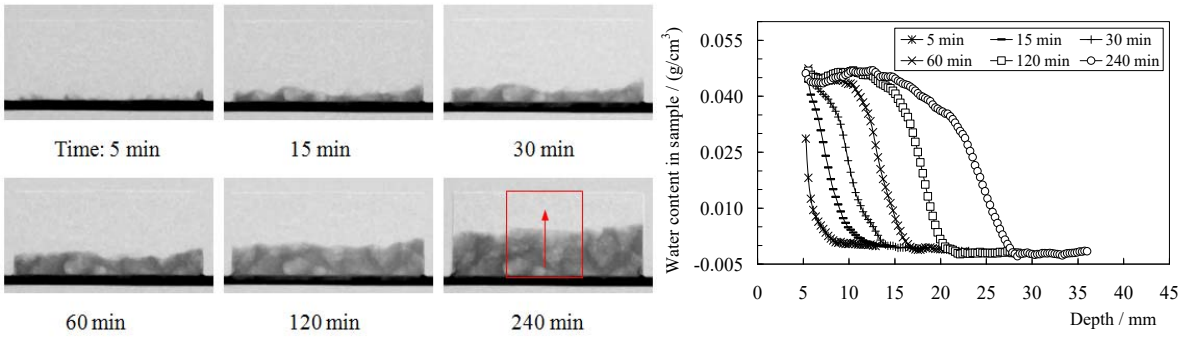

Figure 4 Neutron images of water penetration into neat concrete without air entrainment before frost damage after different durations of contact with water and the corresponding moisture distribution in concrete

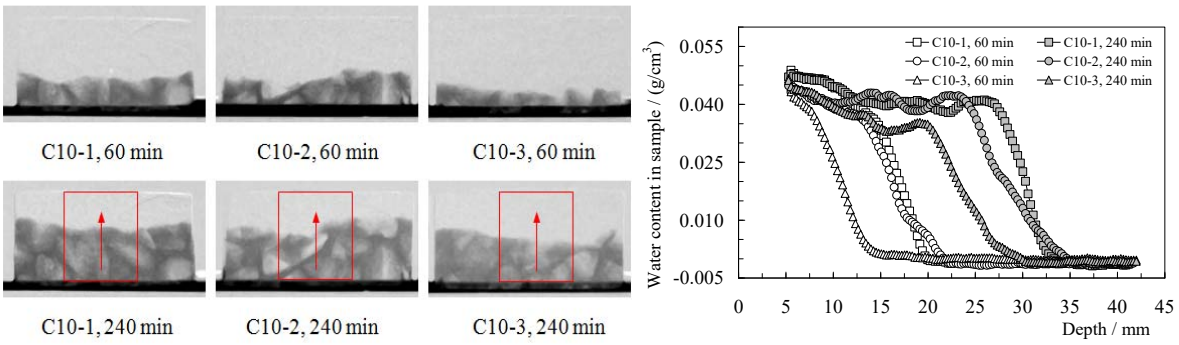

Figure 5 Water penetration into layers of concrete C, having different distances from the surface, after 10 freeze-thaw cycles after 60 and 240 minutes of contact with water, and the moisture distributions.

Water Penetration into Air Entrained Concrete after Frost Damaged

Direct observation of water penetration into concrete prepared with air entraining agent by neutron radiography is shown in Figure 6. The resulting moisture profiles are shown next to the images in Figure 6. The water front moves into this type of concrete with slightly lower rate as compared with normal concrete (see Figure 4). This tendency has been observed before by ordinary capillary suction tests and it can be explained by the fact that the artificially introduced spherical air pores break the capillary force locally. The artificial air pores will be filled with water very slowly and this is probably the reason why we observe two levels of water content in the distribution curves. The pores, which remain empty for a long time even if concrete is in contact with water, assure increased frost resistance. Water in the smaller pores in hardened cement paste around the comparatively big artificial pores is under high capillary under-pressure and therefore it cannot enter the bigger spherical pores.

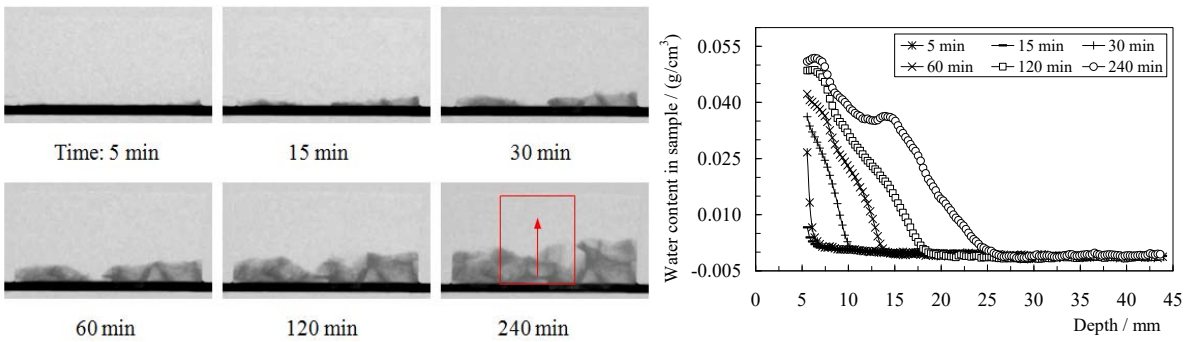

Figure 6 Water penetration into air trained concrete before frost damage and the corresponding moisture distributions in concrete

In a similar way, we followed the process of water penetration into different layers of concrete type CA after 50 and 200 freeze-thaw cycles by neutron radiography. Selected neutron images are shown in Figure 7 and Figure 8 for 50 and 200 freeze-thaw cycles respectively. If we compare these results with those obtained on concrete type C without air entrainment after 10 frost cycles (see Figure 5), it can be seen that concrete type CA absorbs after 50 and 200 freeze-thaw cycles less water than concrete type C after 10 cycles. This indicates the high efficiency of air entrainment to improve frost resistance of concrete. In addition, compared with results obtained on concrete type CA without frost damage (see Figure 6), there is no obvious difference observed on concrete type CA after frost action, with the exception of sample CA200-1. This means that air entraining improves frost resistance significantly but in long lasting contact with water and under a high number of freeze-thaw cycles concrete eventually will be damaged. Under these conditions more rigorous protective measures will be needed.

The obtained digital images on concrete type CA after 50 and 200 freeze-thaw cycles were also evaluated. Detailed evaluation provides us with quantitative moisture distributions. Results along the vertical direction of the rectangular area marked in the images are shown in the right of Figure 9. Water profiles measured in concrete type CA from the surface to the centre after 50 freeze-thaw cycles are nearly the same as results found in specimens without frost action. Even after 200 freeze-thaw cycles, water profiles have not strongly increased except for the surface near layer.

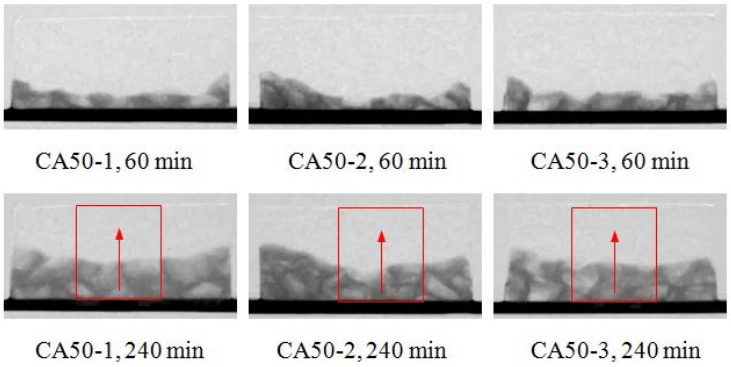

Figure 7 Water penetration into layers of concrete CA, having different distances from the surface, after 50 freeze-thaw cycles

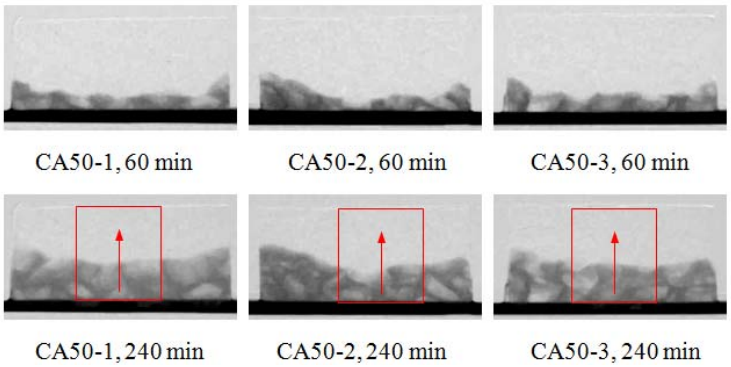

Figure 8 Water penetration into layers of concrete CA, having different distances from the surface, after 200 freeze-thaw cycles

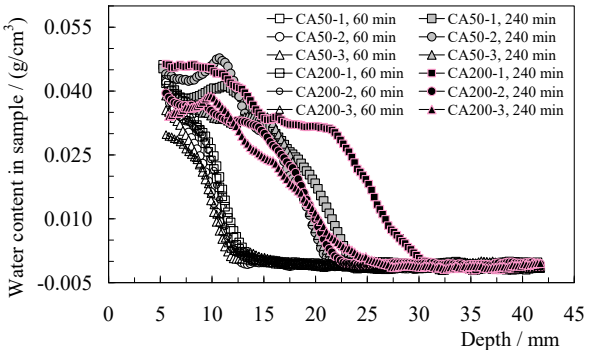

Figure 9 Moisture profiles in layers of concrete CA, having different distances from the surface, after 50 and 200 freeze-thaw cycles after 60 and 240 minutes of contact with water.

CONCLUSIONS

Investigations into the water penetration into undamaged and frost damaged concrete by eutron radiography are described in this paper. Based on the results obtained, the following conclusions can be made: (1) Water penetration into ordinary concrete is increased significantly by frost damage. From the surface to the centre of the tested concrete samples, the rate of water penetration decreases. A damage gradient can be observed. (2) After 50 freeze-thaw cycles, water penetration into air entrained concrete did not vary significantly as compared to values obtained on undamaged concrete. After 200 freeze-thaw cycles, however, the surface near zone absorbed more water although the dynamic elastic modulus as measured on the bulk material has not decreased. Damage concentrated into a thin surface near layer. (3) In addition to the common frost damage induced by freezing of water in narrow gaps and in nano-pores, differential deformations between hardened cement paste and aggregates may also induce damage into the interfaces.

ABSTRACT

Performance based engineering (PBE) is increasingly recognised as the gold standard for ensuring structural safety under extreme loading conditions such as a post-flashover fire. While no universally agreed methodology exists for implementing PBE for various kinds of extreme loadings in general, there are three clearly defined stages for doing so in order to design or assess structural resistance under fire loading. The fire loading is characterised in the first stage, which may range from simple prescribed time-temperature relationships if standard fires are adopted, which is against the spirit of PBE, to an expensive computational fluid dynamics simulation, which in most cases would constitute overkill. A number of options are available and gradually being developed that lie between these two extremes. A realistic characterisation of the load should in general allow the possibility of non-uniform heat fluxes to structural surfaces, which makes the second stage of determining structural temperatures very tedious. Furthermore, the computational models used in the third stage of determining nonlinear structural response are usually very different from the models used in the second stage thereby requiring significant manual intervention by the analyst. In the author's view this, bar the need for further research on realistic fire scenarios, is the greatest obstacle in carrying out PBE for structural fire resistance design. This paper presents a simulation tool developed within the open source software framework OpenSees with the aim of integrating all the stages of the analysis discussed earlier in order to make PBE feasible even for design offices with modest resources in terms of trained analysts and computing hardware.

INTRODUCTION

In modern day design of structures, durability of structures under natural and man-made hazards has been given more prominence to ensure their longevity. There has been a trend in the structural design industry to adopt performance-based design due to numerous advantages over conventional prescriptive approach. Performance based design methodology is now being extended to enhance the fire performance of structures. To achieve this, structural engineers are required to have better understanding of the global behaviour of structures under common fire scenarios, such as standard and parametric fires, or localised travelling fires for buildings with large compartments. One way to make this happen is by performing automated sequential thermo-mechanical analyses using a single numerical tool. The need for such tool was recommended in the proceedings of a workshop held at NIST (National Institute of Standards and Technology), suggesting to establish a framework (or more likely a patchwork) of models to couple the fire exposure, heat transfer to the structure and structural response in order to support performance-based design (Grosshandler 2002).

In general, there are two types of computer programs for simulating structural behaviours in fire: research-oriented and for commercial use. The former such as SAFIR, VULCAN, and ADAPTIC address specific modelling problems, because of a limited number of users and a vanishingly small team of developers. Therefore these frameworks have natural limitations in their capabilities. The development of such software is academic-research driven and highly prone to the risk of losing valuable development work when team members leave the research group. Commercial software packages such as ABAQUS, ANSYS and DIANA are used by researchers and industry across the world. However limited access to source codes; lack of transparency of the computational framework; and the high cost of purchase and maintenance are major limitations.

In 1997, an open source software framework, Open System for Earthquake Engineering Systems (OpenSees) was developed at the University of California, Berkeley (McKenna 1997). It was initially designed to simulate non-linear response of structural frames under seismic excitations. OpenSees has an object-oriented architecture and is written in C++. Object-oriented capabilities enable structural engineers to focus on modelling objects that also have their own attributes and functions rather than just data. Major attributes such as elements, materials, analysis procedures, and solution algorithms are designed as individual objects and they can be added into the framework freely by anyone anywhere (Usmani *et al*. 2012). An active group of OpenSees experts moderate the framework using a version control system, Subversion. This attracts the researchers from across the globe to contribute their piece of code to the original framework and help make it more robust and bug-free.

In 2009, OpenSees was adopted at the University of Edinburgh to further develop it to perform structural fire analysis. Significant contributions in terms of heat transfer and fire modules have been made to the framework in developing the 'Thermal' version of OpenSees (Jiang Y. Q. 2013). Temperature dependent formulations have been incorporated for basic element types, beam element and shell elements to account for the thermal effects (Jiang J. 2013). Material library of the original framework has also been updated by adding new temperature dependant material models for steel and concrete based on Eurocodes (Zhang 2014).

Development of OpenSees Thermal is an ongoing project and is presently limited to only a few elements, material models and fire scenarios. This cannot fully exploit the great potential of the OpenSees framework. Furthermore, a single software to carry out the full set of analyses which includes relatively realistic fire load modelling (e.g. localised and travelling fires); heat transfer to structural components (by radiation, convection, conduction); and the entire structural response, is still unavailable. In order to move towards a more comprehensive solution for a unified analysis, development of an OpenSees based research tool named SIFBuilder was started in 2014 (Jiang *et al*. 2014), which aims to perform automated structural fire analyses for large structures under realistic fires. It is a comprehensive computational tool, which could enable structural engineers to obtain the structural response automatically with the application of the fire load on the structure in the same manner as any other form of load and so provide a performance-based structural fire engineering tool.

THE SIFBUILDER SIMULATION TOOL

Unlike commercial packages, neither OpenSees nor SIFBuilder has a graphical user interface (GUI). However, it has a script based user input capability. Similar to other commonly used FEM software, SIFBuilder requires the user to input basic structural information for generating the structural model. Procedural scripts are written to specify geometry, materials, loads, heat transfer parameters, fire type, analysis procedures, solution algorithm and output requirements using Tool Command Language / Tool Kit (Tcl/Tk). A typical user input script for model generation includes: model type definition for identifying the dimension of analysis (2D or 3D), geometry of the structure (bay length in each directions in a Cartesian coordinate system), material type and cross section type for the structure members, and boundary conditions for the structural model.

Following model generation, the user defines the structural loading and thereafter the fire loading information. SIFBuilder is programmed to hold the thermal loading information throughout the structural analysis. Subsequently, the heat transfer analysis module launches and the nodal temperature histories are automatically mapped to the fibres of the structural mesh. Following the heat transfer analysis, structural analysis is performed on the building, accounting for the degraded material properties. Hence, the output generated will be the result of a thermo-mechanical analysis in response to realistic fire scenarios. Figure 1(a) shows the flow chart of different operations in the project SIFBuilder.

Model-Generation

As mentioned in the previous section, the OpenSees framework lacks a pre-processor, and the procedures for model generation are written in Tcl. A series of higher level Tcl commands are created for generating relatively complex structural models easily and quickly, by just providing the geometry information of the structure. Currently, SIFBuilder is capable of generating a regular 3D framed-structure including the floor slab as shown in Figure 1(b).

The basic structural frame model available in SIF builder has also been extended to generate reduced models such as the X-Z grillage model (see Figure 1(c)) with slabs and skewed angles, beneficial in representing asymmetric geometry or bridge models. Similarly 2D frames and even single beams and columns can be generated.

Material Libraries

OpenSees has a rich source of material libraries for both steel and concrete. Moreover, its open source development makes it easy to include user defined materials. The thermal version of OpenSees consists of Eurocode and non-Eurocode based temperature dependent material models. A good choice of material models is essential in performing thermo-mechanical analysis.

Structural Material

To perform structural analysis at high temperature, Eurocode [ENV 1992-1-2 (Eurocode 2 2004); ENV 1993-1-2 (Eurocode 3 2004)] stipulates uniaxial and multi-axial steel and concrete material models. Some of the material models that have been incorporated in OpenSees material libraries are shown in Table 1. Details of these materials can be found in the research group's web portal (OpenSees Edinburgh 2010).

Table 1. Structural Material Types

ElasticThermal	Steel01Thermal
SteelECThermal	Steel02Thermal
ConcreteECThermal	Concrete02Thermal
DruckerPrager3DThermal	DruckerPragerConcreteThermal

For instance, *SteelECThermal* contains different steel types based on Eurocode classification (Table 2).

Table 2. Steel Types of SteelECThermal Model

TypeTag	Steel Type
EC3	EN1993-1-2:2005 Structural Steel
EC2NH	EN1992-1-2:2004, Class N, Hot Rolled
EC2NC	EN1992-1-2:2004, Class N, Cold Worked
EC2X	EN1992-1-2:2004, Class X

Heat Transfer Material

To perform heat transfer analysis, four types of material are developed: *NWConcreteEC2* for normal weight concrete, LWConcreteEC4 for lightweight concrete, *CarbonSteelEC3*, and *SteelASCE*, which are based the Eurocode and Lie *et al*. (1992). A user defined material model called *SimpleMaterial* is also provided. All these heat transfer materials hold the information on heat transfer parameters such as thermal conductivity, specific heat, density and enthalpy (Jiang Y. 2013).

Element Types

OpenSees offers a extensive element library. Due to its efficiency and high accuracy in thermo-mechanical analysis, *dispBeamColumn3dThermal* (displacement-based 3D beam/column element) and *ShellMITC4Thermal* are chosen as primary element types during the SIFBuilder model generation process. However, other options (shown in Table 3) may also for be considered for this purpose.

Table 3. Structural Element Types

dispBeamColumn2dThermal	dispBeamColumn3dThermal
forceBeamColumn2dThermal	ShellMITC4Thermal

For both 2D and 3D heat conduction analysis, the four-noded and eight-noded quadrilateral elements and the eight-noded brick element are used.

FIRE LOADS IN SIFBUILDER

Fire loads form the salient feature of SIFBuilder tool. A wide variety of well-established fire models are integrated into SIFBuilder, to provide its users the freedom of using different types of fire scenarios (based upon the model types proposed in section 2.1) to assist their design calculations.

Idealised Uniform Fires

Based on the temperature-time curves presented in Eurocode 1 (EN1991 2002), post-flashover fires such as standard fire (ISO-834), hydro-carbon fire, and empirical parametric fire are all implemented in SIFBuilder. Although these fire models are relatively simple, they are still widely used for both research and design purposes in fire safety engineering. A user defined external fire curve is also included for providing more flexibility. These idealised uniform fire models are all assumed to have the same temperature distribution in the entire compartment at a specific time according to Eurocode.

Idealised-non-uniform-fires

Compared to uniform fire models, more advanced non-uniform fire models are provided in SIFBuilder. These non-uniform fire models are capable of producing both spatially and temporally non-uniform temperatures in the compartment.

Localised Fire

SIFBuilder also includes two pre-flashover and localised fire models: Eurocode 1 localised fire model (Hasemi *et al*. 1996) and SFPE localised fire model (Alpert 2002). These two localised fire models are regarded to be very efficient for carrying out simulations such as vehicles burning in an open plan car park building.

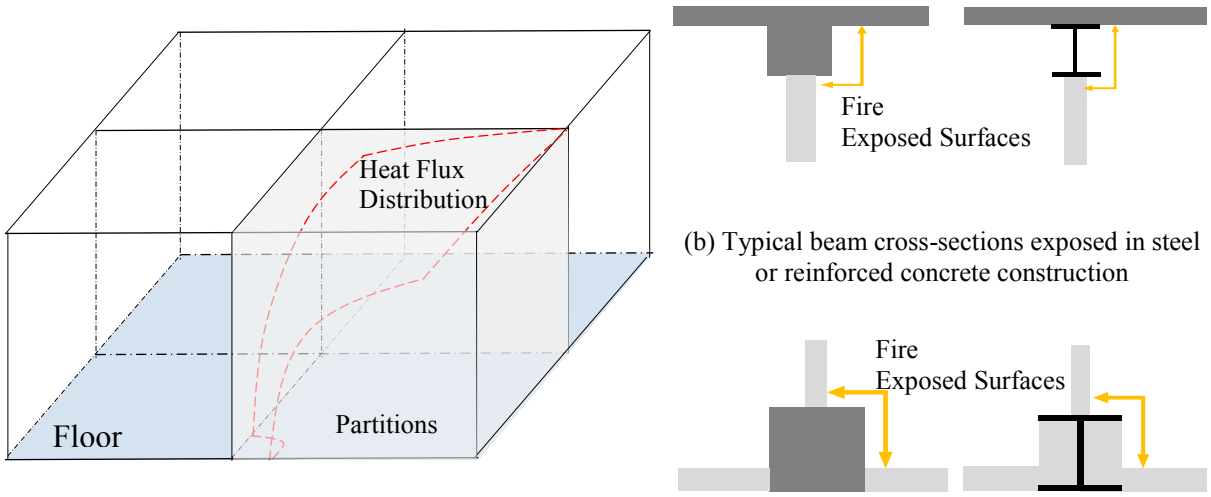
Travelling Fire

Current travelling fire model in Stern-Gottfried and Rein (2012a and 2012b) can be employed in SIFBuilder to simulate the travelling fire and relevant work can be found in (Jiang Y. 2013).

HEAT TRANSFER IN SIFBUILDER

Implementation of Idealised Fires in SiFBuilder

Fire load calculations are succeeded by the heat transfer analysis. SIFBuilder adopts a smart member identification algorithm, where the heat transfer analysis activates on pre-specified members based on their exposure conditions. Figure 2(a) depicts schematically a localised heat flux distribution adopted in a compartment or building sub-frame.



(a) A compartment in a building sub-frame subjected to an idealised non-uniform fire

(b) Typical beam cross-sections exposed in steel or reinforced concrete construction

(c) Typical column cross-sections exposed in steel or reinforced concrete construction

Figure 2. An idealised non-uniform fire in a building sub-frame and associated exposed structural surfaces

Figures 2(b) and (c) shows the exposure conditions in a typical beam and column respectively. These exposure conditions are used by SIFBuilder to obtain time-temperature histories within each structural component. The

key capability of SIFBuilder is enabling consideration of non-uniform heat flux, which is a far more realistic situation for large compartments, where performance-based engineering is usually required.

EFFICIENT HEAT TRANSFER

SIFBuilder is designed for simulating whole-frame structural behaviour in realistic fires. To achieve this, an efficient heat transfer strategy is employed for saving computational resources and offering additional flexibility to the end users.

Repeated tests on the developed module has confirmed that for idealised uniform fires in a compartment, 1D heat transfer for the slab and 2D heat transfer for beam and column cross-sections holds good and hence, this strategy is adopted in SIFBuilder. Since heat flux is spatially invariant over structural component surfaces under idealised uniform fire scenarios this can be regarded as a reasonable approach without significant dispute.

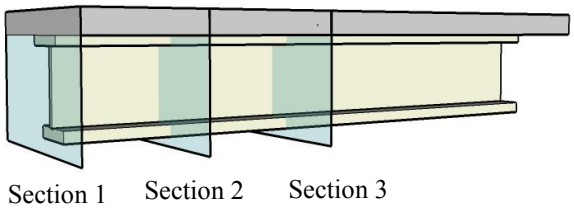


Figure 3. Efficient Heat Transfer for Beam

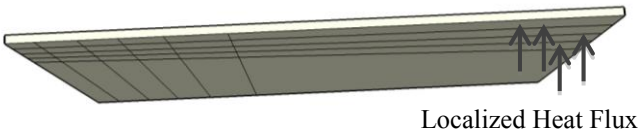

Figure 4. Efficient Heat Transfer for Slab

For compartments under idealised non-uniform fires the incident heat flux on structural members varies with location. The same approach as above here is more questionable, however numerical tests carried out by the authors show that even in this case this approach is highly feasible. Localised 1D heat transfer analysis for the slab and a series of 2D heat transfer for beam and column cross-sections is implemented and temperature-time histories between sections are obtained by interpolation. Schematic representations of this strategy are illustrated in Figures 3 and 4.

DATA OUTPUT & TRANSMISSION

Data Output

As discussed above, both the fire loading calculation and the heat transfer analysis are implemented in a realistic, accurate, and efficient way. Moreover, as this convenient computational tool is not a black box, it is easy for users to customise their models and access the intermediate and final analysis information. The temperature history from the heat transfer module can be easily accessed by defining proper Tcl 'recorder' commands in the model script. Many other simple tasks such as monitoring the analysis by creating break points, obtaining the desirable node output by specifying parameters, simple debugging of the input scripts are made possible by adapting simple tips and tricks offered by Tcl.

Data Transmission

The most prominent feature of SIFBuilder is that it can map the heat transfer temperature results to the structural elements automatically during the analysis. The fire model provides the heat flux exposure evolution in time for all relevant structural surfaces; this information is automatically passed on to the heat transfer module to be used as the boundary condition for the heat transfer calculations, performed efficiently using reduced dimensional

heat transfer at representative cross-sections; this develops a full 3D history of temperature evolution in the structural members for the full fire duration (and through to cooling if desired); finally these temperatures are passed on to the thermo-mechanical response simulation module. The temperature histories are processed to locate and interpolate nine temperature points across the depth of the section, and then further transformed to be applied to the fibers in the structural cross-sections of the exposed structural elements.

APPLICATION EXAMPLES

An idealised frame building is modelled to demonstrate the usage of SIFBuilder. The building is assumed to be comprised of two bays along each direction corresponding to the global x and z axes, respectively, as illustrated in Figure 5. Storey height is set as 5m for the ground floor, above which a 4m high storey is located.

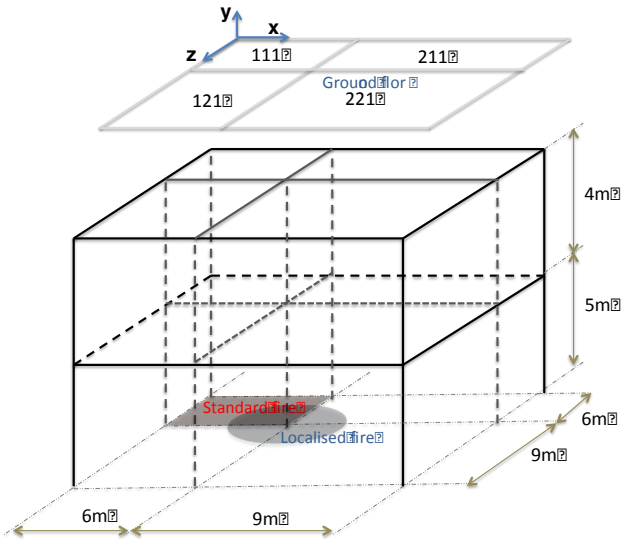

Figure 5. Idealised building configuration

Tcl script for constructing the building model begins with lines written in a simple fashion:

SIFXBay 6 9;
SIFZBay 6 9;
SIFStorey 5 4;

A SIFModel is created based on the above information and governs the building configuration, using which the finite element (FE) models for heat transfer and thermo-mechanical analyses are built up. The FE model requires the section definition in conjunction with a material library. Typical Tcl scripts responsible for material and section definitions are written as follows:

AddMaterial steel 1 –type EC3 3e8 2e11;
AddSection ISection 1 1 0.203 0.102 0.0054 0.009;
AssignSection beams 1;

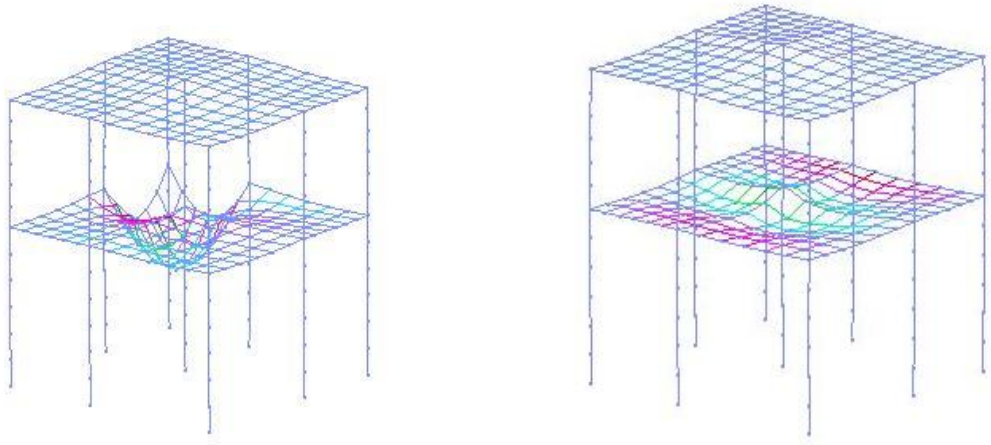
The first line of the code above defines a Eurocode 3 carbon steel material, which is associated with an I-section (UB 203x102x23). This section is later assigned to the beams, whereas for the columns another I section is defined as universal column section (UC 203x203x46) and assigned. Concrete slab of 100 mm thickness has also been included in this model. A uniformly distributed load (2kN/m^2) is firstly applied to the slabs, which is then followed by the fire action. The fire may be a conventionally uniform fire and constrained in one compartment, or it may be defined as spatially localised such as the Eurocode 1 localised fire model. For the first scenario, a uniform fire following the standard time-temperature curve is located in compartment 111 (as Figure 11 shows). The script written in Tcl is:

Addfire –compartment 111 –type Standard;

The second case for localised fire action is given as a fire surrounding the central column and defined as Eurocode 1 localised fire, with the rate of heat release as 4MW, and nominal diameter as 1.0m. The Tcl definition is as follows:

Addfire –compartment 111 121 211 221 –type EC1Local –origin 6 0 6 –HRR 4e6 –Dia 1;

Both of the fires last for half an hour, leading to the totally different responses for this framed structure. Significant deflection of slab can be observed from the compartment where the standard fire was imposed (see Figure 6a). For the localised fire, the slab deflection is not as great but localised to the centre due to the support from the centre column. While the column retains nearly full strength (at temperatures below 400 Celcius) it is forced to bear greater floor load due to its expansion while it loses strength at higher temperatures and may collapse, leading to a progressive collapse of the whole structure (as shown in Figure 6b).



(a) Idealised uniform fire example (a compartment fire)

(b) Idealised non-uniform fire example (a localised fire around the central column)

Figure 6: Deflection profiles at the end of the fire for the two example problems

CONCLUSIONS

A comprehensive structures-in-fire analysis tool is presented that can potentially truly revolutionise performance-based structural fire engineering. However at this stage this tool is primarily meant for researchers to explore the structural response to previously unfeasible (in terms of complexity of modelling and user effort) but realistic fire scenarios. For example the large compartment fires in tall buildings, vehicle fires under bridges, large warehouse type fires etc. Furthermore the tool is entirely free to be used and improved by research users and developers. All the source codes, examples, user and developer manuals on project SIFBuilder may be found at the University of Edinburgh - OpenSees wiki site (OpenSees Edinburgh 2010), so any interested researcher or engineer can review, download, and use it for free.

ABSTRACT

Optimized concrete elements incorporating high-performance, self-consolidating concrete (HPSCC) prestressed with high-strength, lightweight, non-corroding carbon fibre reinforced polymer (CFRP) tendons offer great potential for the growing needs of sustainable modern built environment. However, the fire performance of these novel elements is not well known and must be understood before they can be used with confidence in applications where structural fire resistance is required. The outcomes and insights from an extensive experimental research project on the fire performance of thin CFRP prestressed concrete slabs are presented; fire and elevated temperature tests performed at the material and member levels, using novel testing methods and techniques, are examined. Analysis of the studies showed that: (1) a high propensity for heat-induced concrete spalling results in sudden failure of thin CFRP prestressed HPSCC slabs, and when spalling is avoided failure occurs by loss of prestress anchorage governed by a combination of degradation of the epoxy resin around the surface of the CFRP tendons and loss of the concrete's confining action, due heat-induced transversal forces generated by the CFRP tendons; (2) polypropylene (PP) fibre cross-section and individual fibre length, when added to fresh concrete for spalling mitigation, have considerable influences on the effectiveness of PP fibres at reducing the propensity for heat-induced concrete spalling; (3) the tensile and bond strength of CFRP tendons is more sensitive to elevated temperature than that of the steel prestressing wire; (4) heat-induced transversal (splitting) forces are more likely for CFRP tendons. This extensive experimental programme reveals that conventional fire testing of structural concrete systems, conceived for traditional steel reinforced concrete structural elements, is not necessarily applicable for the design of highly optimized, CFRP prestressed HPSCC elements, and by extension for other similarly novel structural elements.

KEYWORDS

Carbon fibre reinforced polymer, prestressed concrete, fire behaviour, heat-induced concrete spalling, loss of anchorage.

INTRODUCTION & BACKGROUND

Driven by the need for more durable and sustainable concrete structures, there is a growing need for a careful selection, design, and optimization of concrete mixes and reinforcing materials used within the precast concrete industry. Concrete elements incorporating high-performance, self-consolidating concrete (HPSCC) and novel reinforcing and prestressing materials, such as carbon fibre reinforced polymer (CFRP) tendons are one such example (Terrasi, 2007). One example is the application of thin-walled elements as façade beams and columns in building envelopes (see Figure 1), and shows the potential of these structural elements to be widely used in the modern built environment.

The combined use of CFRP and HPSCC enables the design of optimized, low-weight prestressed elements with reduced concrete cover and overall thickness (Seica & Packer, 2007); this gives excellent serviceability (corrosion resistance, high stiffness and fatigue strength). However, the performance of these elements in fire is

not well known (Maluk, 2014) and must be better understood before they can be used with confidence in load-bearing applications where structural fire resistance is required.

The HPSCC used for the elements discussed herein had strength class C90 (minimum 28 days 150 mm cube compressive strength of 90 MPa) and a slump flow of 750 mm. Given the high likelihood of spalling for this mix, due to its high strength and the inclusion of microsilica in the mix (CEN, 2004), PP fibres were included during concrete mixing. The pultruded uniaxial CFRP tendons used were made from Tenax UTS carbon fibres, at a fibre volume fraction of 64%, and Bakelite 4434 epoxy resin. Their design tensile strength was 2,000 MPa, with a design elastic modulus of 150 GPa and a characteristic ultimate strain of 1.33%. The quartz sand coating applied after the initial pultrusion process had an average grain size of 0.5 mm and was bonded using the same epoxy resin to promote a strong bond. The gross (or net) diameter of the CFRP tendons was 5.4 mm and the total diameter, including sand coating, was approximately 6.0 mm (see Figure 1).

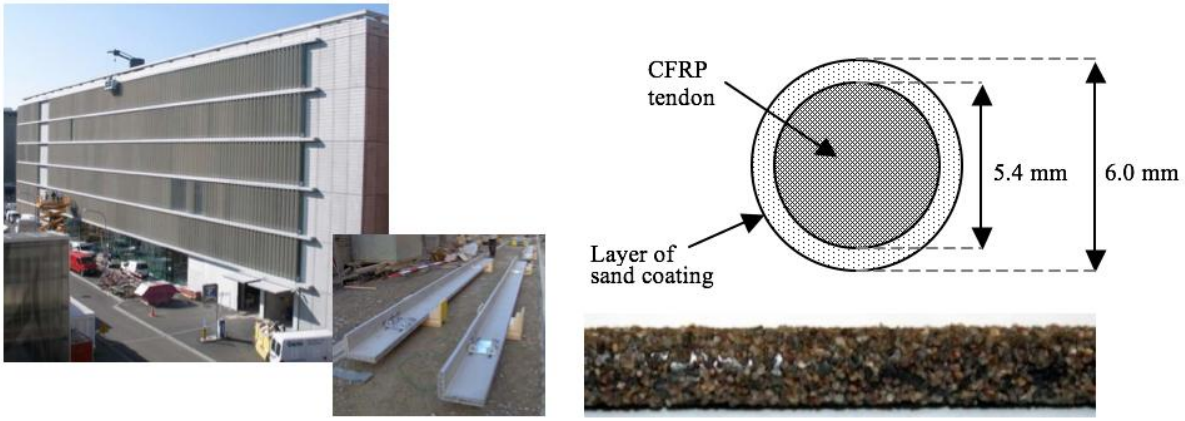

Figure 1 – Application of CFRP prestressed concrete L-shaped beams for structural façade elements in Zurich, Switzerland (Terrasi, 2007), and cross section schematic/photo of the CFRP prestressing tendon used in the current study.

Despite the scarcity of work studying the fire behaviour of concrete structural elements incorporating fibre reinforced polymer (FRP) reinforcements, fundamental differences to traditionally reinforced concrete structural elements have been reported (Maluk, 2014). Two main failure mechanisms when FRP reinforcements are used have been identified to control the fire performance of reinforced or prestressed CFRP concrete elements: (1) the higher propensity of HPSCC for heat-induced spalling and (2) heat-induced loss of bond in anchorage/splice zones.

Heat-induced Concrete Spalling

Heat-induced concrete spalling may be described as the flaking away of the concrete cover at the exposed surface of heated elements (during a real fire or during fire testing) in a more or less violent manner (Maluk, 2014). As a consequence, the concrete cover to the internal reinforcement is inevitably reduced, resulting in more rapid temperature increase of the reinforcement and within the core of the structural element. Spalling may also have direct impacts on the load bearing capacity of an element due to loss of effective cross section. Spalling therefore presents a potentially serious hazard for the fire performance of optimized, thin-walled elements such as those described herein.

Loss of Bond in the Anchorage Zone

Reductions in bond strength between traditional steel reinforcement and concrete are not generally considered to be a governing factor for the fire resistance of steel reinforced or prestressed concrete elements (Katz & Berman, 2000). Conversely, for FRP reinforcements it has been shown that bond strength degradation between FRP tendons and concrete at elevated temperature can be more critical than loss of FRP tensile strength (Bisby & Kodur, 2007). Thus, bond strength reductions are widely considered a limiting factor for the fire safe structural design of FRP reinforced and/or prestressed concrete elements. The magnitude of bond strength reductions and their impacts on the performance of FRP reinforced or prestressed concrete structures in fire remain largely unknown and have not been clearly demonstrated for many relevant applications.

Design codes for the design of FRP reinforced or prestressed concrete structures typically assume perfect bond between FRP reinforcement and concrete for ambient temperature analysis and design (e.g. (FIB, 2006)). The bond strength of FRP reinforcements relies primarily on the strength and stiffness of the epoxy resin at the surface of the reinforcement, which normally incorporates a sand coating, spiral fibre roving, and/or a ribbed shaped resin. However, the resin at the surface of the FRP tendon will soften at temperatures below 200°C for most available products (Maluk et al., 2011); hence the assumption of perfect bond at elevated temperature is not appropriate.

Furthermore, FRP reinforcements exhibit vastly different coefficients of thermal expansion (CTEs) in their longitudinal and transverse directions, and these also differ substantially to that of concrete. For example, CFRP reinforcements tend to have lower (even negative) CTEs in the longitudinal direction, while in the transverse direction their CTEs are governed by the matrix polymer and can be up to an order of magnitude larger than for concrete. The CTE for FRPs is traditionally examined in the range of temperatures before decomposition of the matrix polymer; i.e. less than 300-350°C (Maluk, 2014).

Some prior studies have aimed at understanding the effects of differential thermal expansion between FRP reinforcements and concrete (e.g. (Aiello et al., 2001)). It is thought that the development of heat-induced transversal forces leads to the development of longitudinal splitting cracks along the reinforcement, and possibly to loss of the concrete cover's ability to provide sufficient confining action for anchorage to be maintained. It is expected that this would be exacerbated by large in-depth temperature gradients in the concrete during fire (Maluk, 2014).

RESEARCH SIGNIFICANCE

It is widely perceived that reinforced or prestressed concrete structural elements incorporating FRP reinforcements have lower fire resistance than equivalent steel reinforced or prestressed elements (Terrasi et al., 2012). However, comparatively few comprehensive fire studies have ever been performed on these novel elements; little is known about the true response of these elements during fire. The current paper presents results from a suite of seven experimental research projects shedding light on the relative importance of understanding, from first principles, the fire behaviour of thin CFRP prestressed HPSCC elements.

TEST METHODS AND RESULTS

The outcomes of seven linked experimental research projects performed by the authors are presented and examined. Tests carried within these projects were performed at varied scales and employed a wide variety of experimental techniques, all aimed at a better understanding the fire behaviour of CFRP prestressed slabs.

Study #1: Large-scale furnace tests

A series of standard large-scale furnace tests (i.e. fire resistance tests) were performed during 2009 and 2010 (Terrasi et al., 2012), and an additional test was executed in 2013 (Maluk et al., 2015). During each of these tests, five large-scale, loaded CFRP prestressed HPSCC slabs were tested simultaneously in a single standard floor furnace test (see Figure 2) at the Swiss Federal Laboratories for Materials Science and Technology (EMPA). The design of the slabs was aimed to evaluate a range of design parameters relevant to CFRP prestressed slabs:

- inclusion of PP fibre type (monofilament, multifilament, and fibrillated)
- inclusion of PP fibre cross-section (18 or 32 μm circular, or 37 × 200 μm^2 rectangular);
- inclusion of PP fibre length (3, 6, 12, or 20 mm);
- inclusion of PP fibre dose (between 0 and 2.43 kg of PP fibres per m^3 of concrete);
- age of concrete concrete (between 0.9 to 22.3 months);
- overall slab depth (45, 60, or 75 mm);
- length of unheated overhangs (160 or 280 mm);
- initial prestress level (800, 1000 or 1200 MPa); and
- presence of CFRP anti-bursting grids within the anchorage zones.

The initial prestress level was calculated based on the gross cross-sectional area of the tendons; i.e without considering the layer of sand coating (see Figure 1). It is noteworthy to point out that for prestressed concrete elements, the ends the slabs are commonly labelled as active end (stressing end) and passive end (dead end). All CFRP tendons were located at the slab mid-depth, with a tolerance of ±2 mm, to obtain a nominally concentric prestressing force. All slabs were 200 mm wide. Lateral clear concrete cover at the slab edges was 22 mm in all cases, with a tendon-to-tendon clear spacing of 44 mm.

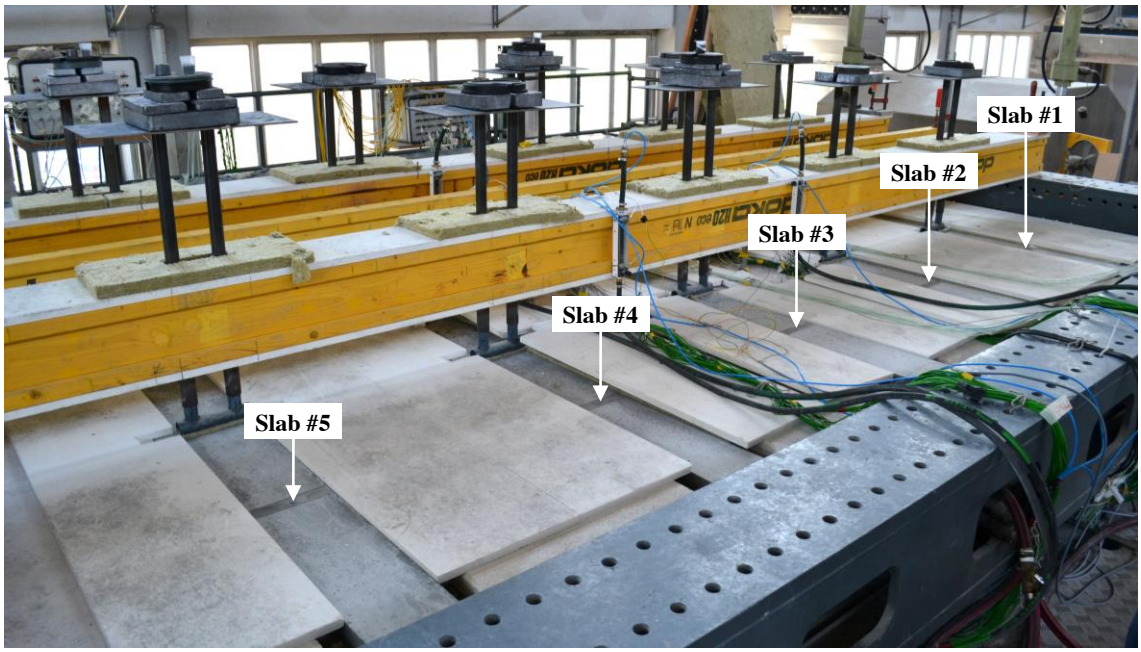

Figure 2 – Photo of a fire resistance test setup showing positions each slab and loading technique used.

The furnace test setup aimed at assuring one-sided heating from below, so the sides of the specimens were fully insulated. The heating regime was executed according to the requirements of the standard time-temperature curve (CEN, 2012). Sustained mechanical loading was applied to simulate an in-service condition for the slabs, in simply-supported four-point bending. The applied load was designed to be sufficient to achieve decompression at the extreme tension fibre within the constant moment region; this corresponds to a typical design service load condition for a façade element of this type in a real building (Terrasi, 2007). Loading was imposed 30 minutes prior to start of heating.

A detailed description of the test setup and analysis of the results from all of the large-scale furnace tests performed are thoroughly presented elsewhere (Terrasi et al., 2012; Maluk et al., 2015). During testing, slabs were instrumented with:

Temperature gauges inside the slabs – Through-thickness temperature measurements were taken at midspan at eleven depths from the exposed surface of each of the slabs. Temperature measurements were also taken at several locations in the anchorage zones along the lower edge of one of the central CFRP tendons. Bare K-type thermocouples (TCs) were used in all cases, and special care was taken during the casting process to ensure precise placement of the TCs at the intended locations inside the slabs.

Midspan vertical displacement gauges – Midspan vertical deflection was measured using linear voltage displacement string pot transducers, anchored on a beam resting on top of the furnace.

Draw-in gauges – Aiming to measure possible draw-in of the CFRP tendons during testing, due to loss of anchorage, semi-disposable custom-built "pi" displacement gauges (pi-gauges) or laser reflectometers were used. These were placed at either end of the slabs (active and passive ends).

For all slabs tested (five slabs in each of the six furnace tests executed), time-to-failure occurred anywhere between 12 and 90 minutes from the start of the test. Some slabs were able to carry their sustained service load for more than 90 minutes of fire exposure, at which point the tests were halted. Failure of the slabs was driven by one of two phenomena:

- multiple (or in some cases even a single) heat-induced spalling events, which resulted in total collapse of the test specimen (see Figure 3), or
- progressive loss of bond in the anchorage zones, leading to more gradual collapse of the test specimen (see Figure 4).

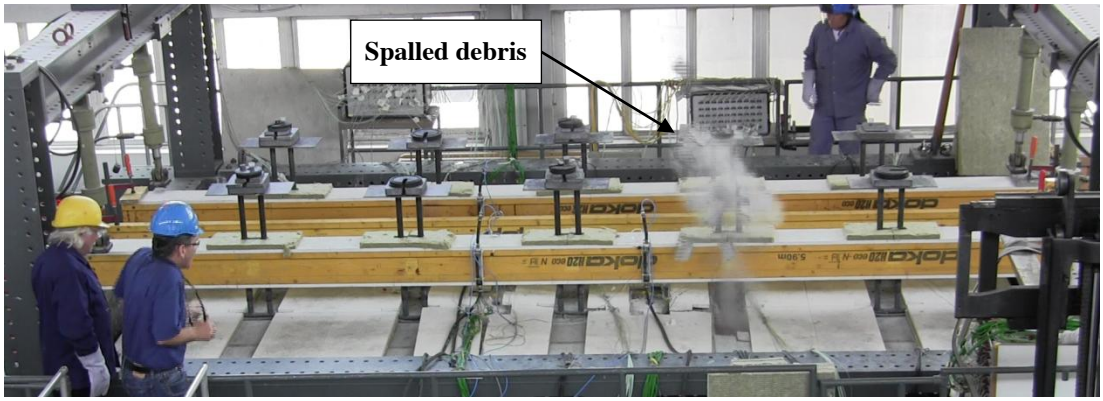

Figure 3 – Heat-induced concrete spalling and immediate collapse of a slab, 12 min from the start of the test.

During progressive loss of bond in the anchorage zone the following events were identified:

Increase in the rate of midspan deflection – This occurred when the temperature of the CFRP tendons at midspan was about 310°C (see Figure 4). The temperature of the CFRP tendons at the anchorage zone (200 mm from the end of the slab) at this moment was about 70-80°C for the 45 mm thick slabs, and 120-130°C for the 60 mm thick slabs.

Appearance of the first longitudinal splitting crack at the unexposed surface – This occurred when temperature of the CFRP tendons at midspan was between 320 and 390°C (refer to Figure 4), regardless of the temperature in the unheated overhangs. Longitudinal splitting cracks were first observed at the unexposed surface (i.e. top surface), near the midspan region.

Failure (i.e. collapse) – The midspan temperature of the CFRP tendon at failure of the slabs was higher for slabs that incorporated CFRP grids within the anchorage zones. Slabs which had no CFRP grids failed when the temperature of the CFRP tendons at midspan was about 460°C, while the same occurred when temperature of the tendons at midspan was about 590°C for slabs including CFRP grids in their anchorage zones.

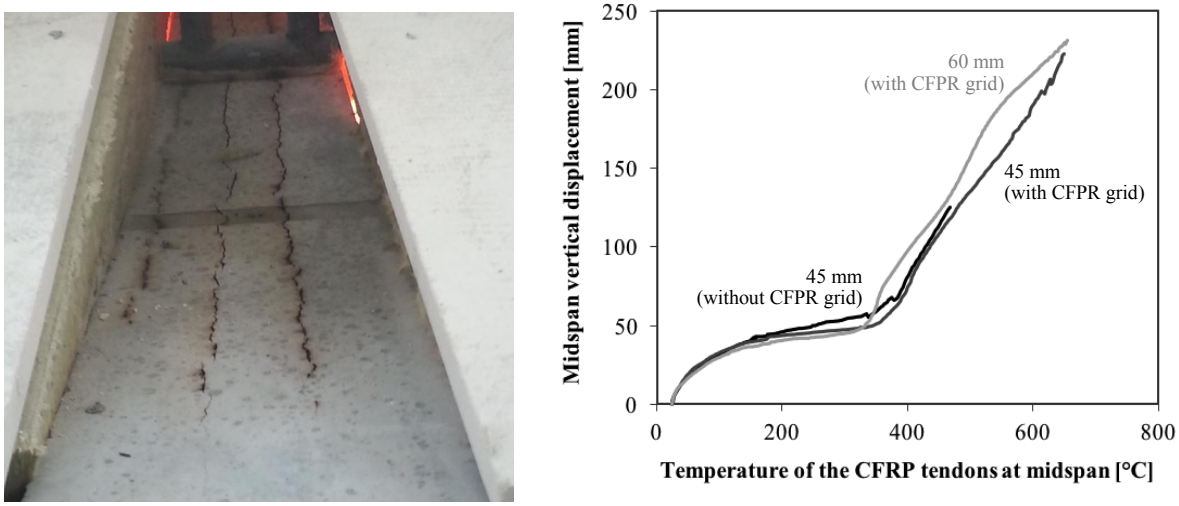

Figure 4 – Typical longitudinal splitting cracks at the unexposed surface of heated slab shortly before failure and variation of midspan vertical displacement with temperature of the CFRP at midspan. Data in the graph corresponds to identical CFRP prestressed HPSCC slabs with 160 mm unheated overhangs and an initial prestress of 1000 MPa, but varying overall slab depth and presence of CFRP anti-bursting grids within the anchorage zones.

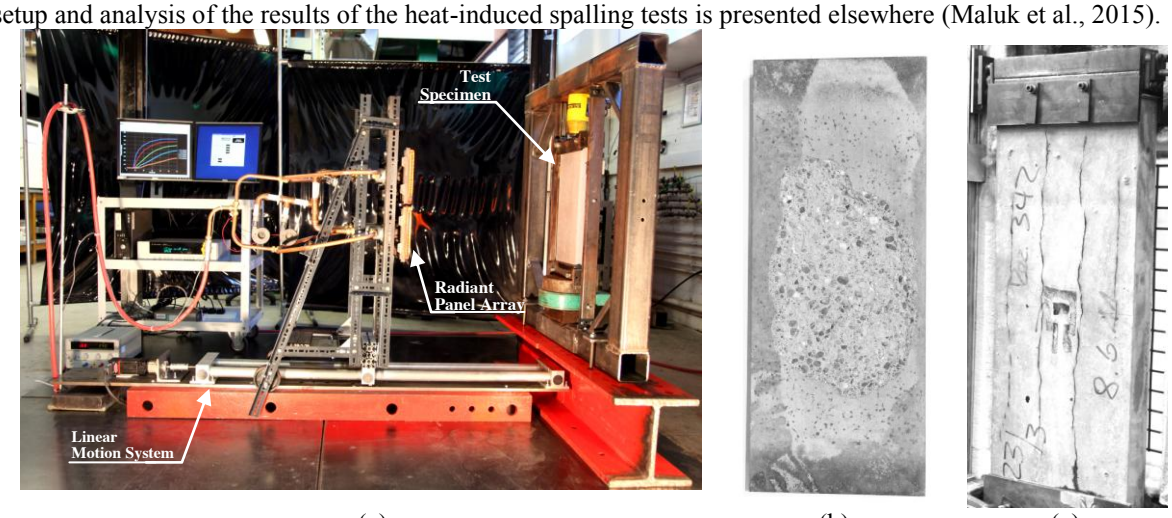
Study #2: Heat-induced spalling tests

For this study, a H-TRIS (Heat-Transfer Rate Inducing System) test method and apparatus was used for studying the propensity for heat-induced spalling of concrete for medium-scale specimens cast with different concrete mixes (see Figure 5). Rather than taking the traditional approach of fire testing by controlling the gas temperature inside a fire testing furnace, the H-TRIS test method permits direct and independent control of the thermal boundary conditions; it does this by controlling the time-history of incident radiant heat flux at the exposed surface of a test specimen (Maluk et al., 2015).

The imposed thermal boundary conditions were aimed at replicating the in-depth heating conditions (i.e. in-depth thermal gradients) experienced by concrete specimens that had previously been measured during the large-scale fire resistance tests of similar specimens and concrete mixes (above and (Maluk, 2014)). The specified time-history of imposed incident radiant heat flux aimed to give equivalent in-depth temperature distributions within the concrete as measured during the fire resistance tests. A detailed description of the test setup and analysis of the results of the heat-induced spalling tests is presented elsewhere (Maluk et al., 2015).



(a) (b) (c)

Figure 5 – Photograph of (a) H-TRIS during testing of medium-scale concrete slabs, (b) a typical specimen after spalling, and (c) a typical specimen after the formation of longitudinal splitting cracks.

Medium-scale unreinforced and unstressed concrete specimens were tested using H-TRIS in a vertical orientation, with heating from one side (see Figure 5). Recognising that scaling of test specimens in structural fire resistance testing is debated on various grounds (Maluk, 2014), sample dimensions in the direction of the principal heat flow were taken as the same as those used for the prior large-scale furnace test specimens. Thus, medium-scale specimens had 45 × 200 mm^2 cross-sections and an overall length of 500 mm.

Specimens were tested either under a free-to-expand (unrestrained) condition or under sustained compressive load to simulate prestressing. Based on prior research (Maluk, 2014), the service pre-compressive stress within the concrete at the end of a prestress transfer zone was conservatively defined as 12.3 MPa (i.e. prestressing losses due to elastic shortening, shrinkage, creep effects, and thermally induced prestressing forces were neglected). This concentric compressive load was applied using notionally rotationally fixed-fixed end conditions. Load was held constant for the duration of the tests using a hydraulic load control system (i.e. the applied compressive load was maintained, counteracting potential effects from thermal expansion and elastic modulus changes of the test specimen during heating). Unloaded test specimens were left free-to-expand (under rotationally fixed-fixed end conditions). All tests were performed in triplicate for each specific concrete mix and restraint condition.

This study confirmed that the inclusion of PP fibres has a positive effect on reducing the propensity for heat-induced concrete spalling. Additionally, test results showed that: (1) inclusion of PP fibres with smaller cross-sections has a positive influence in reducing the propensity for spalling; (2) mixes cast with relatively short (3 mm long) PP fibres exhibit a higher propensity for spalling than practically identical mixes (equivalent PP fibre dose) with longer PP fibres (6 or 12 mm long); (3) monofilament or multifilament PP fibres type showed a lower propensity for heat-induced concrete spalling relative to those cast with fibrillated PP fibres; and (4) specimens in which spalling occurred under sustained compressive stress also suffered from spalling when tested under a free-to-expand conditions.

Study #3: Pullout tests

Pullout specimens, which are shown schematically in Figure 6, consisted of concrete cylinders with diameters of 100 mm and lengths of 250 mm. Each cylinder had a single embedded prestressing bar (CFRP or steel). The casting moulds were designed in such way that the reinforcement was placed vertically and axisymmetrically. Bond breaker was placed over the top and bottom 50 and 40 mm of the bonded length within the cylinders, respectively. The bonded length was chosen as 160 mm because this was determined to be the prestress transfer length for the CFRP tendons at ambient temperature, as measured in prior research (Maluk et al., 2011). Special consideration was given to the procedure used for accurately measuring of the slip of the reinforcement at both the loaded and free ends of the cylinders – a novel digital image correlation analysis technique was used (see Figure 6). The image correlation technique was verified using conventional linear potentiometers (LPs), which were also used to measure slip at both ends. Temperatures were measured along the bonded length with embedded thermocouples.

Examination of the pullout test results showed that the bond strength capacity of CFRP tendons proved to be far more sensitive than the tensile strength at elevated temperatures. Furthermore, various aspects of bond performance at elevated temperature, for both CFRP tendons and steel wires, remain poorly understood and require additional investigation. A detailed description of the test setup and analysis of the results of the pullout tests is also presented elsewhere (Maluk et al., 2011).

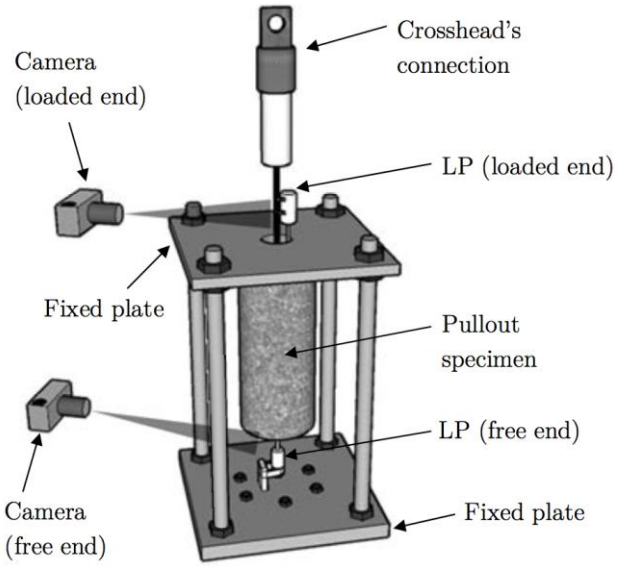


Figure 6 – Schematic of pullout test setup.

Study #4: Tensile Strength Tests

The tensile strength of both steel and CFRP reinforcements is reduced at elevated temperatures. For cold-drawn steel prestressing wire, the relationship between tensile strength and temperature is relatively well established and is available, for example, in Eurocode 2 (CEN, 2004). However, the effects of elevated temperature on the tensile strength of the CFRP prestressing tendons used in the current study were not known. Transient elevated temperature tensile strength tests (load-then-heat) were performed for both the steel wires and the CFRP tendons at sustained stress levels of 800, 1000 MPa, and 1200 MPa. The wires/tendons were loaded under displacement control at ambient temperature, and the load was maintained while the tendon was heated at 10 °C/min until tensile failure occurred. It is noteworthy that the anchorages were protected from exposure to elevated temperature throughout the testing (the grips were outside the thermal chamber).

Figure 7a presents the results the elevated temperature tensile strength results for the CFRP tendons. Also included in this figure are the results of thermogravimetric analysis (TGA) performed on the CFRP material; this is explained and discussed under Study #5. Figure 7a shows that the CFRP tendon also experiences considerable reductions in tensile strength with exposure to elevated temperature. On average, the CFRP tendon is slightly more sensitive to elevated temperature than the steel wire, experiencing failure at temperatures about 10 to 50 °C lower than the steel at the same stress level. Since the tensile strength of the CFRP is clearly less sensitive to the effects of elevated temperature than its bond strength, the conventional design methodologies applied to steel prestressed concrete cannot be applied to CFRP prestressed concrete (indeed, there is some

evidence that the conventional approach for steel prestressing may require re-evaluation, since the bond of steel prestressing wire to concrete is also sensitive to elevated temperature exposure).

Figure 7b shows the ultimate tensile strength reduction curve recommended by Eurocode 2 (CEN, 2004) for Class A cold-drawn prestressing steel. It is clear from this figure that prestressing steel suffers considerable reductions in tensile strength at elevated temperature. The figure also shows, as expected, that the Eurocode 2 (CEN, 2004) tensile strength reduction recommendations are conservative (by about 50 to 100 °C) with respect to the testing methods and materials used in the current study.

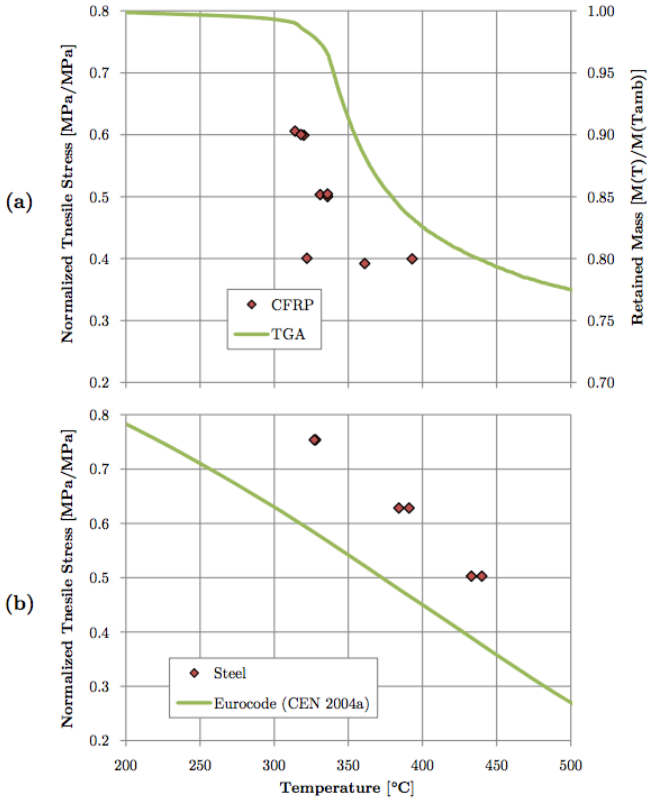

Figure 7 – Transient elevated temperature tensile strength test results for (a) CFRP tendons and (b) steel wires, compared with TGA results (Study #5) and Eurocode (CEN, 2004), respectively.

Study #5: Micromechanical tests

Test results from a Dynamic Mechanical Analysis (DMA) are widely used to define the upper temperature limits for FRP materials used in infrastructure applications (ACI , n.d.); for instance in terms of the glass transition temperature (T_g) of the polymer resin matrix. DMA was used to measure the value of $T_{g\text{-}onset}$ for the CFRP tendons used herein. The measured $T_{g\text{-}onset}$ was 121 °C. It is worth highlighting that a variety of other definitions for T_g may also be used with a DMA analysis (*Tan δ* peak, for instance) depending on the particular industry and jurisdiction (Maluk et al., 2011). The DMA, which in essence measures the viscoelastic response of materials as a function of temperature, was used testing rectangular cross section CFRP specimens of 2x4 mm, 15 mm long cut from a CFRP tendon and subjected to single cantilever sinusoidal loading. The loading frequency was 1 Hz and the heating rate was 3 °C/min.

It was desired to determine if there is any obvious relationship between either $T_{g\text{-}onset}$ or the measured reductions in the storage modulus of the resin and the bond strength (or tensile strength) of the CFRP prestressing tendons. A thorough analysis of these test results, presented elsewhere (Maluk et al., 2011) showed that that the relationship between polymer resin stiffness and bond strength is much more complex than can be defined simply with reference to T_g.

A Thermo-gravimetric Analysis (TGA), which in essence measures the mass loss of a test specimen during its increase in temperature, as performed on a small, 46.3 mg specimens cut from the CFRP tendons. The goal of this test was to examine if the temperature of resin decomposition, $T_{d\text{-}onset}$, could be used to provide an indication of the temperatures which may lead to tensile failure of the CFRP tendons under service prestress levels (see Figure 7). A heating rate of 20 °C/min was used. Previous research has shown that while the polymer resins used in FRP manufacturing are sensitive to temperatures in the range of 45-100 °C (Maluk et al., 2011), carbon

fibers are essentially insensitive to temperatures as high as 600 °C. However, interaction between the fibers in an FRP component is essential to provide stress transfer between individual fibers and to prevent failure of the bulk material upon loading.

Study #6: Heat-induced transversal forces tests

The H-TRIS test method used within Study #2, was used for studying the effect of heat-induced transversal forces due to the differential thermal expansion between CFRP tendons or steel wire, and concrete. These tests were performed on unstressed, reinforced test medium-scale specimens (see Figure 5). Tests were continued for a total duration of 60 minutes. The specimens were placed in the supporting frame (see Figure 5) and subjected to heating so as to generate the same thermal gradients as would have been experienced in the midspan region of the large-scale specimens tested in the fire testing furnace.

During testing, the exposed and unexposed surfaces of the medium-scale specimens were monitored for surface longitudinal splitting cracks. Longitudinal splitting cracks at the unexposed surface of the specimens appeared at about 12 minutes from the start of the tests. Figure 5 shows photographic evidence of the longitudinal splitting cracks at the unexposed surfaces of the CFRP reinforced specimens after cooling. It is noteworthy that no surface longitudinal splitting cracks were observed at the exposed or unexposed surfaces of the steel reinforced medium-scale specimens. The temperature of the CFRP tendons was about 150°C is when surface cracks were first observed at the unexposed surface of all the specimens tested. At the exposed surface, no visible cracks were observed, however flames were observed 27-32 minutes from the start of the test, the moment at which the temperature of the CFRP tendons was about 300-350°C.

Study #7: Thermal Expansion Tests

Measurements on the transversal coefficient of thermal expansion (CTE) of CFRP tendons were performed in accordance with the relevant ASTM test standard (ASTM , 2006); between 20 and 260°C. Decomposition of the CFRP's epoxy resin matrix was observed at higher temperatures. The measured thermal elongation (Δl/l) in the transversal direction of the CFRP tendons is shown in Figure 8. Also, Figure 8 shows the thermal elongation for prestressing steel and concrete (with siliceous aggregate) prescribed in typical design guidelines (CEN, 2004). Results from these measurements show that thermal elongation in the transverse direction is considerably higher than that of concrete (or steel).

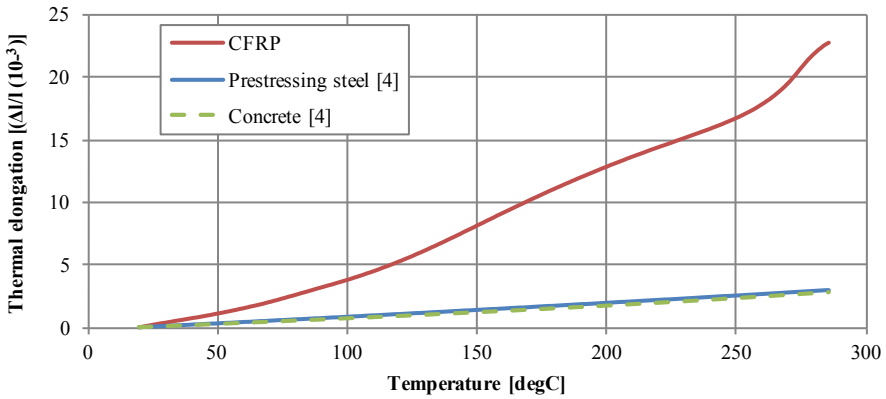

Figure 9: Measured thermal elongation of CFRP tendons in the transverse direction.

OVERALL OUTCOMES AND CONCLUDING REMARKS

The suite of work presented in this paper has demonstrated the high propensity for heat-induced concrete spalling and the complexities associated with structural failure due to loss of bond strength capacity of pretensioned CFRP tendons, both of which are relevant to the fire performance of thin CFRP prestressed concrete slabs, present designers and researchers with a number of significant challenges. Nevertheless, there is an opportunity to build on the development of a fundamental and practical understanding of the fire behaviour of these novel structural elements, and to use this knowledge to improve structural fire resistance design of all structural elements, both novel and conventional. In relation to the failure mechanisms of thin CFRP prestressed concrete slabs in fire, the overall outcomes of this broad experimental research project are:

Heat-induced Concrete Spalling

Polypropylene fibres with reduced cross-section and/or large individual lengths showed a more negative influence on slump flow, compared to PP fibres with increase cross-section and short individual lengths. Inclusion of PP fibres showed no obvious influence on moisture content or compressive strength. Design code guidance on PP fibre inclusion is non-conservative and requires revision.

Loss of Bond in the Anchorage Zone

Whilst no attempt was made to individually identify the influence of thermo-mechanical bond degradation versus thermo-mechanically induced longitudinal splitting cracking on the loss of anchorage in CFRP prestressed HPSCC slabs, the tests confirmed that a combination of both mechanisms is likely relevant. Irrespective of all design parameters assessed in this study, loss of anchorage appeared to begin when the temperature at the lower edge of a central CFRP tendon at midspan was in the range of 310°C, regardless of the temperature at the unheated overhangs outside the heated span. This confirms the potential triviality of prescribing an unheated overhang length for the fire resistance design of precast CFRP prestressed HPSCC slabs (Terrasi, 2007).

A proper understanding of the response of these elements is needed before they can be designed and implemented with confidence; this is unlikely to be achieved by performing additional standard fire resistance tests in furnaces. Both heat-induced concrete spalling and loss of anchorage are difficult to be rationally investigated with a low number of test specimens, despite considerable instrumentation during testing. What is needed is a fundamental scientific understanding of the thermal and mechanical fire behaviour of these elements at the material, member, and system levels; this can be accomplished using a range of conventional and bespoke test methods and procedures, many of which are now being used by the authors (e.g. (Maluk, 2014)).

ABSTRACT

Although structurally significant building fires are rare events, their occurrence can cause substantial damage and may lead to partial or complete system collapse. While fireproofing has proven to be effective in mitigating the effect of severe fires, it is rated for only a certain time and will eventually fail to provide adequate protection during a large or extended fire event. Furthermore, fireproofing typically is rated using a standard fire exposure, such as ISO 834 or ASTM E119, neither of which represent realistic fire exposures in an actual building. With the worldwide move toward performance-based fire protection engineering, understanding and quantifying system behavior through advanced numerical simulations, especially during the heating and cooling phases of realistic fire exposures, is essential for establishing proper performance-based provisions for fire engineering that ensure both safe and economical design. This paper highlights current challenges in simulating the effect of fire on steel components and frames, including proper representation of loading and boundary conditions, geometrical nonlinearities, material inelasticity, and numerical instabilities. The structural models considered include 2-D line elements, 3-D continuum elements, and multi-resolution models. In addition, the advantages and drawbacks of these models are highlighted and the implication of their features is discussed. The highlighted modeling approaches and the corresponding results shown can be used by engineers for selecting the most economical and effective techniques for simulating the response of components and structural systems to scenario fire hazards accurately.

KEY WORDS

Fire, finite element analysis, steel structural buildings, reduced beam section connections.

INTRODUCTION

The response of steel structures subjected to fire loading has gained the recent attention of structural engineers and researchers, motivated both by historical fire events, which resulted in significant structural damage and subsequent loss of life, and by the prospects of achieving better performance at reasonable cost. Current provisions do not address the effects of realistic fire conditions on the thermal and structural interactions among frame members and global system response. Therefore, there is an obvious need to quantitatively understand the behaviour of steel framed buildings under realistic fire conditions at the component and system levels. This need could be realized through experimental testing or numerical simulations. Undoubtedly both tools are essential for developing such guidelines. Generally, physical laboratory models can provide an understanding of structural behaviour under specific loading and boundary conditions and are further utilized to calibrate numerical finite element models that then can be used to evaluate the response of the structural component system under a wide range of loading scenarios, system configurations and boundary conditions.

The use of numerical modelling to evaluate the behaviour of steel elements and frames during a fire has received significant attention with recent improvement in computational capabilities. Various numerical studies have been reported in the literature to assess the effects of fire loading on the local and global response of steel structural buildings (Saab and Nethercot 1991; Gu and Kodur 2011). Numerical finite element analyses have been also performed to evaluate the behaviour of individual beams under fire loads (Vila Real *et al*. 2004). In these analyses, the slenderness ratio, various fire scenarios, the location of restraints at supports, temperature-dependent structural steel properties, level of mechanical loads have been varied. For the exposure of steel columns to elevated temperatures, various numerical analyses have been conducted, including the work of Tagaki and Deierlein (2007), who examined the effects of various parameters on stability and strength of steel columns under fire loads including different types of axial restraints, level of axial load, and eccentricity of axial load. Numerical studies were also conducted to evaluate the performance of various types of steel beam-to-column connections subjected to fire loading (Yu *et al*. 2008; Hu and Engelhardt 2014). Other numerical studies

exist in the literature on beam-column connection under elevated temperature including various studies that have been conducted on single and double shear tab connections both in the US and Europe. Quiel and Garlock (2008) provided comprehensive information on modelling techniques for 3-D structural connections including suggestions on element types, integration order, meshing, material properties, contact configuration, and solving techniques. Memari and Mahmoud (2014) conducted a numerical study on the performance of 2-D steel moment-resisting frames (MRFs) with reduced beam section (RBS) connections under various single-bay compartment fire scenarios. The study showed that the global stability of steel MRFs with RBS connections is not affected by a single bay fire exposure. Agarwal and Varma (2014) arrived at a similar conclusion and showed that a perimeter column in a steel MRF is not at risk of buckling when subjected to axial demand resulting from load redistribution caused by inelastic buckling of a gravity column in a corner compartment fire. In addition, global stability and progressive collapse have been investigated in steel frames subjected to elevated temperatures (Sun *et al*. 2012).

This paper highlights challenges in conducting numerical simulations under elevated temperatures, including challenges associated with specified thermal loading, boundary conditions, material properties, and stability of numerical solutions. In addition, the paper covers alternative approaches by which the performance of structural steel connections and frames can be evaluated under various fire scenarios. This includes assessment using temperature-adaptive mechanical boundary conditions, assessment of 2-D steel frames with RBS connections, and assessment of multi-resolution steel frames with RBS connections.

SIMULATION CHALLANGES

Specified Thermal Loading

The challenges associated with thermal loadings lie in the selection of fire scenarios and the description of temperature variation with time. In the analysis of framed buildings under fire, the selection of fire cases to be analysed is generally geared towards either evaluating what might be considered a worst-case scenario or evaluating an ensemble of randomly or logically selected fire cases. The worst case scenario is typically viewed to be one compartment fire in the exterior bay in the first story of a multi-bay multi-story structure. In the case of conducting analysis under various fire cases, single and multiple floor fires as well single and multiple bay fires typically are considered. A more comprehensive, yet challenging, approach to develop such scenarios is to use a set of conditions that defines the development and spread of fire based on the distribution of combustion products throughout a building or part of a building. This set of conditions is outlined in ISO/TR-13387-2 (1999) and in the Society of Fire Protection Engineering (SFPE) Engineering Guide (2007), which accounts for both hazard and risk analysis as outlined in detail in NFPA 72 (2013).

The time-temperature curves used in fire simulations fall into two basic categories: standard fire curves, such as ASTM E119 (2012) and ISO 834 (2012), or parametric fire curves such as those generated using the Eurocode 1 (2002) or the SFPE Engineering Guide (2007) methods. The main principle behind the standardized curves is to expose a single structural member or assembly to a standard fire with designated fuel load and intensity. The component passes or fails the test depending on whether the peak temperature attained on the unexposed surface of the tested component exceeds a limiting temperature, whether the tested specimen fails in a way that allow hot gases to escape, or whether the specimen can withstand a pressure from a hose stream during a rating period of from 30 minutes to 4 hours. Many numerical studies have adopted these standardized fire curves to evaluate the response of components or sub-assemblies under elevated temperatures. The main issue with the standard fire curves is that they were developed nearly a century ago to provide prescriptive ratings and are not characteristic of a fire in a realistic modern building. They presume an inexhaustible supply of fuel during the rating period. Furthermore, they were developed assuming fuel loads that were commonly found in buildings when the test was first developed; modern fuels result in fires with significantly faster growth rates and higher radiative fractions that affect fire spread rates. In contrast, the parametric fire curves are intended to be used as design fires in compartment fire models. The parametric curves are quantitative temporal descriptions of assumed fire characteristics based on appropriate fire scenarios and include an initial post-flashover heating phase, a cooling phase, and a constant ambient temperature phase. These curves typically account for heat release rate, size of fire, yield of products of combustion, temperatures of hot gases, and time to key events such as flashover. The cooling phase in the parametric curves is both realistic and appropriate since significant structural demands may be generated in the building system due to differential cooling of elements.

Specified Boundary Conditions

Boundary conditions of varying degrees of complexity have been employed for modelling the thermal constraints provided to beams and columns during a fire (Ali *et al*. 1998; Yin and Wang 2004; Huang *et al*.

2006; Valente and Neves 1999; Yu 2006; Dwaikat and Kodur 2010; Sarraj *et al*. 2007; Hu and Engelhardt 2010; Da Silva *et al*. 2005; Kodur and Dwaikat 2009; Keller and Pessiki 2012). Figure 1 provides a depiction of some of the various boundary condition configurations that have been implemented in previous studies for evaluating the response of steel members and connection under fire. All boundary conditions require assumptions regarding the fixity of the degrees of freedom. A recent study (Mahmoud *et al*. 2015) utilized the concept of adaptive boundary conditions to account for the effect of frame in-plane restraint variation throughout the fire on the performance of moment connections, which will be discussed later in more detail. Keller and Pessiki (2012) also considered restraint variation but only in the axial direction of a member in a beam-column sub-assembly. The inclusion of proper boundary conditions in the assessment of sub-assemblies under elevated temperature is critical since the simulation results are highly dependent on the specified boundary conditions. For example, the use of fixed boundary conditions at the end of the sub-assemblies might drastically overestimate the thermally-induced axial, shear, and moment demands while the use of pinned conditions might underestimate the moment demand. One approach to alleviate such a problem is to construct the finite element model in such a way that the lengths of the beam and column representation in the model are terminated at the inflection points. This will eliminate the need for using rotational restraints at the member ends. However, the computational time might increase substantially since longer beams and columns will have to be used, which will increase the number of elements and nodes used in the simulation.

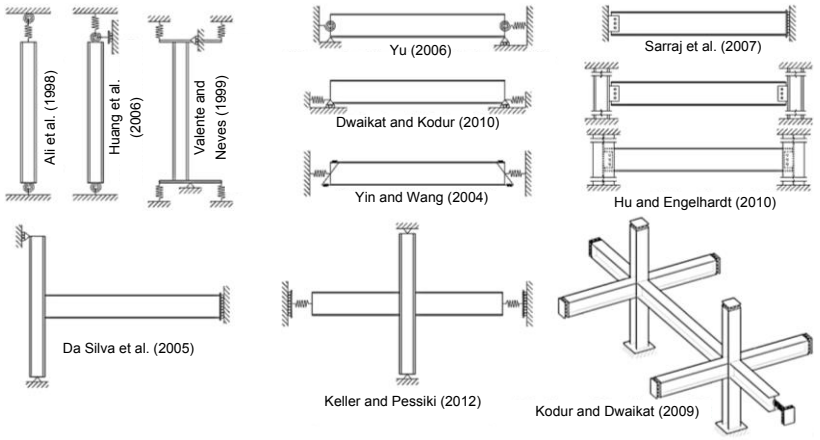

Figure 1 Implemented boundary conditions utilized in previous studies for structural members and connections under fire exposure

Specified Material Properties

Accurate thermal, mechanical, and damage models for structural materials, covering a wide range of temperature variation, must be specified in the numerical models to ensure accurate and reliable results. A quick review of existing material models under elevated temperatures reveals the need for further refinement of the existing material models to eliminate notable differences between what is adopted in existing codes. For example, the present specific heat model in ASCE (ASCE 1992) differs from its EC 3 (EC3 2005) counterpart above 200^{o}C, with the difference especially apparent at and above 700^{o}C. There are also differences between the two models of thermal conductivity of steel between 20^{o}C to 1000^{o}C, although the differences are less for specific heat. While more data exist on the mechanical properties of steel at elevated temperature in comparison to the thermal properties, large scatter still exist between the different models available in the literature. For the ASCE and EC 3 models specifically, large variation is evident for both the yield stress and elastic modulus for the full range of temperature evaluated, 20^{o}C to 1000^{o}C, with strong variation between 200^{o}C to 800^{o}C. While the stress-strain curves at elevated temperatures for both models are more rounded than at ambient, the ASCE model has a more pronounced plastic flow region than the EC 3 model. These differences in shape lead to differences in the inelastic stability limits of columns and laterally unsupported beams. Another example of differences in material properties can be found in a recent study conducted at the National Institute of Standards and Technology (NIST) where the listed properties are different than those listed in EC3 (Luecke 2014). Noteworthy, that the mechanical properties in AISC 360 (AISC 2010) are comparable to that of EC3. Thermal properties are however not provided in AISC 360.

An accurate prediction of the plastic deformation and failure of steel elements essentially requires proper capturing of material damage. Damage initiation under elevated temperature can be modelled using the Johnson-Cook damage model (Johnson and Cook 1985). The ductile damage initiation criterion defines the equivalent plastic strain as a function of stress triaxiality, strain rate, and homologous temperature. The model incorporates linear evolution of the damage variable with effective plastic displacement, which represents a linear stress-

strain softening response. Even though its parameters allow its use in simulations under fire loading, the Johnson-Cook damage model has mainly been used in previous studies under ambient temperature and seldom for the evaluation of damage under elevated temperature. One of the drawbacks of the Johnson-Cook model is that it does not account for shear-dominated failures since stress triaxialities alone cannot be relied upon for predicting such failure modes (Wen and Mahmoud 2015).

The variations in the material models highlighted above can be attributed to three main reasons. First, current knowledge on high-temperature properties of steel is based on limited material tests. Second, available high temperature material properties are only based on the heating phase of fires with no consideration to the cooling phase. Third, standard test methods for evaluating high temperature properties are non-existent; as a result, some data in the literature are based on transient tests while other data are based on steady-state tests.

Numerical Instabilities in Computational Analysis

One of the main challenges in conducting numerical simulations under fire loadings is the potential for substantial geometrical nonlinearity and material inelasticity, which can pose significant convergence challenges during the simulations. Generally, three requirements are essential for the convergence of finite element simulations: 1) completeness, 2) compatibility, and 3) stability. Completeness refers to the elements having sufficient order to capture the analytical solution in the limit of a mesh refinement process. Compatibility requires that the shape functions provide displacement continuity between elements. This is often an issue in cases where nodes are left unmerged; thereby creating unintentional discontinuities or cracks that can go unnoticed in models with substantial number of elements and nodes. Stability is typically an issue if the system of finite element equations violates certain conditions, resulting in zero-energy modes in elements in addition to excessive element distortion. This could result in the presence of an ill-conditioned stiffness matrix. While difficulties in convergence may be an indication of the onset of local or global instability, marking the presence of local buckling or system collapse, careful evaluation of the reasons for the model failing to converge may reveal other causes. Convergence can be checked using many different solution variables such as strain energy, maximum displacements, maximum stresses, and many others. However, strain energy is generally viewed as the best variable for such evaluation since it provides the smoothest convergence plots. It is generally not recommended to evaluate convergence based on maximum stress values since the maximum stress is a local rather than a global measure.

METHODOLOGY

Various numerical studies have been conducted to evaluate the response of steel frames and sub-assemblies under elevated temperatures. These studies are typically conducted using either line element models and 2-D or 3-D continuum models, or a combination of line elements and continuum elements. Boundary conditions generally are fixed, pinned, or somewhere in between (i.e. semi-rigid). The methodologies discussed below outline recent studies conducted by the authors in which various modeling techniques were used, including 3-D component level analysis using adaptive boundary conditions, 2-D system-level analysis using line elements, and 2-D system-level analysis using multi-resolution elements (3-D continuum and line elements). The simulations conducted with adaptive boundary conditions utilized the time-temperature curve shown in Figure 2 (a) (Quiel and Garlock 2008) while the simulations using the line-element models and the multi-resolution models utilized the curve shown in Figure 2 (b) (EC1 2002). All analyses were conducted using an uncoupled thermal-mechanical analysis with time-temperature curves that included both heating and cooling phases. First, a transient heat transfer analysis was conducted to obtain the transient nodal temperatures. Once the heat transfer analysis was completed, a thermal-mechanical analysis was employed by importing the corresponding nodal temperature from the results of the transient heat transfer analysis. Both material and geometric nonlinearities were included in the studies. The discussion will not focus on the details of the structures, the sub-assemblies, or the fire cases but rather on the modeling approach used. Selective results will however be highlighted in the results section.

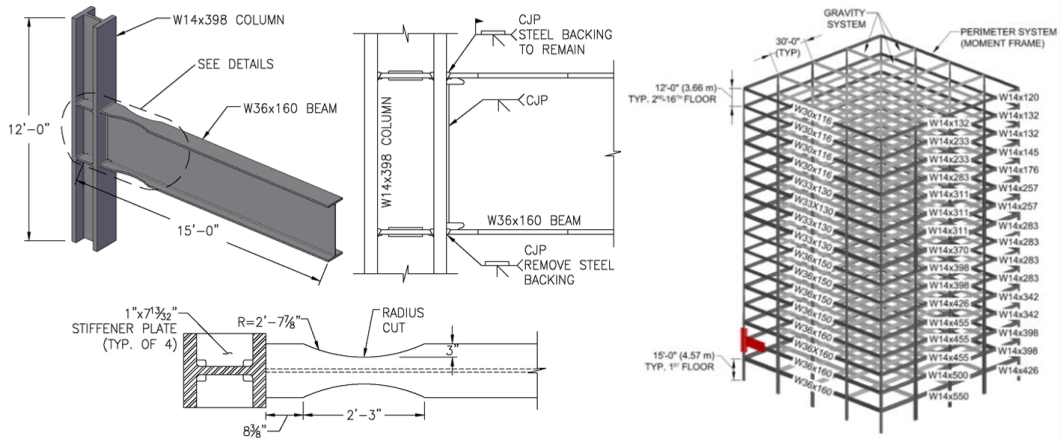
Temperature-Adaptive Mechanical Boundary Conditions

The reduced beam section (RBS) connection shown in Figure 3 (a) is modeled using 3-D solid elements in ABAQUS and is an exterior connection at the 2nd floor of the 16-story special moment resisting frame shown in Figure 3 (b). RBS connections are fabricated by removing a portion of the beam flange near the beam-column joint to allow for energy dissipation away from the column face during seismic events, thereby reducing the seismic demand on the weld and other critical details at the beam-column interface. Two different boundary conditions are modeled. The first model, termed 'realistic', includes restraints in all three planar degrees of freedom (DOF), including the coupled transverse-rotational DOF, and is believed to be the most realistic representation of the planar boundary conditions. The second model is termed 'fixed' and has the tips of the beam and column fully fixed in all three planar DOFs to represent unrealistic worst case boundary condition.



(a) (b)

Figure 3 a) Details of the modelled RBS connection and b) location of connection in the subject frame

For the realistic restraint model, the beam-column is treated in isolation and connector elements are used at the end of the sub-assembly to model the stiffness of the surrounding frame. A translational "Cartesian" element and rotational "Rotation" element are selected for the connector elements in ABAQUS, which allows the coupled stiffness matrix for the element to be directly specified. Utilizing this element type permits the fully coupled stiffness of the surrounding frame to be modeled, which otherwise is not possible if spring elements are used. The coupled stiffness includes not only the axial, transverse, and rotational stiffness values but also the transverse-rotational stiffness of the frame excluding the modeled connection. The restraints are determined throughout the entirety of the fire simulation by developing a line element model of the whole frame and subjecting the frame to a compartment fire using a specified time-temperature curve. The simulation of the full frame model is terminated at twenty representative times throughout the fire and a series of deformation-controlled analyses is performed to evaluate the restraint stiffness provided by the framework surrounding the

sub-assembly at those twenty discrete points using static analysis to populate the elements of the stiffness matrix. The stiffness values obtained are then used to update the connector elements of the 3-D connection sub-assembly to capture the evolution of restraint provided by the frame over the duration of the fire. Figure 4 provides a depiction of the transient restraint stiffness for the 16-story sub-assembly.

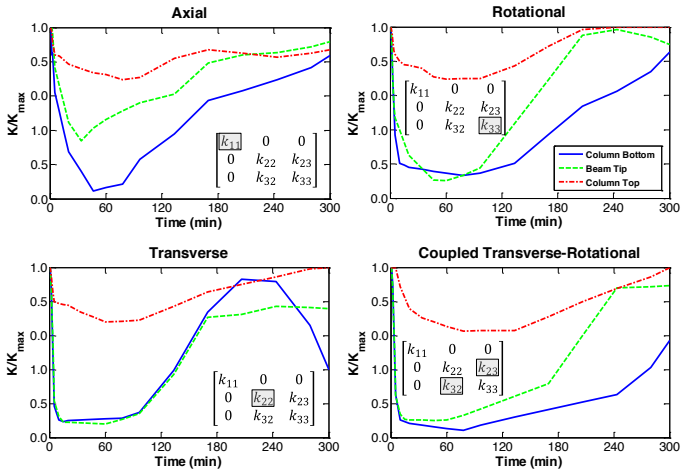


Figure 4 Normalized restraint stiffness values for connection sub-assembly in the16-story frame

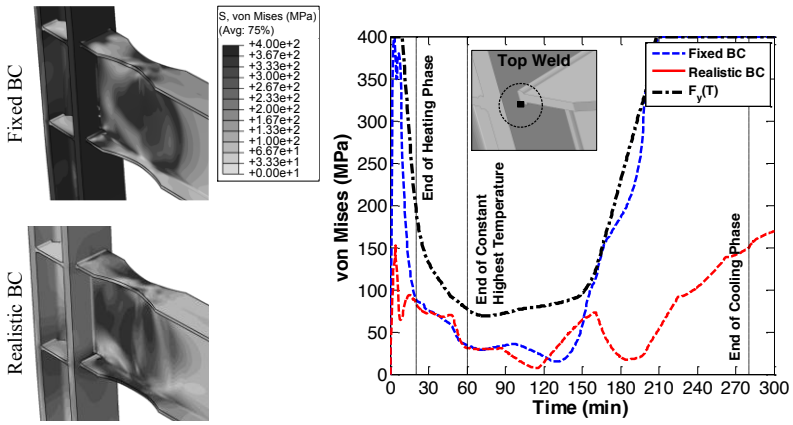
The effect of boundary conditions on the damage patterns observed following the cooling phase shows large variations in the extent of local buckling in the flange and web of the beam in the reduced section for the two sets of boundary conditions as shown in Figure 5 (a). This is further demonstrated by the localized stresses at the top weld connecting the beam to the column, as shown in Figure 5 (b), where large von Mises stresses are developed in the case of fixed boundary conditions.



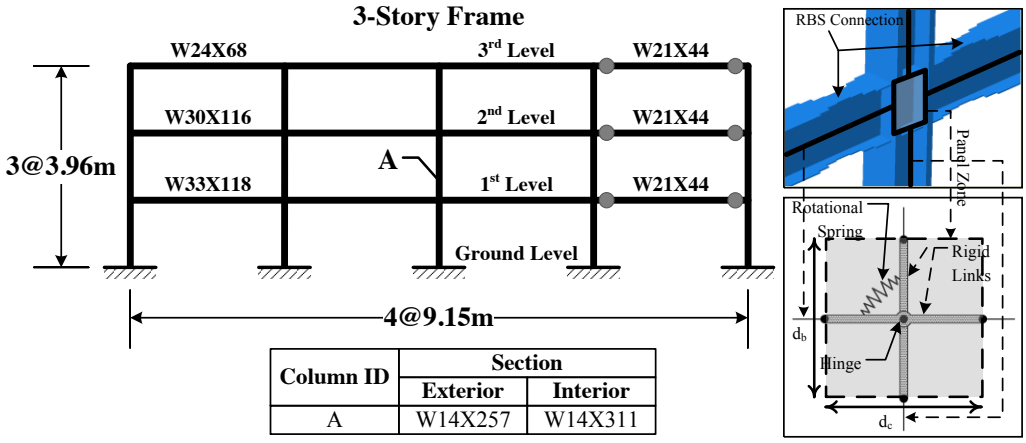
(a) (b)

Figure 5 a) von Mises stress contour in the connection under different restraint conditions and b) localized von Mises stress in the top weld at the column face.

2-D Steel Frames with RBS Connections

The special moment resisting frame shown in Figure 6 (a) is comprised of beams and columns with W-shapes and welded reduced beam section connections. In the transient heat transfer and mechanical models, 1-D line elements are used for the beams and columns. To create the connection geometry with the proper radius transition, the RBS connections are represented in the 2-D frame using piece-wise elements as shown in Figure 6 (b). The column panel zone behavior is represented using the scissors model (Krawinkler 1978) shown in Figure 6 (b), which was constructed using two rigid links that are hinged together at the mid-point and connected to the remainder of the frame using beam connectors to constrain all planar 3 degrees-of-freedom of one node to an adjacent node. In addition, a linear rotational spring with stiffness proportional to the beam and column sizes constrains the two rigid links together as shown in the figure. The P–Δ effect on the moment resisting frame, associated with the interior gravity frames, is taken into account by simulating the gravity frames using a leaning column (Yun *et al*. 2002). These models are simplistic in nature and do not pose significant challenges in their development. However, certain shortcomings might result from the use of such

models including their inability to capture local buckling, strain gradients through the element thickness, and localized stresses and strains at critical details including for example cutouts and weld access holes.



Column ID	Section	
	Exterior	Interior
A	W14X257	W14X311

(a) (b)

Figure 6 a) Elevation view and configuration of the 3-story SMRF frame and b) piece-wise approximation of the connection with a scissors model representing the panel zone

Four different fire scenarios were simulated to evaluate the response of the frame when subjected to a compartment fire, as shown in Figure 7 (a). Examples of response parameters include the developed axial force (P) in the beams (Figure 7 b) as well as Inter-story Drift Ratio (IDR) (Figure 7 c). Figure 7 (b) shows the evolution of axial forces in the beam for each fire case with axial compressive forces developed during the heating phase and axial tension during the cooling phase. Upon cooling, residual axial tensile forces remain in the beams as shown in the figure. Larger IDR values are obtained when the exterior bays are subjected to the fire loading (Figure 7 c), which can be seen in the odd-numbered fire cases. This is because when the interior spans are subjected to fire, larger lateral restraints are provided by the beams and columns at both sides of the fire-exposed bay.

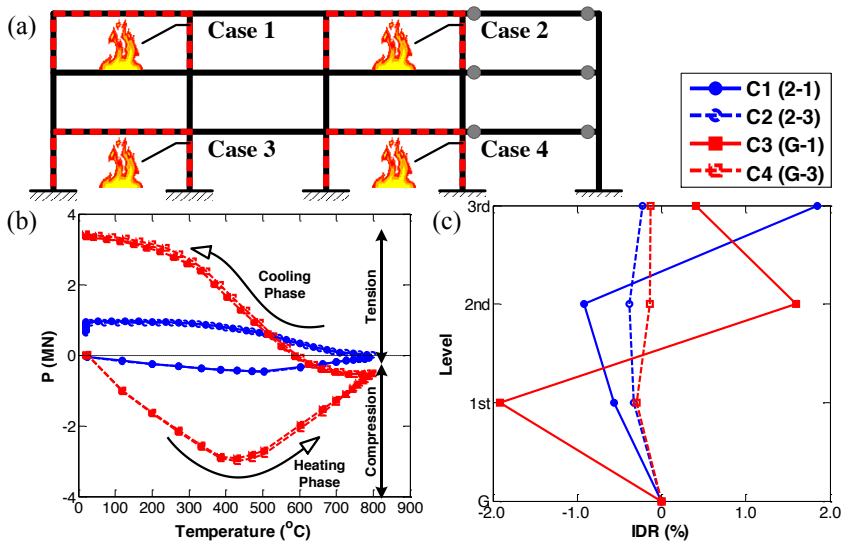


Figure 7 a) Fire cases evaluated, b) evolution of axial forces in the beam, and c) resulting inter-story drift for each fire case

Multi-Resolution Steel Frames with RBS Connections

Multi-resolution numerical models are those which employ detailed 2-D or 3-D continuum elements that are integrated with line element models. The use of continuum models captures the localized demand while the line element models provide realistic boundary conditions to the localized model, yielding the global response of the structural system. The top of Figure 8 (a) shows an example of a 3-story SMRF with RBS connection subjected to fire in the first three bays. The selected RBS connection was modelled using solid elements while the remainder of the frame was modelled using line elements. In this model the 3-D connection was extended to

mid-span and mid-height of the corresponding beam and columns, respectively. The 3-D RBS connection was also laterally braced, in accordance with the AISC Seismic Design Manual (2008), to prevent out-of-plane deformation under inelastic behaviour. Multi Point Constraints (MPCs) were used to connect thermal and mechanical degrees of freedom of the line elements to those of the solid elements. All other modelling details were similar to what has been explained in the previous section. The finite element model is shown in the bottom portion of Figure 8 (a) and the deformed shape of both the frame and the 3-D connection are highlighted. The localized response at the peak and at the end of the time-temperature curve is shown in Figure 8 (b). The demand at the end of the time-temperature curve (i.e. end of cooling phase) clearly is much larger, particularly in the panel zone of the beam-to-column connection, as would be expected. Large stresses are also observed at the weld access holes and the top and bottom flange welds connecting the beam to the exterior face of the column flange. As previously mentioned, this approach allows the evaluation of the influence of the surrounding structure on the response of the connection, or the detailed modelled component, under fire loads in addition to the evaluation of the global performance of the frame. However, a shortcoming of this approach is its inability to capture the out-of-plane response of the 2-D frame as influenced by extension and contraction of girders and floor beams of the interior gravity frames, perpendicular to the plane of the 2-D moment frame.

CONCLUSIONS

This paper provided an overview of the challenges associated with conducting numerical simulations under realistic building fires, including issues related to the use of simplified and unrealistic thermal loadings, idealistic boundary conditions, inaccurate and inconsistent material properties, and the lack of numerical convergence. Examples of alternative approaches for conducting numerical assessment of RBS connections and frames were presented, including the use of temperature-adaptive mechanical boundary conditions, 2-D line element models, and multi-resolution models that integrates both line and continuum elements for the evaluation of local behaviour and global response. Additional research is needed to address many of the issues mentioned to allow for more accurate prediction of response under fire loading and to support performance-based engineering of buildings for fire conditions.

ABSTRACT

Light gauge steel frame (LSF) wall systems are increasingly used in residential and commercial buildings as load bearing and non-load bearing elements. Conventionally, the Fire Resistance Levels (FRL) of such building elements are determined using approximate prescriptive methods based on limited standard fire tests. However, recent studies have shown that in some instances real building fire time-temperature curves could be more severe than the standard fire curve, in terms of maximum temperature and rate of temperature rise. This has caused problems for safe evacuation and rescue activities, and in some instances has also lead to the collapse of buildings earlier than the prescribed fire resistance. Therefore a detailed research study into the performance of LSF wall systems under both standard fire and realistic fire conditions was undertaken using full scale fire tests to understand the fire performance of different LSF wall configurations. Both load bearing and non-load bearing full scale fire tests were performed on LSF walls configurations with varying number of plasterboard linings, and stud section sizes. The non-load bearing fire test results were utilized to understand the factors affecting the fire resistance of LSF walls, while load bearing fire test results were used to understand the effects exposure to realistic design fire time-temperature curves. This paper presents the results of full scale experimental study on different wall configurations, highlights the effects of realistic design fire time-temperature curves on wall panels and the factors affecting the fire resistance of LSF walls.

KEYWORDS

Light gauge steel frame walls, standard fire curve, realistic design fire time-temperature curve, fire resistance level (FRL), load bearing walls, non-load bearing walls, gypsum plasterboards and studs.

INTRODUCTION

Light gauge steel frame (LSF) wall systems are widely used in residential and commercial buildings as both load bearing and non-load bearing elements. They are made of cold-formed steel sections and lined with gypsum plasterboard with and without insulations (Figure 1). Cold-formed steel sections include stud and track sections, where studs carry the vertical load and tracks connect the studs to make the frame. These wall systems when used in buildings should satisfy the building safety requirements specified in the standard codes of practice. One such stringent requirement in building regulation is fire safety, and it is specified in terms of Fire Resistance Level (FRL). FRL is the length of time a member can withstand fire exposure in a standard fire resistance test without losing its stability, integrity and insulation failures. FRL of building elements should provide adequate protection time in a fire event, for safe evacuation, fire service intervention and for rescue activities.

Cold-formed steel stud sections are usually thinner than hot-rolled steel sections and have different buckling modes of failure and deformation, which are not commonly encountered in normal structural steel design. Also under fire conditions, these thin cold-formed steel sections heat up quickly resulting in fast reduction in its strength and stiffness. Hence, plasterboards are used as lining material to protect the steel sections from heating up rapidly together with insulation material. Gypsum plasterboard linings are commonly used as lining material in framed construction. Gypsum plasterboard has fire resistance properties better than most of the other similar materials. Pure gypsum consists of calcium sulphate with free water and chemically combined water. When exposed to fire, gypsum crystals will absorb the heat and will undergo dehydration and decomposition process, thus it delays the temperature rise of LSF wall assemblies. Other materials in gypsum plasterboard such as glass fibre, vermiculite and perlite additives will also improve the durability and the performance when exposed to

fire conditions. The gypsum plasterboard type includes specially manufactured fire resistant gypsum plasterboards or the general purpose plasterboards in thicknesses ranging from 8 to 20 mm. Similarly the insulation type includes rock fibre, glass fibre or cellulose fibre in different thicknesses and densities. The type and thickness of plasterboard and insulation used will also significantly influence the fire ratings of LSF wall panels when subjected to fire from one side as they delay the temperature rise of the stud. LSF wall panels when exposed to fire from one side tend to bow towards the fire side due to differential thermal expansion of steel studs. The studs heated from one side will develop a temperature gradient across the stud cross-section. This non-uniform temperature distribution will induce thermal bowing and non-uniform distribution of strength and stiffness of steel in studs in load bearing wall panels. These effects will make the behaviour even more complicated when subjected to non-uniform elevated temperatures under different buckling modes.

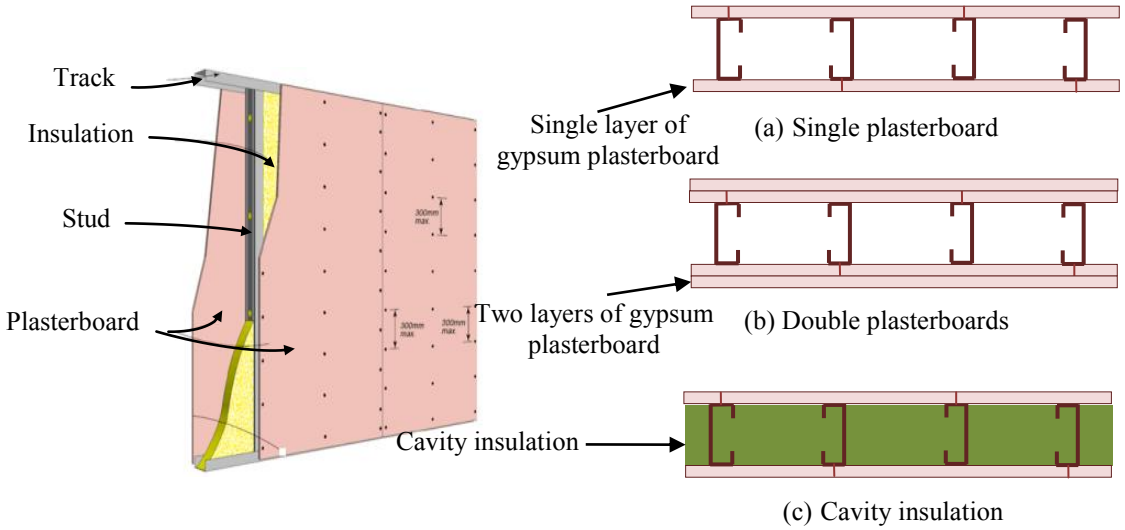

Figure 1 Light gauge steel frame (LSF) wall systems

At present, FRL of a LSF wall panel is assigned based on the results of standard fire tests. In AS 1530: Part 4 (SA 2014) the standard fire time-temperature curve was used to obtain the FRL of LSF wall systems. This standard fire curve originated from the application of wood burning furnaces in the early 1900s, and was later modified slightly to give faster temperature rise for the first few minutes of burning to represent the gas fired furnace temperatures (Babrauskas and Williamson 1978). However, it is believed that this approach was not based on the knowledge of fire severities in real buildings. Since then, no significant change has been made to this standard time-temperature curve, which is being used to calculate the Fire Resistance Levels (FRL) of building elements until now (Nyman 2002). The buildings constructed at the time this empirical equation was developed were typically heavy timber construction compared to the modern buildings with a higher level of usage of thermoplastic materials, synthetic foams and fabrics. The changes in fashion trends and materials used for furnishing have resulted in significant differences in the composition of fire loads in modern buildings.

The standard fire time-temperature curve should represent most of the potential fires in buildings. However, at present it does not meet this requirement. This was shown by many researchers using compartment tests where the maximum temperature in a natural fire exceeded that of the standard fire time-temperature curve within a short period of time from ignition (Nyman 2002, Lennon and Moore 2003 and Jones 2001). The shape of the fire curve strongly relates to the behaviour of an element in a fire. Natural building fires have a decay phase whereas the standard fire time-temperature curve rises continuously. This may be conservative for long duration average temperature rise fires, but not for short duration very hot fires. Although there has been significant research on the structural and thermal behaviour of LSF walls exposed to standard fire time-temperature curve, very few attempts have been made to study the behaviour of LSF wall panels exposed to realistic design fires. Fire testing based on the standard fire curve will give good comparative results for building systems tested under identical conditions, and also valuable basic data. However, in recent years it has been shown that these results do not provide accurate fire resistance levels (FRL) for residential and commercial buildings, which have a high fire severity (Jones 2001, Nyman 2002 Lennon and Moore 2003 and Abecassis-Empis et al. 2008). Therefore there exists a need to provide a model that will allow the practicing engineers to accurately predict the structural and thermal behaviour of LSF wall panels when exposed to real building fires.

On the other hand, the behaviour of LSF wall insulation, plasterboards, steel studs and wall configurations were not fully understood and there were conflicting observations and outcomes in the past (Feng and Wang 2004,

Kodur and Sultan 2001 and Alfawakhiri 2001). According to Feng and Wang (2004), the cavity insulation was found to be improving the fire resistance of load bearing steel stud wall panels. However, Gunalan et al. (2013), Kodur and Sultan (2001) and Alfawakhiri (2001) concluded that the cavity insulation reduces the FRLs of load bearing wall panels. Similarly, in the past the effects of stud depth, thickness of the plasterboard and wall configurations on non-load bearing wall panels have not been assessed in relation to the fire resistance of wall panels. Hence a research study was undertaken and this paper presents the details of this experimental study, which was conducted to investigate the fire performance of load bearing and non-load bearing LSF wall panels made of different wall configurations and exposed to both standard and realistic design fire time-temperature curves. Details of the fire test set-up, procedure and the results to demonstrate the influence of wall configurations, stud depth and realistic fire time-temperature curves on LSF walls are presented in this paper.

EXPERIMENTAL STUDIES

Test Specimens

A full scale experimental study was conducted in the Structural Research Laboratory of Queensland University of Technology to evaluate the fire performance of LSF wall panels. Test specimens were selected to represent a range of wall configurations used in the industry. The objective of this study is to gain in depth behaviour of LSF wall panels when exposed to both standard fire and realistic design fire time-temperature curves. Hence the basic parameters include different steel stud section depths, wall configurations and fire time-temperature curves. Table 1 gives the details of the non-load bearing full scale fire tests exposed to standard fire time-temperature curve, while Table 2 gives the load bearing tests exposed to both standard fire and realistic design fire time-temperature curves conducted as part of this study.

Table 1 Details of non-load bearing wall fire test configurations

Test	Configuration	Stud			Gypsum Plasterboard	Insulation Type
		Type	Thickness	Depth		
A1	Single Plasterboard	Type-A	1.15 mm	92 mm	13 mm	-
A2		Type-A	0.55 mm	76 mm	16 mm	-
A3		Type-A	0.75 mm	150 mm	16 mm	-
A4	Double Plasterboards 	Type-A	1.15 mm	92 mm	16 mm	-
A5	Cavity Insulation 	Type-A	1.15 mm	92 mm	16 mm	Glass fibre (75 mm thickness x 600 mm - 11 kg/m^3)

Table 2 Details of load bearing wall fire test configurations

Test	Configuration	Fire Curve	Description
K1		Standard fire curve	Type-B Studs (92*1.15 mm thick G500 studs) Axially loaded with 15 kN per stud (LR=0.2)
A6	Single Plasterboard	Realistic fire curve (EU-1-0.08)	
A7		Realistic fire curve (BFD-1-0.08)	
K2		Standard fire curve	Type-B Studs (92*1.15 mm thick G500 studs) Axially loaded with 15 kN per stud (LR=0.2)
A8	Double Plasterboards	Realistic fire curve (EU-2-0.03)	
A9		Realistic fire curve (BFD -2-0.03)	

Note: Load per stud was calculated as load ratio x ambient temperature capacity of stud (77 kN).

The experimental program consisted of full scale fire tests of 11 LSF wall panels of sizes varying from 2.4 m x 2.1 m to 3.0 m x 3.0 m (5 non-load bearing and 6 load bearing walls). Load bearing Tests K1 and K2 were conducted by Gunalan et al. (2013) for standard fire time-temperature curve. Test specimens A1 to A3, A6, A7 and K1 were lined with single layer of gypsum plasterboard and A4, A8, A9 and K2 were lined with two layers of gypsum plasterboards on either side of the studs. Test specimen A5 was lined with single layer of gypsum plasterboard and cavity insulated with Glass fibre insulation (75 mm thickness x 600 mm width - 11 kg/m^3). The

non-load bearing wall panels were made of 3 m long web stiffened lipped channels (Type A) Studs, while load bearing wall panels were made of 2.4 m long G500 lipped channels (Type B) studs (see Tables 1 and 2).

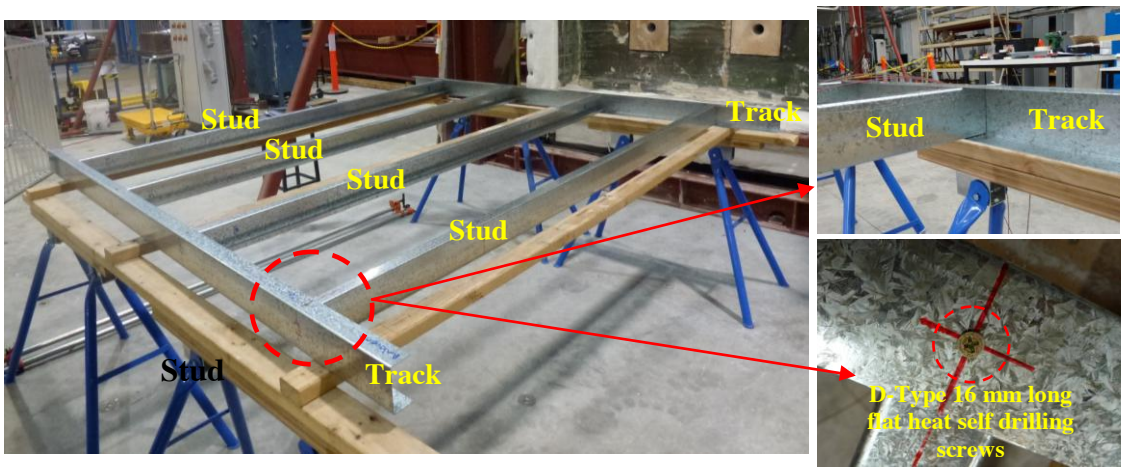

Figure 2 LSF wall frame – Stud to track connection

All the LSF wall panels consisted of cold-formed steel studs (Type A or B) spaced at 600 mm and tracks made of unlipped channels. The studs were inserted inside the tracks, and the stud and track flanges were screwed together using D-Type 16 mm long flat head self drilling screws (Figure 2). LSF wall frame was lined with a single layer of fire rated gypsum plasterboard to accommodate two vertical joints on each side of the wall frame. The plasterboard joints were staggered to avoid a single stud having plasterboard joints on both sides. 25 mm long D-Type self drilling screws were used to fix the gypsum plasterboards at 300 mm spacing along the studs and 200 mm staggered spacing over the plasterboard joints. In Test specimen A5, the cavity between the studs was filled with 75 mm thick Glass fibre insulation and where second layer of gypsum plasterboard exists (Test specimens A4, A8, A9 and K2), it was fixed horizontally using 45 mm long bugle head screws. All the plasterboard joints were protected with two coats of plasterboard joint filler material and with a 50 mm wide paper based tape sandwiched between two coats of filler material. The recessed plasterboard edge was filled with two nearly equal thickness joint filler coats and finished to the top level of the plasterboard.

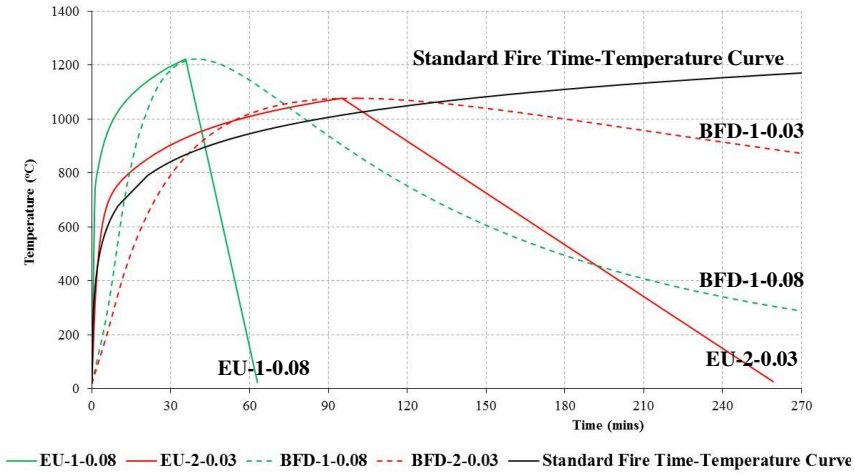

Figure 3 Realistic design fire time-temperature curves used in fire tests

Test specimens A1 to A5, K1 and K2 were exposed to standard fire time-temperature curve and A6 to A9 were exposed to realistic design fire time-temperature curves. The review of the existing fire time-temperature curves identified three basic fire parameters to define the fire time-temperature curve in a compartment, namely; fuel load, ventilation opening and thermal properties of the compartment lining materials. Therefore to study the effect of realistic fire time-temperature curve on the fire performance of LSF wall panels Eurocode parametric fire curve (ECS, 2002) and Barnett's BFD curve (Barnett 2002) were considered. Both Eurocode parametric fire curve and BFD fire curve allows a fire time-temperature curve to be developed using the above three fire parameters. Fuel load values of a compartment depend on type of building, compartment usage, and geographic

location of the building. The changes in the fashion trends and use of latest synthetic materials have resulted changes in the fuel load values in modern buildings. However, for the worst case fire scenario an average value 780 MJ/m^2 was selected. This value was based on Eurocode 1 Part 1.2 (ECS 2002) and incorporating the design actions a fuel load density of 1268 MJ/m^2 was used in this study. For ventilation opening two opening factors, 0.08 and 0.03 m$^{1/2}$ were chosen to represent the rapid and prolonged fires, respectively. The thermal properties of the compartment lining materials for this study was chosen to be light gauge steel frame partition walls and ceiling, and concrete floor slab to represent a single story residential building. Figure 3 shows the developed realistic fire time-temperature curves for use in this experimental study. Details of the development of these realistic design fire curves are given in Ariyanayagam and Mahendran (2014 and 2015). Single gypsum plasterboard lined Test specimens A6 and A7 were exposed to rapid realistic design fire time-temperature curves EU-1-0.08 and BFD-1-0.08, respectively, and double gypsum plasterboards lined Test specimens A8 and A9 were exposed to prolonged fire curves EU-2-0.03 and BFD-2-0.03.

Test Set-up and Procedure

Fire tests were conducted in a specially designed loading frame, shown in Figure 4. Loading frame consisted of two universal columns on either side of the furnace, bolted to the floor and a universal beam at the top and bottom levels. Another universal beam was placed on the floor and hydraulic rams were positioned on top of it at a spacing of 600 mm, so that were directly under the studs. The test wall panel was unrestrained on its vertical sides with the gap between the supporting frame and the test wall panel filled with ceramic insulation.

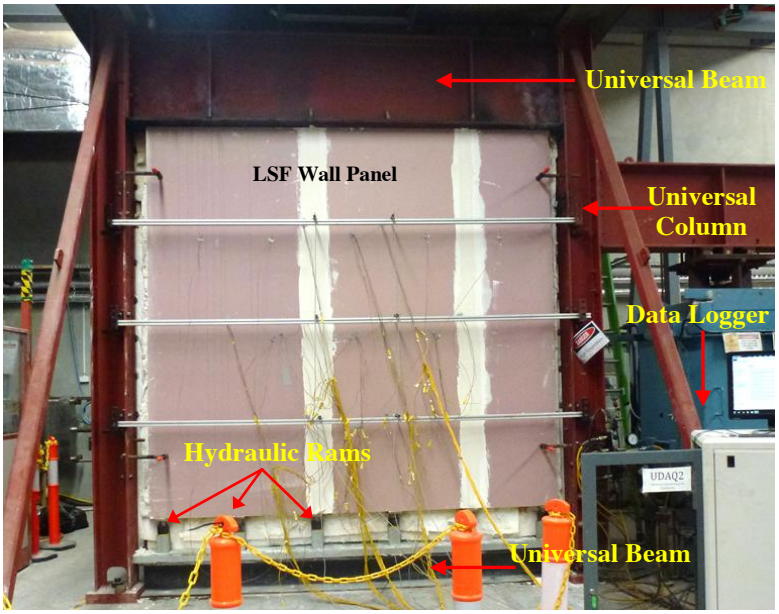

Figure 4 Fire test set-up

An axial compressive load of 15 kN per stud was applied to each of the studs of the load bearing fire Test specimens A6 to A9, K1 and K2, while a small load of 0.5 kN was applied to the studs of the non-load bearing fire Test specimens A1 to A5. The axial deformations and lateral deflections of studs were measured at six locations. Type-K thermocouples were used to measure the temperatures in the wall specimens. The stud and gypsum plasterboard surface temperatures were also measured at 0.25H, 0.50H and 0.75H, where 'H' is the height of the wall panel. At each height on the studs, thermocouple wires were connected to their hot and cold flanges, and web elements. Figure 5 shows the locations of the thermocouples across the test wall specimen.

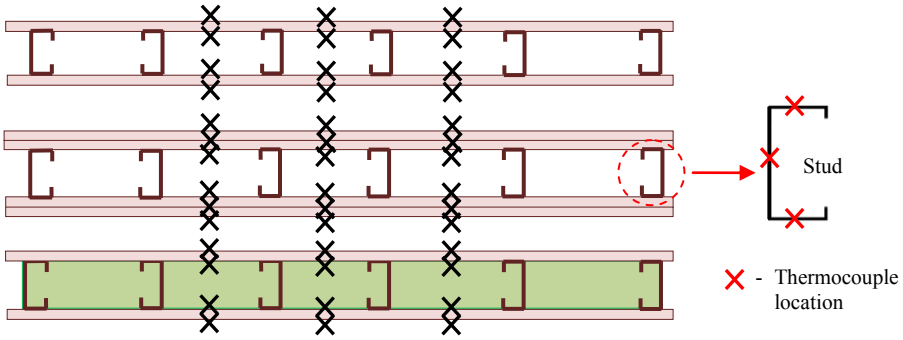

Figure 5 Locations of thermocouples on test wall specimen

RESULTS AND DISCUSSIONS

Non-load Bearing Wall Fire Tests

Five non-load bearing full scale fire tests were conducted to evaluate the fire performance of LSF wall assemblies (Table 1). The wall panels were exposed to the standard fire time-temperature curve based on AS 1530.4 (SA 2014). Table 3 summarizes the test results of these five non-load bearing wall fire tests. In all the tests approximately after 3 to 5 minutes of starting the furnace, smoke and steam was visible at the top of the specimen for 5 to 8 minutes. Also water drops were seen along the edges of the bottom Universal Beam (UB) section of the loading frame. All the test wall panel failures were due to the insulation failure criterion either based on the average or maximum temperature limits, and integrity or structural failures were not observed in these tests. Insulation failure criterion is based on average and maximum temperature limits. Average temperature limit is defined as 140^{o}C+ambient temperature at the start of the fire test while the maximum temperature limit is 180^{o}C+ambient surface temperature. In Tests A2 to A5 insulation criterion was reached based on the maximum temperature limit, whereas in Test A1 it was based on the average temperature limit. This was due to the fire side plasterboard fall-off or the plasterboard joint opening up in Tests A2 to A5, thus it caused the ambient side plasterboard temperatures to rise rapidly and to reach the maximum temperature insulation temperature limit. This shows that the partial fire side plasterboard fall-off is critical and can influence the insulation failure time as it leads to a rapid localized temperature rise on the ambient plasterboard surface, where fire side plasterboard fall-off occurs. Figure 6 shows the average plasterboard time-temperature curves measured across the wall panel.

Table 3 Fire test results – Non-load bearing wall panels

Test	Configuration	Ambient Temp. at the start of test (^{o}C)	Wall Panel Failure Time	Failure Criterion	Ambient Plasterboard Surface Temp at failure (^{o}C)	
					Avg	Max
A1	Single Pb–92mm Stud	30	60 mins	Insulation (Avg-Temp)	170.6	186.2
A2	Single Pb–76mm Stud	29	68 mins	Insulation (Max-Temp)	133.0	210.1
A3	Single Pb–150mm Stud	27	76 mins	Insulation (Max-Temp)	142.1	208.0
A4	Double Plasterboards	30	197 mins	Insulation (Max Temp)	143.1	210.1
A5	Cavity Insulation	28	98 mins	Insulation (Max Temp)	136.1	208.6

Effect of Wall Configuration

Three different LSF wall configurations (single plasterboard, double plasterboards and cavity insulation wall panels) were tested to investigate the effect of different wall panels on the fire performance of non-load bearing wall panels. Test A1 (single plasterboard) failed in the insulation criterion after 60 minutes of fire exposure, whereas Test A5 (cavity insulation) and Test A4 (double plasterboards) wall panels also failed in the insulation criterion but after 98 and 197 minutes, respectively. This shows that there is significant increase in FRL due to the use of double plasterboards on non-load bearing wall fire tests. Also Test A5 gave a higher FRL than Test A1 (98 vs 60 minutes). However, it is to be noted that Test A1 wall panel was lined with 13 mm thick gypsum plasterboards and Test A5 was lined with 16 mm thick gypsum plasterboards. Hence it is believed that if 16 mm plasterboards were used in Test A1 instead of 13 mm thick plasterboards, it could have given higher FRL than 60 minutes, and demonstrated the actual fire performance of cavity insulation. Figures 6(a) and (e) shows that after 20 minutes of fire exposure Average Fire Pb1-Cavity temperature increased rapidly in cavity insulated wall

panel (Test A5) compared to single plasterboard lined wall panel (Test A1). For instance, in Test A5, Avg Fire Pb1-Cavity surface temperature of 500°C was reached at 28 minutes, whereas it was at 38 minutes in Test A1. Also the difference between the cavity facing plasterboard temperatures (Fire Pb1-Cavity and Cavity-Ambient Pb2) was very high in Test A5. This is due to the use of insulation in the cavity, as it traps the heat on the fire side causing the fire side plasterboard temperature to rise rapidly. Hence in cavity insulated wall panels, fire side plasterboard will dehydrate and soften much earlier than the single plasterboard lined wall panel test. However, it is to be noted that for non-load bearing walls ambient side plasterboard temperature is the important parameter in determining the insulation failure criterion, and this was well achieved by the cavity insulation wall panel. For instance, in cavity insulated wall panel (Test A5) Avg Cavity-Ambient Pb2 surface temperature reached 500°C at 90 minutes, whereas it was at 57 minutes in single plasterboard Test A1. This shows that the use of cavity insulation in Test A5 has helped to improve the fire performance.

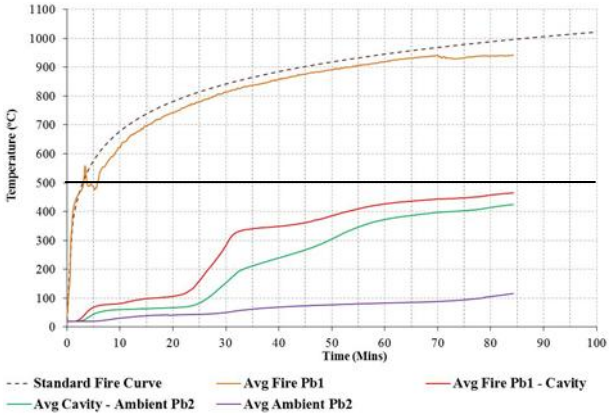
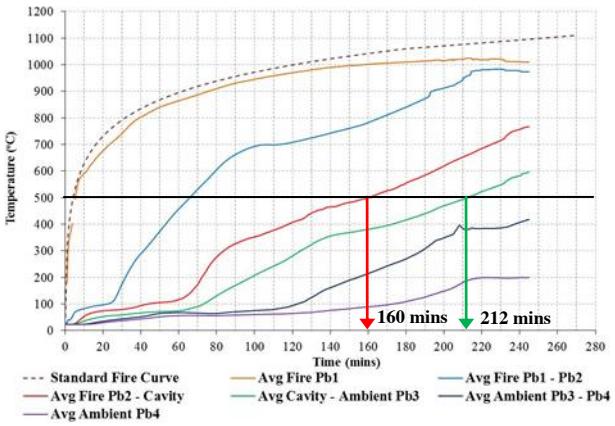
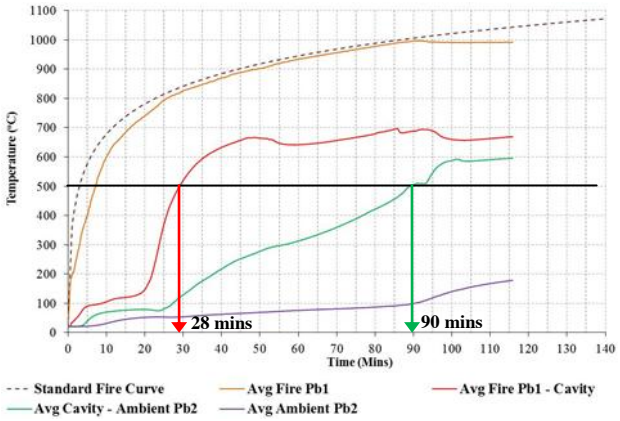
(d) Single plasterboard (76 mm stud and 16 mm gypsum plasterboards) - Fire Test A2



(c) Single plasterboard (150 mm stud and 16 mm gypsum plasterboards) - Fire Test A3



(b) Double plasterboard (92 mm stud and 16 mm gypsum plasterboards) - Fire Test A4



(a) Cavity insulation (92 mm stud and 16 mm gypsum plasterboards) - Fire Test A5

Figure 6 Average plasterboard surface time-temperature curves – Non-load bearing wall fire tests

Effect of Stud Depth

Two different stud depths (76 and 150 mm) were tested to investigate the effect of stud depth on the fire performance of single plasterboard lined non-load bearing wall panels. Both 76 mm studs (Test A2) and 150 mm studs (Test A3) failed in the insulation criterion after 68 and 76 minutes, respectively. This shows that there is insignificant difference in FRL due to the use of studs with larger depths. However, it is to be noted that both tests failed in the maximum temperature limit in the insulation criterion, and this maximum temperature was recorded only at a particular area on the ambient plasterboard surface. This was due to the premature partial collapse of the fire side plasterboard. Thus it allowed the ambient side plasterboard temperatures to rise rapidly and to reach the maximum temperature limit insulation criterion. However, a significant increase in FRL was noted in the use of larger stud depth when the average plasterboard surface temperatures are used. For instance, in Test A2 (76 mm Stud) plasterboard surface temperatures (Avg Fire Pb1-Cavity and Avg Cavity-Ambient Pb2) reached 500^{o}C at 54 and 66 minutes, respectively, whereas in Test A3 (150 mm Stud) both these plasterboard surfaces did not reach 500^{o}C even after 84 minutes of fire exposure (see Figures 6(b) and (c)). This shows that there is significant increase in FRL due to the use of studs with larger depths in non-load bearing wall panels.

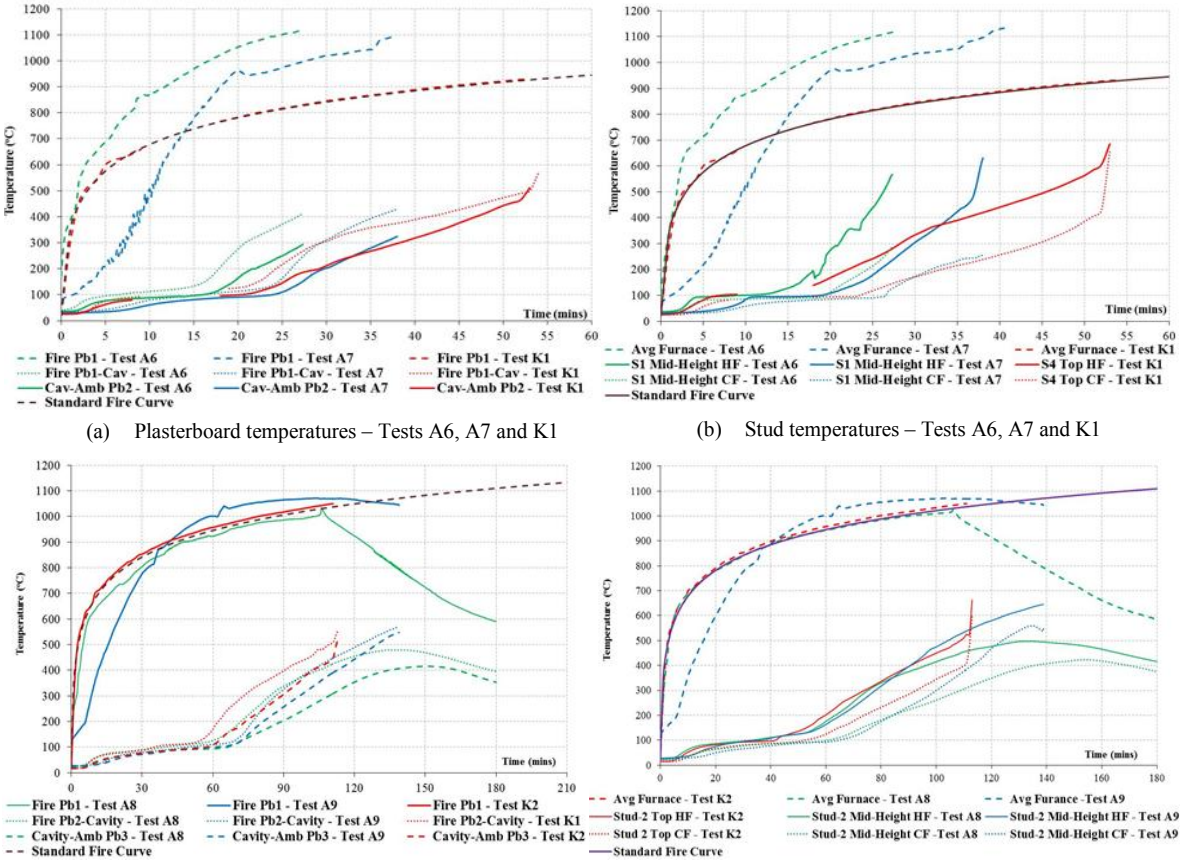
Load Bearing Wall Fire Tests

Effect of Realistic Design Fire Time-temperature Curves

Table 4 Fire test results – Load bearing wall panels

Test	Configuration	Fire Curve	Wall Panel Failure Time	Failure Criterion	Maximum Stud Temperature (^{o}C)	
					Hot Flange	Cold Flange
K1	Single Plasterboard	Standard fire curve	53 mins	Structural Failure	685#	659#
A6		Fire (EU-1-0.08)	28 mins		567#	286#
A7		Fire (BFD-1-0.08)	39 mins		630#	258#
K2	Double Plasterboards	Standard fire curve	111 mins	Structural Failure	663	599
A8		Fire (EU-2-0.03)	-	No Failure	497	423
A9		Fire (BFD-12-0.03)	139 mins	Structural Failure	645	560

Note: # - see Figure 7(b), rapid stud temperature rise was noticed near the stud failures.



(a) Plasterboard temperatures – Tests A6, A7 and K1

(b) Stud temperatures – Tests A6, A7 and K1

(c) Plasterboard temperatures – Tests A8, A9 and K2

(d) Stud temperatures – Tests A8, A9 and K2

Figure 7 Average plasterboard surface and stud time-temperature curves – Load bearing wall fire tests

Single gypsum plasterboard Tests A6 and A7 structurally failed after 28 and 39 minutes, respectively, while double plasterboard lined Test A9 structurally failed after 139 minutes of fire exposure (Table 4). Test A8 did not fail under any failure criteria even after 180 minutes of fire exposure. Test A8 fire curve (EU-2-0.03) was nearly identical to the standard fire curve in the fire growth period until 105 minutes and then had a decay phase. The failure of Test K2 exposed to the standard fire curve at 111 minutes indicates that the Fire curve (EU-2-0.03) with the decay phase was less severe than the standard fire curve (Figure 7(c)). Also the failure times of Tests A6 to A9 and Tests K1 and K2 indicate that the fire curve had a significant influence on the FRL of wall panels. For instance, Test A7 was exposed to a lower temperature gradient fire curve (BFD-1-0.08) than the other two fire curves in Figure 7(a) and the plasterboard temperatures also followed the same with a time lag. As expected this time lag was due to the different rates of temperature rise, where the low rate of temperature rise delayed the dehydration of plasterboards.

In all three single plasterboard Tests A6, A7 and K1, the structural failure occurred in the stud as a result of partial plasterboard fall-off. This is clearly noticeable with a rapid temperature rise in the stud temperatures (see Figure 7(b)). The stud failure hot flange temperatures of Tests K1, A6 and A7 vary significantly for the same wall configuration (685, 567 and 630^{o}C). This is because the plasterboard calcinates and shrinks quickly at rapid temperature rise conditions, thus it caused the plasterboards to fall-off and studs to fail in minor axis buckling. However, the stud failure hot flange temperatures agreed well for double plasterboard Tests K2 and A9 (663 and 645^{o}C). Test A8 stud hot flange temperature reached only 497^{o}C at 140th minute, hence it did not fail. Also it can be seen in Test A8 that the stud temperature increased even in the decay phase of the fire (see Figure 7(d)). Hence this implies that studs could fail during the decay period if they had reached the critical hot flange temperature. Also in Test K2, a partial plasterboard fall-off was noticed near the failure of the stud. Hence the studs reached the critical hot flange temperature and the studs failed under the structural failure criterion. Therefore it can be concluded that if similar conditions exist, i.e. restraints and applied loads are similar, the load bearing wall stud failure depends on its maximum hot flange temperature for any fire time-temperature curve.

CONCLUSIONS

This paper has described an experimental study of the fire performance of LSF wall panels. Details of fire tests and the results are presented and discussed. The study has shown that the use of double layers of plasterboard will give superior fire performance for non-load bearing wall panels as it delays the ambient plasterboard temperatures, use of cavity insulation will have only a limited increase in FRL. The use of larger stud depth has been shown to increase the FRL of non-load bearing wall panels. Further the study highlighted the importance of using realistic design fire curve in the testing of LSF wall panels, and showed that the fire performance of LSF walls depends on the shape of the fire curve including the rate of temperature rise. It concluded that the structural failure of load bearing wall panels depends mostly on the stud hot flange temperature for similar wall configurations. This experimental study has also shown that the partial fire side plasterboard fall-off is a critical factor in determining the FRL, as it will prematurely initiate the failure of both load bearing and non-load bearing LSF wall panels.

ACKNOWLEDGMENTS

The authors would like to thank Australian Research Council and Australian building industries for supporting this research student. They would also like to thank Mr Kyoungsoo Go and Technical staff for their assistance in the testing of wall panels and QUT for providing the necessary facilities to conduct this research project.

ABSTRACT

Fire design stakeholders such as architects, regulators, fire service, etc., often have different opinions about which passive fire protection approach is the most appropriate one in meeting structural fire performance objectives. There are many options for protecting steel buildings in a fully developed fire, but there is the need to identify a strategy that could satisfy at best the different and sometimes conflictual stakeholder desires, thereby reducing design uncertainties. This paper proposes a three-stage approach to address this issue: (i) stakeholder engagement, to identify and extract stakeholder desires; (ii) decision analysis, and; (iii) risk-based parametric study. The paper focuses, in particular on the first two stages. The first stage describes the process of identification and extraction of stakeholder desires in steel structural fire design from literature and structured interviews through a stakeholder engagement plan. The second stage of the decision-making process is demonstrated using a simple stakeholder goal-rating and multi-criteria decision analysis (MCDA). In particular, the use of analytic hierarchy process (AHP) is proposed to manage the multiplicity of stakeholder desires towards common decision-criteria, manage possible inconsistent goal-rating, and to rank the different proposed passive fire protection options.

KEYWORDS

Stakeholder goal, structural fire design, fire protection, multi-criteria decision analysis (MCDA), analytic hierarchy process (AHP).

INTRODUCTION

Generally, building designs can be achieved by using prescriptive or performance-based codes (Alvarez *et al*. 2013). Prescriptive codes are established design requirements that stipulate the means of compliance but often without clear statements of their objectives, while in performance-based codes the desired design objectives are stated and designers are given the freedom to choose a solution that will meet the objectives. Performance-based design codes are being adopted in many countries due to their flexibility in satisfying design objectives and required performance of buildings. Studies have shown that building owners, architects, fire engineers, building insurers, fire service and authorities having jurisdiction are involved as stakeholders in most fire safety designs (Meacham 2000; Alvarez *et al*. 2013; and Park *et al*. 2014). These stakeholders have particular interests in specific design options and as a result of the flexibility of performance-based codes, the stakeholders in some scenarios misinterpret the codes, thereby compromising safety, causing delays and increasing costs. These factors present uncertainties in the design of buildings.

The fire design of buildings will typically need to consider the ability of the structure to resist fire. There are a number of options available to steel structural fire designers to achieve this goal such as compartmentation, concrete encasement of steel, board systems, intumescent coatings, and the use of unprotected steel. Using these options with a performance-based code may lead to uncertainty as to which is the most cost-effective. A robust decision-making process mitigates these uncertainties to achieve structural fire design adequacy of steel buildings. The divergent views of fire engineers and other practitioners in the fire industry during the 2014 New Zealand Ministry of Business, Innovation and Employment (MBIE) open stakeholders' forum gives further credence that steps need to be taken towards an agreed decision-making process within the fire design context. For instance, architects are keen on building aesthetics and prefer the use of intumescent coatings for passive fire

protection of steel-framed buildings due to their aesthetic appeal (Meacham 2000). In contrast, the structural engineer could recommend partial or full concrete encasement of steel which eliminates the disadvantages of intumescent coatings such as adhesiveness and non-uniform thickness, but may increase the weight of the structure (Buchanan 2001). Each of these options will likely have different costs in terms of design, installation and maintenance. These situations illustrateun balanced stakeholder desires which give way to fire design uncertainties and highlight the need for optimised decision-making in order to fully take advantage of performance-based design.

To solve this problem, there is need to extract the views of stakeholders and understand their desires. Tools are also needed to process the stakeholder views in order to rank their design options for suitable decision-making. This paper presents an overview of the MCDA and AHP techniques. Building on findings from literature, the paper proposes a framework for the use of MCDA and AHP to manage divergent desires of steel structural fire design stakeholders. Finally, the paper explains the framework and approach with an example, which demonstrates how the AHP is used to manage the multiplicity of stakeholder desires towards common decision-criteria, manage possible inconsistent goal-rating, and to rank the different passive fire protection options.

BRIEF OVERVIEW OF MCDA AND AHP

Multi-Criteria Decision Analysis

Multi-criteria decision analysis (MCDA) is a widely used technique in operation research to solve complex problems that are characterised by divergent objectives, uncertainties, dissimilar data, varying interests and perspectives (Mateo 2012). MCDA is structured to provide more information on the contextual problem and stakeholder desires, and can aid a participatory process for the purpose of fairness and transparency, which are features that make the technique acceptable to stakeholders (Nordstrom *et al*. 2012). MCDA solutions assess available options with respect to the common decision criteria and rank the options for a decision to be made.

There are many MCDA solutions which can be applied depending on the peculiarity of the multi-criteria decision scenario. For example, the analytic hierarchy process (AHP) has been used for a hospital management decision problem (Saaty 1994a), the technique of order of preference by similarity to ideal solution (TOPSIS) was applied in decision-making for seismic structural retrofitting (Caterino *et al*. 2009), and the Extended Goal Programming (EGP) was considered for participatory forest planning (Nordstrom *et al*. 2012). In some cases, hybrid-MCDA solutions have been adopted e.g. AHP+TOPSIS, analytic network process (ANP) + VIKOR etc (Jato-Espino *et al*. 2014). Regardless of the type or form of application, MCDA solutions are mainly designed to help the decision-makers to approach a suitable decision, but not to make the actual decision.

Analytic Hierarchy Process (AHP)

Saaty in the early 1980s developed a decision-making process known as analytic hierarchy process (AHP), in which a problem is broken down and the solutions of the sub-problems are combined to aid the decision-makers to approach a decision. This tool entails the decomposition of a problem into a hierarchy of decision criteria and options, weighting them based on pairwise judgements to determine the performance/dominance of the criteria to the decision makers and aggregating these performance scores to rank the options (Saaty, 1980, 1994b). AHP allow for a consistency check of all pairwise comparisons, given that human beings are inconsistent in such judgements (Coyle 2004). Hence, this MCDA solution has been widely applied in over 20 countries in solving decision-making problems ranging from policy making, product marketing strategy, military analysis to cost-benefit assessment in construction (Jato-Espino *et al*. 2014). Recently, Yan *et al*.(2015) applied AHP to formulate an index criterion score system of fire risk assessment in a large business district.

There are many ways to carry out MCDA using AHP but in this paper, a summary of the procedure by Saaty(1980, 1994a)and Coyle (2004) is presented. Firstly, a goal must be stated, the key decision criteria are defined, and the sub-decision criteria are classified under their parent-key decision criterion as deemed appropriate taking into consideration the multiplicity of the stakeholder desires. In some scenarios, decision-makers may work as a group and agree on common decision criteria and sub-criteria. The competing options are identified at this stage as well. The second phase involves pairwise comparisons based on the level of importance in different categories using the Saaty's reciprocal pairwise comparison scale shown in Table 1.Here, values from Table 1 are assigned to each compared pair of criteria or options according to the intensity of the opinion of the decision-maker. The criterion or option with greater importance for every compared pair is assigned a whole number, while the other criterion or option in that same paired comparison is assigned the reciprocal of the whole number. The categories of pairwise comparisons in the AHP are thus classified: Category A is the pairwise comparison of the key decision criteria against each other with respect to the stated goal; and the

pairwise comparison of the competing options against each other with respect to the stated goal. Category B is the pairwise comparison of the sub-criteria against each other with respect to their parent-key decision criteria as classified and Category C is the pairwise comparison of the options against each other with respect to every sub-decision criterion in the decision problem.

Table 1 Saaty's rating scale (Coyle, 2004)

Intensity of importance	Definition	Explanation
1	Equal importance	Two factors contribute equally to the objective.
3	Somewhat more important	Experience and judgement slightly favour one over the other.
5	Much more important	Experience and judgement strongly favour one over the other.
7	Very much more Important	Experience and judgement strongly favour one over the other. Its importance is demonstrated in practice.
9	Absolutely more important	The evidence favouring one over the other is of the highest possible validity.
2,4,6,8	Intermediate values	When compromise is needed.

In the third phase, these pairwise comparison ratings are presented in the form of matrices. For every matrix, each element compares the intensity of importance of a criterion or option against each other, where 1is retained for a criterion or option compared against itself. This completes the pairwise comparison matrices, which are thenready for further assessment. In scenarios where decision-makers carried out the pairwise comparisons individually, there will be need to aggregate the individual ratings for each category to form a single or common group judgement of the criteria or options. In the aggregation of the various ratings of the decision-makers, either the arithmetic mean method (AMM) or the geometric mean method (GMM) is used. AMM represents an average interval of all ratings in a category, while GMM represents an average ratio of the same ratings. Using any of the methods, all decision-makers become a new individual whereby the aggregation of all of the individual matrices form a single group matrix at different categories. The GMM method used in aggregating individual judgements and priorities for ease of decision analysis has been explained elsewhere by Forman and Peniwati(1998). The GMM equation is thus:

$$Z^{[G]} = (z_{ij}^{[G]}), \text{ where } z_{ij}^{[G]} = \prod_{p=1}^{a} (z_{ij}^{[G]})^{\alpha_p},\ i, j \in \{1, n\} \quad (1)$$

$Z^{[G]}$ is the geometric mean of the group; $z_{ij}^{[G]}$ is the aggregated judgements for the compared criteria or options i and j; a represents the number of decision makers, p is the p-th decision-maker with weight represented as α_p. The value for α_p is dependent on the weights assigned to decision makers, and $\alpha_p = 1/p$ if the decision-makers are assumed to have the same weight.

The fourth phase is to weight the key decision criteria, sub-criteria and options to determine their performance scores at each aggregated category. The dominance of a particular criterion or option is also deduced from this evaluation. In AHP, the performance scores of the key decision criteria and options are evaluated using Eigenvalue theory. Here Eigenvectors (performance scores) are assigned to the criteria or options from aggregated matrices of pairwise comparisons. These performance scores are determined by multiplying the entries in each row of the matrix, then calculating the n^{th}root of the rows' products give good approximations, which are summed up. This sum is used to normalise the elements of the performance scores to add up to 1.00. The consistency ratio (CR) of the aggregated pairwise ratings are checked by further normalisation of the performance scores with the matrix row entries to achieve a consistency index (CI), given as;

$$CI = \lambda_{max} - n / (n - 1) \quad (2)$$

where λ_{max} is the mean of the normalised new performance scores and n is the total number of weighted criteria or options.

CI is then divided by the corresponding value for n from Saaty's random judgement table of large matrix samples shown in Table 2.

Table 2 Saaty's random consistency index values for different values of n (Saaty, 1980)

1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
0	0	0.58	0.90	1.12	1.24	1.32	1.41	1.45	1.49	1.51	1.48	1.56	1.57	1.59

Saaty (1980) and Coyle (2004) mention that a CR > 0.10 means that the pairwise judgements of the decision makers are at the consistency limit and in practice, it is unacceptable if it increases toward unity. In the case of determining the true performance scores of the sub-criteria under their parent-key decision criteria, the Eigenvalue process is applied but each resultant Eigenvector is multiplied by the performance score of their parent- key decision criterion. Hence, the summation of the performance scores of the sub-criteria must equal the exact value of their respective parent-key decision criterion performance score, and the summation of performance scores of all key decision criteria must equal 1.00.

The fifth phase of the AHP involves synthesis of performance scores of the options with respect to the sub-criteria under each key decision criterion. This is aimed at determining the preference scores of the competing options, which can be carried out either in the distributive or ideal synthesis mode. In the distributive (dominance) mode, the performance scores of each option are multiplied by the sub-criteria performance scores and summed to obtain the synthesis of overall preference scores of the options. Notably, the preference scores sum up to 1.00 and the dominance of an option can be deduced. In the ideal (performance) mode, the best option under each sub-criterion is normalised to 1.00 as a benchmark; then the other performance scores are divided by the score of the best option, multiplied by the respective sub-criteria performance scores and summed as well. This implies that the preference scores of any option do not depend on the performance scores of others except for the chosen benchmark option (Saaty 1994a). The total value from the addition of the summed-up column is used to normalise them to add up to unity. As part of the AHP guideline, Millet and Saaty (1999) suggests that the distributive synthesis mode should be used when the decision-makers wish to assess the amount of dominance of one of the options and the dependence among these options, given a unit weight distributed among them under a criterion; while, the ideal mode should be used to evaluate the performance of each option relative to a chosen benchmark.

The final phase of the AHP decision analysis is to rank the assessed options in order to aid decision-making. However, where benefits and costs are considered, the key decision can go in three directions: whether the benefits justify their costs, whether the costs outweigh the benefits or both variables are too close to call. Saaty (1994a) suggests that in complex decision-making problems, cost criteria with respect to the options should be separated and synthesised when all the benefits of the competing options have been assessed. Therefore, when these two variables are separated, they produce a scenario to determine benefit-cost ratios given as:

$$B_i/C_i \tag{3}$$

where B_i is the benefit preference score of the options and C_i is the cost preference score of the options.
Result from this calculation ranks the competing options and presents the option with the highest benefits and least costs as the top ranked option.

PROPOSED FRAMEWORK

The first part of the approach in balancing stakeholder desires is to engage the fire design stakeholders in a structured discussion to elicit their views toward an optimised decision-making outcome. In such participatory discussion, the stakeholders are given the opportunity to rate their fire protection preferences and decision criteria in designing steel buildings for fully developed fires. This paper proposes a three-phase stakeholder engagement plan consisting of planning, preparation and engagement, response and rating. The planning phase includes identification of the stakeholders involved in the decision making for an appropriate design option and getting their consent for stakeholder meetings. Meetings are scheduled at the preparation and engagement phase and structured for participatory discussions during the response and rating phase.

A questionnaire that consists of a pairwise comparison scale is employed in the stakeholder meetings to aid the stakeholders in rating the fire protection options, decision criteria and sub-criteria as the case may be.
Research has identified key decision criteria and sub-criteria (NZFS 1975; Spearpoint 2008; Alvarez *et al*. 2014 and Park *et al*. 2014)as shown in Table 3. In future, the stakeholders may be allowed to include and rate other desires they deem necessary.

Table 3 Key and sub-decision criteria desired by fire design stakeholders

Key decision criteria	Sub-decision criteria
Economy (costs)	Building cost, constructability, maintainability
Socio-environmental	Environmental sustainability, human comfort
Effectiveness	Fire spread beyond compartment, business continuity
Safety	Clarity in design details and specifications, building regulation approval, accessibility for fire-fighting operations

It is also ideal to construct hierarchical trees for costs and benefits to represent a breakdown of the decision problem into levels. The goal of choosing the best fire protection option should be placed at the top i.e. Level 1, the key decision criteria is placed at Level 2 and linked to the goal at Level 1, followed by the sub-decision criteria placed at Level 3 and linked to their respective parent-key decision criteria at Level 2. The fire protection options are placed at the base (Level 4) to complete the hierarchical tree.

In order to decide on the suitable fire protection option for the structural fire designs of steel buildings given the multiplicity of fire design stakeholder desires, a MCDA using the AHP procedure described in the previous section is proposed. The resultant performance scores are synthesised in the distributive and ideal modes and compared to identify dominance and performance of the fire protection options based on the pairwise ratings allotted by the stakeholders. A flowchart of the proposed framework in managing the decision problem described in this paper is shown in Figure 1. The AHP is applied bearing in mind that the fire design stakeholders are to make a decision that suits them out of the ranked fire protection options in consideration that the technique is not designed to make decisions for the users.

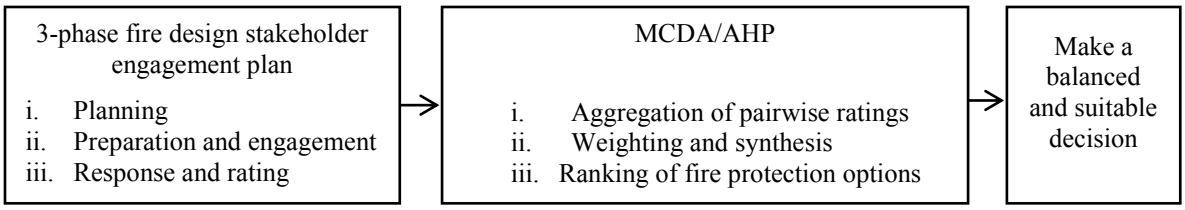

Figure 1 Proposed framework

At the weighting and synthesis phase of the AHP, the resultant performance and preference scores can be entered appropriately under the respective levels on the constructed AHP-hierarchical trees.

PILOT STUDY EXAMPLE

For the purpose of conducting this pilot study as well as demonstrating the approach described in this paper, ten full-time and part-time postgraduate students from the fire engineering programme at the University of Canterbury, were chosen. Several of the students have had a few years of professional engineering experience or are currently employed by fire engineering companies. The goal for this pilot study was stated as *'choose a cost-effective fire protection option for a steel-framed building'*. The stakeholder engagement plan was employed in which a questionnaire was constructed consisting of pairwise comparison matrices of the key and sub-decision criteria listed in Table 3 and the following passive fire protection options: *compartmentation, intumescent coatings, concrete encasement of steel (full or partial), board systems (e.g. gypsum, plaster etc.) and unprotected steel*. The Saaty-reciprocal pairwise rating scale shown in Table 1 was included in the questionnaire to aid the students in rating the fire protection options and decision criteria for steel structural fire design according to the intensity of their feelings during the scheduled meetings. The participants carried out the pairwise comparison ratings of the decision criteria and options individually.

The pairwise comparisons were carried out as described in the AHP procedure in categories. One of the participants' results of a pairwise comparison of the fire protection options with respect to the goal (Category A) of the pilot study is shown in Table 4. In this matrix, it is seen that the participant having used the Saaty rating scale, rated board systems as 'much more important' than compartmentation and allotted the value, 5 to board systems in the column on the left of the matrix. The participant also allotted the reciprocal of 5 i.e.1/5 to compartmentation in the top row of the matrix, as being 'much less important than' board systems. After the goal-rating exercise, participants selected the stakeholder that best represents their rating; and from a simple look at their ratings, the authors categorised their desires and preferences as shown in Table 5.

Table 4 Pairwise comparison matrix for fire protection options by a participant in the pilot study (Category A)

	Compartmentation	Intumescent coatings	Board systems	Concrete encasement	Unprotected steel
Compartmentation	1	1	1/5	1/3	1
Intumescent coatings	1	1	1/3	1	1
Board systems	5	3	1	3	1
Concrete encasement	3	1	1/3	1	1
Unprotected steel	1	1	1	1	1

Table 5 Divergent views of participants in the pilot study

Stakeholder role	No. of participants	Key decision criteria in order of importance to participants	Preferred passive fire protection option of participants
Building owners	1	Effectiveness, economy (costs), safety, socio-environmental	Compartmentation
Architects	2	Socio-environmental, effectiveness, safety, economy (costs)	Intumescent coatings
Building contractors	1	Economy (costs), safety, effectiveness, socio-environment	Concrete encasement of steel (full or partial)
Fire protection engineers	2	Safety, effectiveness, socio-environmental, economy (costs)	Compartmentation
Structural fire engineers	2	Safety, effectiveness, economy (costs), socio-environmental	Concrete encasement of steel (full or partial)
End-users (community)	2	Safety, effectiveness, socio-environmental, economy (costs)	Compartmentation

The divergent views of the participants are clear in Table 5and it identifies the likely dominance of a specific decision criterion, fire protection option and data skewness. Therefore, decision analysis is considered necessary to assess the competing fire protection options with respect to the key and sub-decision criteria in order to rank the fire protection options appropriately. Two hierarchical trees of benefits and costs were constructed as described in the proposed framework. The 'economy', key decision criterion, is separated from 'safety', 'socio-environmental', 'effectiveness'(deemed as benefits) and all economy-sub-criteria are identified as costs in this context. This is to allow for a broader view of the decision problem and thorough analysis of the competing variables (benefits and costs) to enable balanced decision-making.

Given that each individual carried out their ratings independently, there is the need to aggregate the results of the rated stakeholder desires to form a common or single group judgement for each category of pairwise comparisons. GMM is used for all the aggregation calculation as given in Eq. 1. One of the aggregated results is shown in Table 6. In this case, Table 6(a) is $Z^{[G]}$; $z_{ij}^{[G]}$ is the result from the 10×10 matrix-multiplication of the individual pairwise comparisons of the benefits key decision criteria (Category A) from the 10 participants and to the power of α_p. Notably, this pilot study assumed that all the participants are decision makers having same weight ($\alpha_p = 1/a$), where $a = 10$ (number of participants).

The AHP-Eigenvalue calculation is employed in weighting the aggregated ratings. Table 6 shows the performance scores (Eigenvectors) of the aggregated benefits key decision criteria. Here, 'safety' has the highest performance score, 0.48 from the Eigenvalue calculation and the summation of the performance scores equal 1.00.

Table 6 Group aggregated matrix and weighting of key decision criteria category

(a) Group aggregated matrix

	Safety	Socio-environmental	Effectiveness
Safety	1.00	1.62	2.19
Socio-environmental	0.61	1.00	0.81
Effectiveness	0.45	1.53	1.00

(b) Weightings from Eigenvalues

Performance scores (Eigenvectors)
0.48
0.24
0.28
Total = 1.00

Consistency checks for all the aggregated pairwise ratings are carried out using the AHP guideline and Eq. 2. The pairwise comparisons of the benefits key decision criteria gives CR = 0.10, which is on the margin of acceptability. The performance scores achieved from the AHP-Eigenvalues calculation of each category are indicated on the hierarchical trees in their respective levels as shown in Figures 2 and 3.

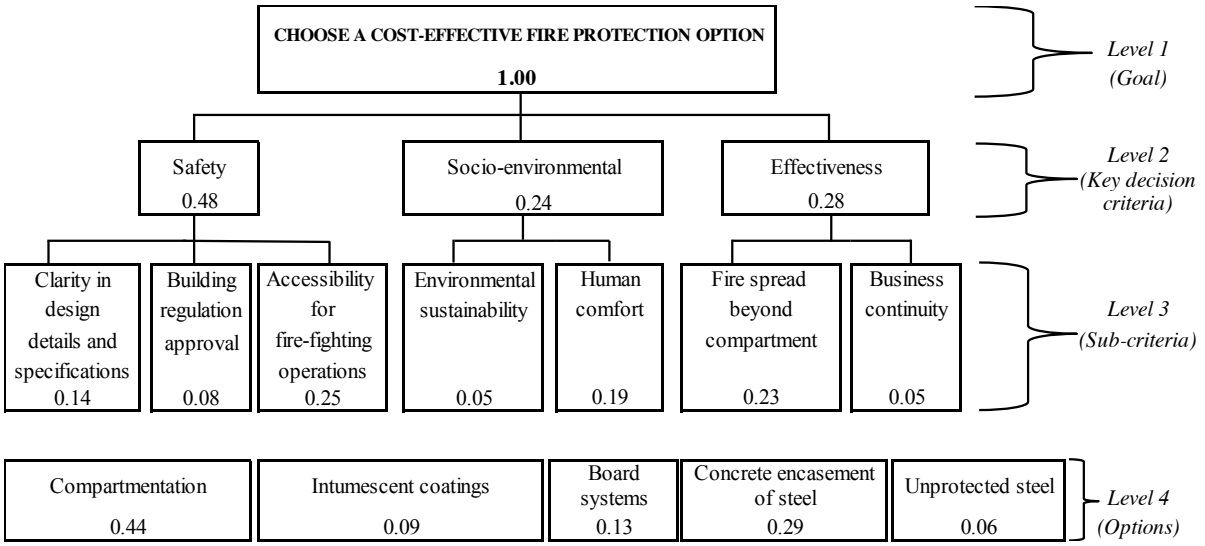

Figure 2 Ideal mode -AHP-benefits hierarchical tree of the decision criteria and passive fire protection options

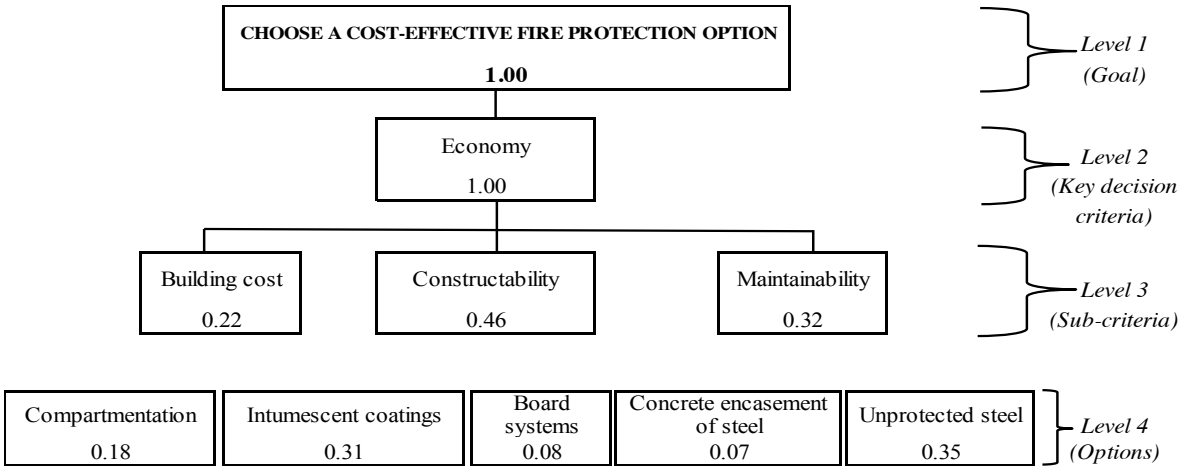

Figure 3 Ideal mode- AHP – costs hierarchical tree of the decision criteria and passive fire protection options

The benefits sub-criteria aggregated matrices achieved from their pairwise comparisons with respect to their parent-key decision criteria, are also weighted using the Eigenvalue procedure. In this scenario, the sub-criteria Eigenvectors are multiplied by the performance score of their respective parent-key decision criterion to achieve their performance scores. The calculated sub-criteria performance scores are indicated at Level 3 on Figure 2. In the benefits hierarchical tree, the summation of the sub-criteria performance scores (Level 3)under each key decision criterion of Level 2 equals the performance score of their respective parent-key decision criterion (Level 2). The performance scores of the sub-criteria under 'economy' were calculated using the same Eigenvalue procedure. Here 'economy' is treated as a single variable; hence all sub-criteria performance scores sum-up to 1.00 as indicated in Figure 3.

In completing the decision analysis for this pilot study, the performance scores of the competing fire protection options, achieved from their pairwise comparisons with respect to all sub-criteria in the pilot study (Category C) are synthesised in the distributive and ideal mode. The synthesis results are presented in Table 7. In the distributive synthesis mode, compartmentation is the dominating fire protection option as shown in Table 7, hence the normalised benchmark value of 1.00 seen in the compartmentation column (CPT) in the ideal mode. The preference scores of the fire protection options produced by the two synthesis modes are similar irrespective of the benefits and costs performance scores of the sub-decision criteria and fire protection options. For instance, Table 7 shows that the preference scores of compartmentation are 0.45 and 0.44 in the benefits distributive and ideal mode synthesis rows respectively and 0.17 and 0.18 in the costs distributive and ideal mode synthesis rows. The preference scores of the fire protection options in the benefits and costs ideal mode are also indicated on their respective hierarchical trees as an example.

Table 7 AHP-distributive and ideal mode synthesis to determine preference scores and ranking of options

	Distributive mode						Ideal mode				
	Performance scores	CPT	ITC	BSY	CEC	UPS	CPT	ITC	BSY	CEC	UPS
Benefits sub-criteria											
Clarity in design details & specifications	0.14	0.44	0.07	0.12	0.31	0.06	1.00	0.16	0.27	0.70	0.14
Building regulation approval	0.08	0.44	0.07	0.12	0.31	0.06	1.00	0.16	0.27	0.70	0.14
Accessibility for fire-fighting operations	0.25	0.44	0.07	0.12	0.31	0.06	1.00	0.16	0.27	0.70	0.14
Environmental sustainability	0.05	0.52	0.07	0.18	0.18	0.05	1.00	0.13	0.35	0.35	0.10
Human comfort	0.19	0.36	0.15	0.11	0.33	0.05	1.00	0.42	0.31	0.92	0.14
Fire spread beyond compartment	0.23	0.57	0.05	0.13	0.21	0.05	1.00	0.09	0.23	0.37	0.09
Business continuity	0.05	0.27	0.14	0.22	0.27	0.09	1.00	0.52	0.81	1.00	0.33
Benefits preference scores (B_i)		0.45	0.08	0.13	0.28	0.06	0.44	0.09	0.13	0.29	0.06
Costs sub-criteria											
Building cost	0.22	0.06	0.32	0.10	0.07	0.46	0.13	0.70	0.22	0.15	1.00
Constructability	0.46	0.07	0.41	0.08	0.07	0.36	0.17	1.00	0.20	0.17	0.88
Maintainability	0.32	0.40	0.17	0.08	0.07	0.28	1.00	0.43	0.20	0.18	0.70
Costs preference scores (C_i)		0.17	0.31	0.08	0.07	0.36	0.18	0.31	0.08	0.07	0.35
B_i / C_i		2.61	0.27	1.53	4.01	0.16	2.45	0.29	1.54	4.09	0.16

Key: CPT – Compartmentation, ITC – Intumescent coatings, BSY- Board systems, CEC – Concrete encasement UPS – Unprotected steel.

Finally, the benefits and costs ratios of the preference scores of the competing fire protection options are calculated using Eq. 3. Table 7 shows that concrete encasement of steel in the distributive and ideal modes has the highest scores, 4.01 and 4.09 respectively and it is the top-ranked option. These benefits and costs ratios are also presented in a scatter plot for the ideal synthesis mode. The resultant top-ranked fire protection option, 'concrete encasement of steel 'has the highest benefit and least cost from the AHP-decision analysis of the divergent desires of the participants as shown in Figure 4.

DISCUSSION

The decision criteria and fire protection options assessed in the pilot study are valid based on the general view of steel structural fire design objectives and stakeholder opinions in the literature. However, all of the existing decision criteria and passive fire protection options in the design of buildings for fully developed fires were not exhaustively used in this paper, given that it is a pilot study aimed at showing the potential of the adopted technique/process in optimizing stakeholder decision-making. Other decision criteria e.g.: building aesthetics (Park *et al*. 2014), profit-making, code compliance etc.; and passive fire protection options e.g.: sprayed on cement-base material, water filling of hollow steel sections (Spearpoint 2008) could be included in the future. Fire industry stakeholders should be allowed to include all decision criteria and options they deem necessary in structural fire design of steel buildings during the engagement stage. In using AHP, the fire design stakeholders can participate in pairwise ratings as a collaborative group or as individuals at different times and places as in the pilot study, where GMM was used in aggregating individual ratings to achieve single group judgements.

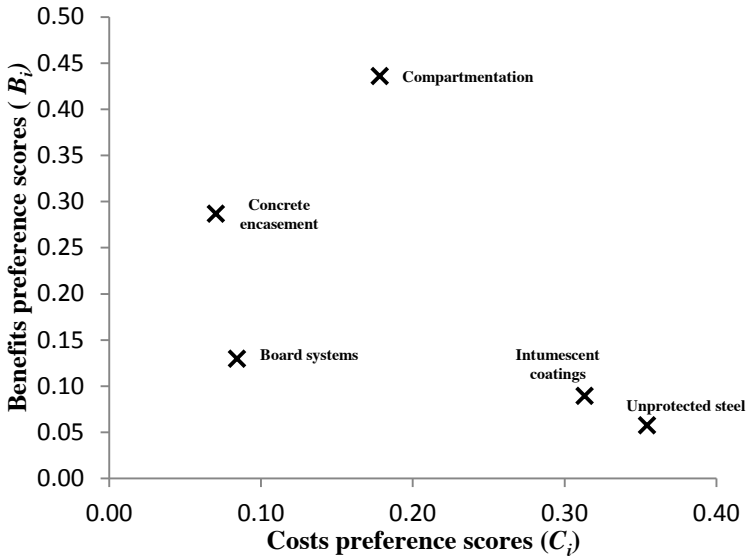

Figure 4 Ideal mode benefits versus costs preference scores for the passive fire protection options

The capability of AHP and other MCDA solutions to manage stakeholder desires and ranking of available options, were designed to help stakeholders to rank their options, but not for the tool to make decisions for the users. For instance, in a scenario where the participants in the example are more interested in the option with the highest benefits regardless of cost, then the second-ranked fire protection option, 'compartmentation' would be the obvious choice. This implies that a top-ranked option is not always the final choice. However, the analysis and ranking enables easy decision-making as it suits the stakeholders. The dominant option from the benefits synthesis may not be top-ranked one, given the costs synthesis as seen between compartmentation and concrete encasement shown in Table 6. In addition, the dominant or popular option among the stakeholders before the MCDA may not also be the top-ranked one at the end of analysis. This is clear where the initial dominance of compartmentation before the decision analysis as shown in Table 5 is compared with its rank after the analysis shown in Table 6 and Figure 4.

Another fundamental capability of the AHP shown in this decision-making process is the transition from the performance scores to the preference scores of the competing options using two distinct synthesis modes. In the pilot study, it can be seen that the different calculation procedure for the distributive and ideal synthesis mode did not produce a difference in the ranking of the fire protection options rather there is only a minor change in the preference scores as shown in Table 7. This may not always be the case in reality or in scenarios of complex decision hierarchies and data skewness. Saaty and Vargas (1993) also showed that there are minor differences in results produced by the distributive and ideal modes in a simulation. A further study of balancing the views offire industry stakeholders would be an opportunity to investigate these differences in a realistic scenario.

In relation to Millet and Saaty(1999),the ideal mode can be deemed appropriate for the synthesis of the competing passive fire protection options with respect to the benefits and costs sub-criteria in the pilot study. This is due to the independence of the competing options and the need to evaluate the performance of each option relative to the dominant option.

CONCLUSION

The purpose of this paper is to explain and demonstrate a decision-making process geared toward balancing stakeholder divergent views in steel structural fire design. The pilot study demonstrates the potential of the MCDA-AHP approach in solving decision problems. The sample population of ten student-participants is insufficient to test the process in real decision-making for fire protection of steel framed buildings. However, the process explained here is not about the outcome rather it is to test the viability of AHP in analysing decision-making problems inherent in steel structural fire design, given the flexibility of performance-based conditions. Hence, the results should not be used as a decision for fire protection.

This study also noted the effects of the weaknesses of AHP in analyzing unbalanced stakeholder desires in complex decision problems, these weaknesses include but are not limited to: outright dominance of a particular criterion or option at different categories of comparisons and inconsistencies of pairwise judgements. For instance, the example revealed some inconsistencies in the participants pairwise comparisons where CR is

exactly 0.10, which is the limiting CR value (Saaty 1980). Coyle (2004) also mentions that items for pairwise comparisons are usually not more than seven. There are fivefire protection options compared in Table 4 hence, there is likelihood of a problem of consistent comparisons if we extend the study to include other fire protection options. A critical assessment of the AHP-ranked fire protection options through a risk-based parametric study has been identified as an additional process to manage the weaknesses from the decision analysis. Presently, there is ongoing research to this effect and will also entail the use of the proposed stakeholder engagement plan to extract the views of fire design stakeholders.

AHP is a viable decision analysis tool and it is proposed for use due to its potential in managing views of fire design stakeholders and helping them make suitable decisions toward designing better steel buildings for fully developed fires, and by extension enhancing the life cycle of engineered structures.

ABSTRACT

The practice of structural fire safety engineering remains to be case-specific and the estimation of fire resistance of structures is mostly deterministic. Many researchers in structural fire engineering utilize the performance-based design method but these studies do not include the inherent uncertainties in both the demand and capacity. This paper investigates the structural fire reliability of tall buildings based on the framework used for earthquake hazard by the Pacific Earthquake Engineering Research (PEER) and Eurocode. The financial district of Istanbul in Turkey is taken as a case study for this research. Parameters such as building type and height, structural system, number of floors, floor area, number of elevators and stairs, the use of fire suppression systems, evacuation routes are provided by the municipalities in order to develop a probabilistic methodology to estimate the fire safety of these structures. The analysis is conducted by estimating the intensity or the hazard curve as described by PEER framework. The hazard domain includes random variables such as the fire load, the opening factor, the fire duration and the maximum fire temperature. The findings of this research will provide essential information on the fire safety risk of each tall building in a densely populated financial district. It will allow the municipalities and fire brigades to have a probabilistic risk assessment of these structures and develop evacuation and human rescue plans accordingly in case of a fire hazard. Further, this research will provide useful data to insurance companies to estimate fire hazard insurance premiums.

Structures in fire, structural fire safety and reliability, performance based design, probabilistic analysis.

INTRODUCTION

A number of fires in the 1960s and 1970s brought attention to the fire safety risk presented by high-rise buildings. Although fire hazards in very tall buildings are essentially the same as in low-rise buildings of similar uses (e.g., business, residential, mixed-use), the consequences of a fire have a potential to be more severe (Quiter, 2012). High-rise buildings differ from lower-height buildings in the following ways considering the fire safety:

- The time necessary for full building evacuation increases with building height. A special consideration must be provided in high-rise buildings employing assembly occupancies with large occupant loads on the upper floors to manage full evacuation.

- High-rise buildings have a greater potential fuel load, since their higher concentration of occupants, hence, more property loss.

- In emergency situations, there may be a delay in reaching the area to provide assistance, especially upper floors of a high-rise building.

- The existence of many individuals assembled in one location at any one time causes a rise of probability that some of these people could be injured or killed, because of a fire incident.

- Stack effect, which means the pressure difference causing temperature differentials between outside and inside temperatures gives birth air to move vertically, either upward or downward in a high-rise building. Subsequently, large uncontrolled fires may cause smoke as a result of the stack effect.

Since fire is such a low probability-high consequence event with considerable costs associated with protection, the use of performance based design frameworks accounting for multiple solutions is attractive, accounting for occupant and property protection. The performance-based engineering allows a broad spectrum of design solutions to be developed for different problems and evaluated based upon their individual merits by allowing either qualitative or quantitative risk of an event (Rini, 2008). Fire events and response of structures to such events involve a great deal of uncertainty. Performance-based design can be used to evaluate performance of a building under potential fire hazards while taking into account the inherent uncertainties in both the demand and capacity.

To predict the probabilistic response in the analysis of structures there have been recent developments by researchers in structural fire engineering area. For example, a review paper on the progress of the structural reliability evaluation in fire has been published by Beck (1985), Fellinger and Both (2000), and Khorasani et al. (2012). Guo et al. (2013) used Monte Carlo simulations to create a reliability-based design methodology. Guo et al. (2013) expressed all of uncertain parameters as random vectors in the reliability analysis. De Sanctis et al. (2011) developed a risk-based methodology for decision-making and representing the physical processes of a fire hazard by using a Bayesian probability network. By using first- and second-order reliability methods (FORM/SORM), a probabilistic approach to fire safety assessment and optimal design of passive fire protection on offshore topside structures is developed by Shetty et al. (1998). Hamilton (2011) Lange et al. (2014) adapted the earthquake framework, which is developed by The Pacific Earthquake Engineering Research (PEER) to structural fire engineering.

A probabilistic methodology is presented in this paper obtained by following the framework of Lange et al. (2014). The framework which is inspired by PEER's earthquake framework involves three main categories: hazard domain, structural response and loss domain, and each of these domains include random variables such as maximum fire temperature, deflection, strength and damage of structural components, however, compartment sizes expressed as deterministic. This paper illustrates a probabilistic risk assessment of high-rise buildings in case of a fire event in the light of the framework of Lange et al. (2014) by taking the maximum fire temperature as the intensity measure and also adding another level of uncertainty in the compartment sizes.

METHODOLOGY

Case Study

As a case study, a compartment by 9.5 m and 6 m from a tall steel building in Istanbul, Turkey is investigated as illustrated in Fig. 1. The 28-story tall steel building has a rather slender design with large-span compartments, and hence, it is an interesting case for structural fire safety. The steel building is designated as an office building. The compartment is designed a steel-framed (composite) floor, which consists of 120mm thick concrete slab with steel mesh reinforcement, four HE400A edge beams and two IPE330 secondary (internal) beams, which are connected to the edge beams with single plate bolted shear connections as denoted by blue circles in Fig. 1. The compartment is assumed to have 3.5m floor height, 1.5m window height (h_w) and 14.25m^2 area of opening (A_w), which gives the maximum opening factor as $F_{v,max} = 0.078\sqrt{m}$. For simplicity, all the boundaries of the compartment (walls, floor and ceiling) are taken as concrete with density ρ=2300 kg/m^3, conductivity k=1.5 W/mK and specific heat c_p=1000 J/kgK. A medium fire growth is assumed for the compartment.

Hazard Domain

The objective of this study is to estimate the fire hazard curve of a typical office-building compartment. There are several measures of the fire intensity such as the fire duration, the peak (maximum) temperature, the rate of heating and heat flux. As a preliminary step, the maximum temperature is taken as the intensity measure in the paper. For the calculation of the fire temperature-time history curve, the Eurocode parametric fire curve method is used (CEN, 2002).

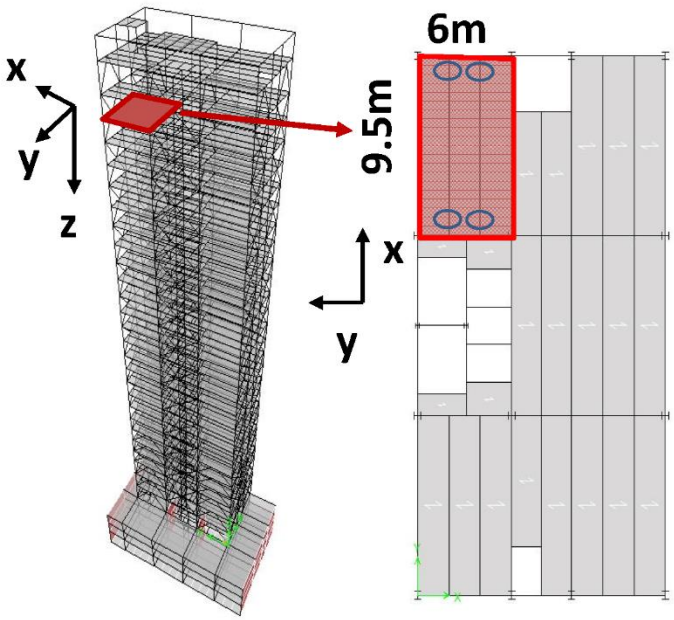

Fig. 1. Case study: (a) 28-story tall steel building and (b) the compartment floor layout.

Fire accidents and fire tests have shown that the thermal model is the most critical stage in the calculation of the temperature reached in a steel member, because, provided the heating rate of the steel member is accurately known, most mechanical models will predict similar deformation characteristics (Kay et al. 1996). There are number of factors for fire intensity measure. Recent papers have been considered duration of burning as fire intensity, however it is discovered that duration of burning is not adequate, fire severity may be a better option to measure intensity of fire. Fire severity can be expressed in terms of parameters such as rate of increase in the temperature in a compartment, duration of the steady burning phase, or peak temperature, heat flux, etc (Lange, 2014). In this study, the peak temperatures from Eurocode parametric fire curve (CEN 2002) are considered. This parametric fire curve gives different time-temperature relationship for a given compartment size, lining materials (e.g. concrete, gypsum wall, brick) and the ventilation openings. The fire is assumed to be a post-flashover fire, which is critical for the structural members. The fire could be ventilation or fire controlled.

RESULTS AND DISCUSSIONS

A Matlab code is written to generate the random variables and to calculate the fire curves according to the Eurocode parametric fire method. The code also checks for ventilation and fuel controlled fire. If the burning period is less than t_{lim} = 20 minutes (medium fire growth), the duration of the heating phase is set to t_{lim}.

Although the specific compartment sizes (9.5m by 6m) are taken, the dimensions are varied by Normal distribution (Eq. 1) using 9.5m and 6m as mean (μ) values, respectively. For both long and short dimension, the same scale factor σ= 3m is used. This scale factor is hypothetical. The goal is to generate a large variation in compartment sizes. The compartment size distributions are shown in Fig. 1. Due to computer speed and memory limitations, 100 samples of each size dimensions are randomly generated. For each sample, the maximum temperature probability density function calculated as described in the following paragraphs.

$$p(compartment\ dimensions) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(x-\mu)^2}{2\sigma^2}} \quad (1)$$

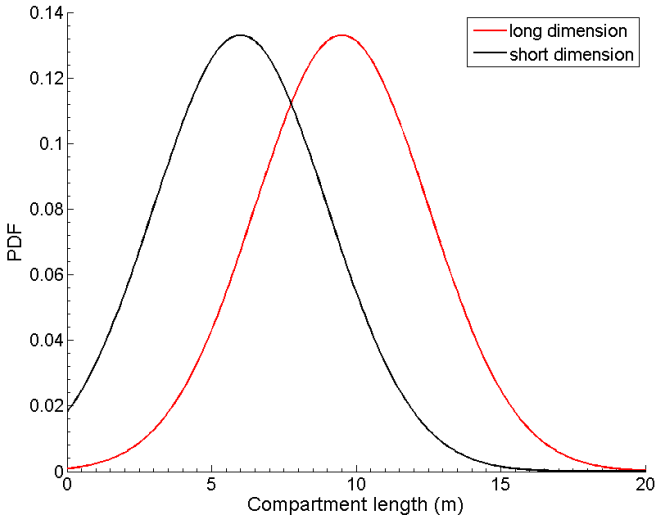

Fig 1. The probability density function of the compartment sizes as Normal distribution.

In Eurocode parametric fire curve method, the characteristic fire load density on the compartment floor (q_k – MJ/m^2) is taken as a random variable and 10,000 samples are generated. The design fire load (q_d) as suggested by Eurocode 1 (CEN 2002) is not used and the effect of the active fire measures are considered when calculating the annual rate of occurrence of fire in later sections. As suggested by Eurocode, the probability density function for the fire load in an office building is taken as Gumbel distribution as in Eq. 2 with mean (μ) of 420 MJ/m^2 and standard deviation (σ) as 126 MJ/m^2, which gives 511 MJ/m^2 as 80% fractile. Table 1 shows the fire load densities for different building categories. Fig. 2 shows the probability density function of the fire load (q_k). The randomly generated numbers are superimposed on the plot.

$$p(q_k) = {}^{1}/_{\sigma}\, e^{-(z+e^{-z})} \qquad (2)$$

$$where\ z = {}^{(x-\mu)}/_{\sigma}$$

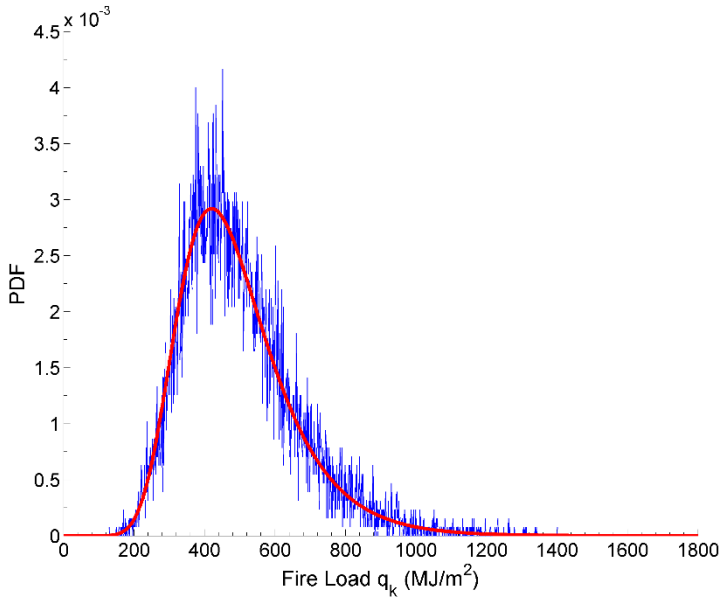

Fig 2. The probability density function and histogram of the fire load as Gumbel distribution.

The opening (ventilation) factor F_v ($\sqrt{m}$) is taken as a random variable and 10,000 samples are generated. The maximum opening factor $F_{v,max}$ is taken as constant, which depends on the given window areas in the compartment. However, the actual opening factor F_v is varied with ξ as shown in Eq. 3 suggested by Joint Committee on Structural Safety (CEN 2002).

$$F_v = (1 - \xi)F_{v,max} \tag{3}$$

The probability density function for the opening factor is taken as Log-Normal distribution with mean (μ) 0.2 $\sqrt{m}$ and standard deviation (σ) 0.2 $\sqrt{m}$. The distribution is truncated at 1.0, since the value of F_v cannot be negative. The associated μ and σ for the normal distribution are -1.956 and 0.833, respectively. Fig. 3 shows the probability density function of the variation in the opening factor load (ξ). The randomly generated numbers are superimposed on the plot.

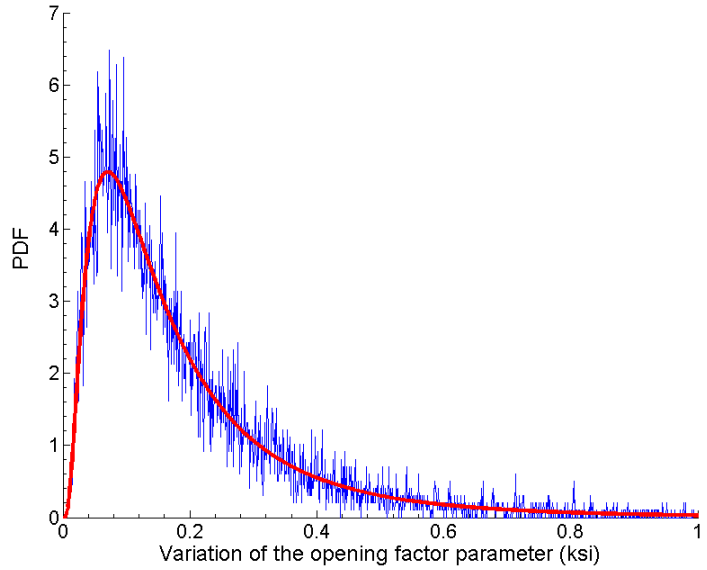

Fig 3. The probability density function and histogram of the variation in the opening factor as Log-Normal distribution.

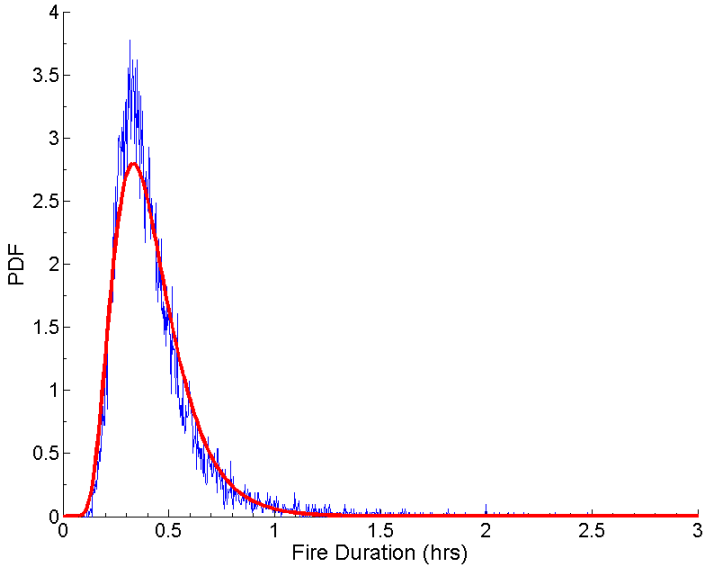

Fig 4. The probability density function and histogram of the fire duration as Log-Normal distribution.

With random sampling techniques using the fire load and the opening factor, the probability density function of the fire duration is created as seen in Fig. 4, which has a shape of Log-Normal distribution with mean (μ) 0.42 and standard deviation (σ) 0.03. By knowing the distribution of the fire duration, the maximum temperatures are readily calculated. As in Fig. 5a, the probability distribution function of the maximum temperatures resembles the Normal distribution with mean (μ) 802 ºC and standard deviation (σ) 54.6 ºC. The annual rate of exceedance of the maximum temperature in this compartment is found by multiplying the annual rate of occurrence in an office building (r_{fi}) with [1-P(T_{max})], where P(T_{max}) is the cumulative distribution function of the maximum temperature distribution as shown in Fig. 5a. The annual rate of exceedance r_{fi} is calculated according to Natural Fire Safety Concept (Schleich 2001) given in Eq. 4. Eq. 4 gives the annual rate of exceedance per m^2 floor size.

$$r_{fi} = p_1 . p_2 . p_3 . p_4 \tag{4}$$

Here, the p values are probabilistic measures, which depend on the active fire mechanisms such as building occupancy category (p_1= 4x10^{-7}) fire brigades (p_2 =1.0), smoke alarms (p_3 = 0.0625) and sprinklers (p_4=1.0) as suggested by Lange et al. (2014). Fig. 5b shows the corresponding hazard curve of the probability of exceeding a given maximum temperature in the compartment. The probability that a fire (with flashover) will break out in the compartment is 5x10^{-8}. If the fire breaks out, the probability that the maximum fire temperature in the compartment is greater than 650 °C is 1.0, which might be a critical temperatures for the load-bearing structural members. However, maximum temperatures greater than 900 °C is unlikely to occur.

If the compartment sizes are varied as shown in Fig. 1, the probability density function of the maximum temperature in the compartment slightly shifts to the left and its standard deviation gets larger when compared to the curve with determinate compartment size. The probability density function with randomized compartment sizes fits to a Normal distribution with mean (μ) 781°C and standard deviation (σ) 83°C as shown in Fig. 6. The corresponding hazard curve is shown in Fig. 7. The annual rate of occurrence r_{fi} (per m^2 floor size) is taken constant as previously suggested. The hazard curve suggests that given the fire breaks out, as low as 600 °C and as high as 1000 °C maximum temperatures are expected. The comparison suggests that in case of a post-flashover fire, the compartment is likely to have lower temperatures if the compartment sizes include some uncertainty. If the entire building is considered with total floor size of 13,200m^2, the annual rate of fire occurrence becomes 6.6x10^{-4}.

CONCLUSIONS

In this paper, a probabilistic approach to structural fire engineering is investigated. The study applies PEER performance based earthquake engineering framework for structures in fire. As a preliminary study, the paper only estimates the intensity measure, which is assumed to be the maximum fire temperatures in the compartment of a 28-story steel building. The results show that the annual rate of exceedance of maximum fire temperature T_{max} > 650 °C is $5x10^{-6}$ and the temperature T_{max} > 900 °C is very unlikely to occur. If the uncertainties in compartment sizes are also included in the analysis, it is observed that the annual rate of exceedance of maximum fire temperature T_{max} > 650 °C is $4.65x10^{-6}$ and the temperature T_{max} > 1000 °C is very unlikely to occur. This result suggests the probability of a very severe fire increases with the uncertainties in the compartment sizes.

Future work will expand this study in several ways. First, the intensity measure will be changed to steel or concrete mean section temperatures, since the structural response is better represented by the material's temperature rather than the fire temperature of the compartment. Next, the structural response of typical steel-framed composite floors will be estimated by considering the floor deflection as the engineering demand parameter.

ABSTRACT

Fire represents one of the most severe threats to the integrity of our built infrastructure. This study focuses on the effects of open-air hydrocarbon pool fires that may result from a tanker truck crash or sabotage since the quantity and flammability of its contents poses one of the worst-case hazards to a nearby bridge. In general, the calculation of a bridge's response to a vehicle-based fire hazard consists of four steps:(1) calculate the fire's characteristics and geometry; (2) calculate the heat transfer from the fire to the structural elements via radiation heat flux; (3) calculate the temperature increase of the structural elements; and (4) calculate the resulting material and mechanical response of the structural elements. The authors have developed a streamlined framework for efficient calculation of these steps which synthesizes numerous models based on both first principles and empirical data to quantify the extent of damage caused by a specified fire threat. Due to its efficiency, this approach can be used to calculate the effects of a range of fire types, sizes, and locations to develop an envelope of performance for which the risk of damage and the effectiveness of potential fire protection measures can be evaluated. The methodology is used to demonstrate the design process for determining fire protection on a cable-stayed bridge. This design example shows that explicitly modeling the fire, rather than using the UL 1709 fire curve, better quantifies the extent of fire effects and potentially reduces the required fire protection based on the available capacity.

KEYWORDS

Cable-stayed bridge, hydrocarbon fire, fire protection.

INTRODUCTION

Cable-stayed bridges have emerged as a popular structural form for many recent bridge construction projects, and a vehicle fire on the bridge deck poses a significant threat to the integrity of the stay cables. Several recent cable-stayed bridge projects have required the development of a Threat, Vulnerability, and Risk Assessment (TVRA) to determine design scenarios to mitigate the effects of blast and fire (Woodworth *et al*. 2015). For fire, these scenarios typically involve the specification of a tanker truck threat with a fuel type and volume – these scenarios apply for both accidental fires (due to vehicular collisions) and intentional fires (due to sabotage). The Post-Tensioning Institute (PTI) has included some considerations for fire resistance in Section 4.5 of their guideline document for the design of stay cables (PTI 2012), but there is a disconnect between these provisions and the typical TVRA fire threats. The PTI provisions are oriented toward the requirement of fire ratings based on standard fire tests in a qualified laboratory. Based on an owner's pre-established requirements for fire resistance, the stay cable assembly is subjected to a temperature time history that simulates a worst-case exposure to a hydrocarbon fire, similar to UL 1709 (UL 2011). The steel strands must demonstrate "fire endurance" of 30 minutes or greater, as determined by the time needed for the steel to reach 300°C. Also, the assembly is then tensioned to 45% of maximum ultimate tensile strength and heated to 300°C, and it must resist these conditions for at least 30 minutes. The PTI document does not provide guidance for calculating the extent of fire exposure or the resulting cable deterioration for realistic fire scenarios that are typically provided in a TVRA. Additionally, little guidance is provided in either the US (NFPA 2013) or European (CEN 2002) standards for the design of bridges to resist fire hazards.

This paper presents an engineering approach for calculating of the extent of fire exposure, the resulting degree of damage, and the required mitigation for stay cables due to a tanker truck fire on the deck of a long-span bridge. This study focuses on open-air hydrocarbon pool fires resulting from a tanker truck crash or sabotage

since the quantity and flammability of its contents poses one of the worst-case hazards to the bridge components. The calculation of a bridge's response to a vehicle-based fire hazard generally consists of four steps: (1) determine the fire's characteristics (e.g. footprint, flame height, duration, and intensity); (2) calculate the heat transfer from the fire to the structural elements; (3) calculate the temperature increase of the structural elements; and (4) calculate the material and mechanical response of the bridge structure.
Using this four-step approach, the authors have recently developed a streamlined framework for efficient calculation of a bridge's response to a large open-air hydrocarbon fire (typically 4 meters to 25 meters across) which results from a tanker truck crash (Quiel *et al*. 2015). The approach synthesizes numerous calculation techniques based on both first principles and empirical data to quantify the extent of damage caused by a specified fire threat. The geometry and intensity of the hydrocarbon fire are calculated based on the pool fire footprint and the fuel properties. Heat transfer to the structure is calculated using a modified discretized solid flame (MDSF) approach, and the resulting thermal response of the bridge's stay cables is then calculated using multiple lumped thermal masses. The model of the stay cable cross section accounts for the potential combustion of the HDPE pipe sheathing, which encases the bundle of steel strands. These temperature time histories are then used to calculate the corresponding structural response. Via this procedure, the proposed framework delivers a novel quantification of the spatial contour and time dependency of stay cable exposure to open-air hydrocarbon fires that result from tanker truck accidents.

Due to its efficiency, this approach can be used to calculate the effects of a wide range of fires sizes (for varying fuel spill footprints) and locations along the deck of a cable-stayed bridge. The results can be used to develop an envelope of performance for which the risk of damage and the effectiveness of potential fire protection measures can be evaluated. The proposed design framework is intended to be used as a tool to calculate the envelope of effects due to potential fire scenarios as they relate to the structural geometry, fire protection requirements, and the structural design of the system. The proposed design framework is not intended to be used as a substitute methodology for situations where a more detailed and computationally intensive approach (via finite element analysis and/or computational fluid dynamics) is warranted, such as in a forensic investigation. The proposed framework may be used as an initial assessment tool to help establish modeling boundaries for the more detailed model or to efficiently develop calculations for a wider range of scenarios. Using an example, the methodology is used to demonstrate the design process for determining the extent and amount of fire protection required for a cable-stayed bridge. This design example shows that explicitly modeling the fire, rather than using the UL 1709 standard fire curve, better quantifies the extent of fire effects and potentially reduces the required fire protection based on the available capacity.

BACKGROUND

Transportation infrastructure is susceptible to fire due to the constant presence of vehicle trafficand the potential for crashed or overturned vehicles and their contents to become fuel sources (especially semi-trucks hauling fuel and other flammable or combustible cargo). Tanker trucks hauling gasoline and diesel, which are common and necessary to meet our society's current transportation demands, have provided the fuel for most of the recent severe fire events involving bridge structures. To date, most bridge collapses due to tanker truck fires have involved common highway overpasses (typically supported by steel girders), which represent the majority of our bridge inventory (Garlock *et al*.2012; Wright *et al*. 2013). However, recent events have shown that long-span bridges (particularly signature or landmark bridges) have also been frequently susceptible to vehicle fires. Fire poses a greater hazard to a long-span bridge than an overpass due to elevated consequences of collapse, elevated impact of closure, and the difficulty of firefighting access. Table 1 summarizes several recent fire incidents for long span bridges in North America which involved burning vehicles. All of the incidents in Table 1 did not result in significant damage or collapse since the fires involved either passenger vehicles or semi-trucks carrying non-hazardous cargo. However, the incidents in Table 1underscore the potential for the occurrence of vehicle fires on the deck of a long-span bridge. Since most long-span bridges must accommodate the transport of fuel and other hazardous cargo, it is reasonable to expect that tanker truck fires similar to those that have caused the collapse of common overpass bridges are at least a statistically possible hazard that should be considered during design.

Few previous research studies have examined the effects of realistic hydrocarbon fires on cable-stayed bridges. Bennetts and Moinuddin (2009) examined the effect of a tanker truck gasoline fire on a simplified stay cable cross-section. In that study, the heat release rate for a tanker truck fire on the bridge deck was calculated using semi-empirical models to estimate the magnitude of maximum fire exposure, which was then applied to the stay cables as an equivalent surface temperature based on a peak heat flux from radiation and convection. The cross-section of the cables was thermally modeled using layered lumped masses to account for potential insulation and multiple layers of steel strand. The resulting deterioration of the cable strength was then evaluated. Woodworth

et al. (2015) used a CFD model to calculate the effects of a pool fire on a simplified stay cable assembly example. The results of these calculations provided a spatial distribution and severity of cable temperature increase due to fire exposure. In this study, significant simplifications were made regarding the cross-sectional calculation for the temperature increase in the steel cable, presumably due to the computational expense of the CFD approach.

Table 1Recent vehicle fire incidents on long-span bridges

Date	Name	Location	Type	Fire Source	Incident Outcome
March 2007	Mezcala Bridge	Guerrero, Mexico	Cable-Stayed	Tractor-Trailer	1 stay cable ruptured due to fire No collapse butextended closure
July 2009	Manhattan Bridge	New York, NY, USA	Suspension	Tractor-Trailer	Minor damage Partial temporary bridge closure
June 2012	Brooklyn Bridge	New York, NY, USA	Suspension	Passenger car	Minor damage Partial temporary bridge closure
August 2013	Queensboro Bridge	New York, NY, USA	Cantilevered Truss	Tractor-Trailer	Some damage to structural steel Partial temporary bridge closure
April 2014	Zakim Bridge	Boston, MA, USA	Cable-Stayed	Tractor-Trailer	Casing of 1 stay cable partially charred Partial temporary bridge closure

METHODOLOGY: A STREAMLINED SIMPLIFIED APPROACH

The methodology for this study implements the aforementioned four-step approach in a streamlined analytical framework - a complete, detailed description is available in Quiel *et al*. (2015).This approach is less computationally intensive than CFD solutions and allows for the pool fire to be rationally represented in the solution. By implementing the four-step approach, staff at Hinman Consulting Engineers, Inc.with researchers at Lehigh University have created FLaME (**F**ire **L**oading **a**nd **M**itigation**E**valuator), an in-house 3D modeling program that links the actual geometry of the structure with the realistic fire exposure. FLaME has been previously used to successfully model the mode and time to failure of the 2007 MacArthur Maze freeway collapse in Oakland, CA (Quiel *et al*. 2015) and has been implemented for several recent bridge design projects to calculate the fire protection requirements for stay cables and other steel bridge elements.

First, the hydrocarbon pool fire is modeled using analytical calculations of the fire characteristics (e.g. flame height, heat release rate, duration, and radiative intensity) based on idealized semi-empirical combustion models. The results of these models can then be used to calculate radiation heat transfer from the fire to the structural elements. For open-air (i.e. unconfined) pool fires of this size, radiation is the dominant heat transfer mode and the effects of convection can therefore be neglected (Babrauskas 1983). Once the heat release rate (Babrauskas 2008) and height (Heskestad 2008) of the fire are calculated for the given fuel type, fuel quantity, and pool size, the fire can be represented with a solid flame model (i.e. a radiation-emitting 3D object with the shape of a cylinder, rectangular box, or other irregular trapezoidal or conical shapes) which can be used to calculate heat transfer to structural elements. The solid flame surfaces are discretized into rectangular elements, each of which emits radiation toward potential targets. Calculating the summation of radiation heat flux from the discretized fire surface elements allows the user to choose varying fire footprint sizes and shapes, as well as assign varying distributions of thermal emissivity from each vertical zone of the fire. The temperature of the structural elements can then be calculated using a multiple lumped mass approach, and the resulting structural response due to the temperature increase can be evaluated.

Step 1: Modelling the Hydrocarbon Pool Fire

To calculate the fire's characteristics, the user must first select the fuel type and volume as well as the footprint (shape and dimensions) of the pool resulting from the fuel spilling from the tanker truck. Variables to consider include the assumed rate of spill, the slope of the roadway, the presence of drainage, etc. For many fuel spills, a rectangular or trapezoidal footprint will account for sloping pavement in either one or two directions, respectively. For simplification, the footprint discussed here will focus on a rectangular shape. Most of the semi-empirical equations for calculating pool fire characteristics are based on the circular pool shape – similar expressions for non-circular pool fires are not widely available. The pool fire diameter, D_f, is a required variable for most semi-empirical calculations, and therefore an equivalent value $D_{f,eff}$ can be calculated using a circle

with the same area as the rectangular footprint. For pool fire footprints with an approximate aspect ratio (long edge to short edge) greater than two, the $D_{f,eff}$ is calculated using a limited area with dimensions of the short edge length by two times the short edge length from the full footprint. $D_{f,eff}$ for areas with aspect ratios greater than 2.5 may lead to inaccuracy when using the circle-based semi-empirical equations (McGrattan *et al*. 2000). Once the maximum heat release rate (HRR) is calculated (Babrauskas 2008), flameheights are calculated using semi-empirical expressions such as those developed by Heskestad (1983) (for no-wind conditions only) or Thomas (1962) (which can accommodate wind tilt).The duration of the pool fire, t_b (sec), can be calculated as the time needed to consume all available fuel over the pool area based on the fuel's mass loss rate, $\dot{m}$", and density, ρ (kg/m^3). A simplified approach to assembling the pool fire's HRR time history would be to assume a constant HRR over the duration t_b. In order to account for a realistic rapid increase of heat release as well as a decay phase, the proposed approach implements a time history model similar to that used for tunnel design fires (Ingason 2006). The time of fire growth, t_g, is taken as the minimum of t_b/5 or 10 minutes, and the HRRexperiences a quadratic increase. The time of fire decay, t_d, is taken as the minimum of of t_b/2.5 or 20 minutes, and the HRR experiences exponential decay.

Step 2: Modelling the Heat Transfer from the Pool Fire to the Stay Cables

The solid flame model with the assumed footprint and calculated height $H_f$is discretized into n total rectangular elements that each emit radiation heat flux. Gasoline and diesel, which together constitute a large portion of overall truck-transported fuel, produce a large amount of soot and smoke during their combustion and develop a vertical fire structure with two zones: the luminous zone (i.e. unobscured flame region) and the smoke-obscured upper region (McGrattan *et al*. 2000). The two-zone characteristic of pool fires involving high-soot yielding fuels has been well established in several recent experimental studies (Munoz *et al*. 2007).Each surface i is assigned an emissive power, E_i(kW/m^2) based on its location in either the luminous zone or the smoke zone. For this study, the luminous zone is modeled as the lower half of the solid flame model, which is conservatively consistent with an experimental study of gasoline and diesel pool fires by Munoz *et al*.(2007). Though several semi-empirical formulas are available to quantify the emissive power of a pool fire's flames and smoke, values of E_{flame} = 100 kW/m^2 and E_{smoke} = 40 kW/m^2 are used for this study, again in accordance with the study of Munoz *et al*. (2007).The radiation heat flux imparted to a target j, $\dot{q}''_j$(kW/m^2), which is located outside the pool fire (i.e. the target is not enveloped by the solid flame model) can be calculated as the summation of each discretized fire surface's emissivity times the view factor from that surface to the target, $F_{i\rightarrow j}$ (dimensionless):

$$\dot{q}_j^{''} = \sum_{i=1}^{n} E_i F_{i\rightarrow j} = \sum_{i=1}^{n} E_i \frac{A_i \cos\theta_i \cos\theta_j}{\pi r_{i\rightarrow j}^2} \qquad [1]$$

where $F_{i\rightarrow j}$ accounts for the area of the fire surface, A_i(m^2); the standoff between the fire surface and the target, $r_{i\rightarrow j}$(m); the absolute angle between that standoff vector and the fire element's normal vector, θ_i; and the absolute angle between the standoff vector and the target's normal vector, θ_j. Fire surfaces that have no "view" of the targets outside the pool fire impart no radiation heat flux.

Step 3: Modelling the Thermal Response of the Stay Cables

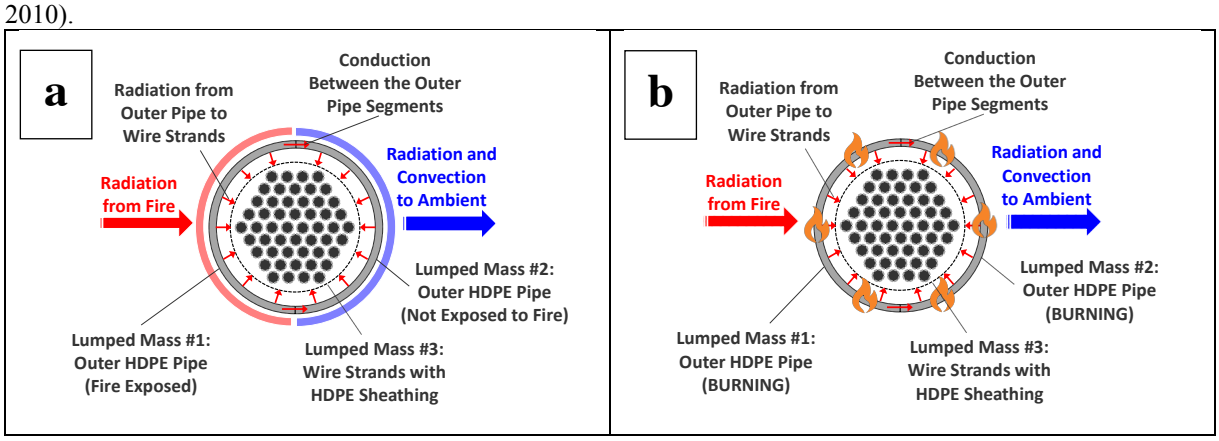
Having obtained the radiation heat flux for each target, the increase in the target's temperature can be calculated using a lumped mass approach. This paper will focus on the calculation of the temperature increase of the stay cables since they provide the primary structural support to this bridge type. Stay cables are represented as lumped mass line elements that are discretized along their lengths into multiple targets for which lumped mass heat transfer is calculated. When calculating θ_j for a line element representing a cable, the normal vector for the line is assumed to be perpendicular to the line element and lies in the same plane as the cable line and the standoff vector between the target j and the radiation-emitting fire surface i. Each stay cable is discretized into elements with no more than a 1-meter length. The cross-section of the stay cable consists of a bundle of 7-wire strands that are encased by a high-density polyethylene (HDPE) pipe, and each strand is sheathed in a thin HDPE sleeve. As shown in Fig. 1a, the cross-section of each element is represented with three lumped masses: (1) the fire-exposed portion of the outer HDPE pipe, (2) the non-fire exposed portion of the outer HDPE pipe, and (3) the bundle of steel strands. For this study, it is assumed that lumped masses #1 and #2 each comprise half of the outer HDPE pipe. The outer HDPE pipe can be modeled both as unprotected or as insulated with fire protection using the same lumped mass approach as that used for insulated steel sections (Buchanan 2002).

Fig. 1 illustrates the stay cable cross-section as it begins to deteriorate due to fire exposure. In Fig. 1a, lumped mass #1 is heated by the fire's radiation, increasing its temperature. Lumped mass #1 subsequently heats lumped mass #2 via conduction along the pipe and via some internal radiation around the strand bundle. It is

assumed for the stay cables in this study that 20% of the radiation emitted by the interior face of lumped mass #1 is transmitted to the interior face of lumped mass #2. This percentage accounts for the radiation that is transmitted around the wire strand bundle through the air gap between it and the outer HDPE pipe. Lumped mass #2 is also cooled via natural convection and radiation to the ambient environment. Lumped mass #3 isheated via 80% of the total radiation emitted from the interior faces of the two lumped masses that comprise the outer HDPE pipe. When encased by the outer HDPE pipe, the wire bundle does not experience any ambient cooling – when the fire ends, it will cool by transmitting radiation back to the outer HDPE pipe as the pipe experiences ambient cooling.

The HDPE is a flammable material and, when heated, will begin to burn when its temperature exceeds 400°C and its surface experiences a critical radiation heat flux greater than 15 kW/m^2 in accordance with HDPE material data in the SFPE Handbook (Tewarson 2008). When this occurs, the section model transitions to that shown in Fig. 1b, which accounts for the combustion of the outer HDPE pipe. For unprotected cables, the outer face of the fire-exposed lumped mass #1 will experience these conditions first due to the direct radiation from the fire. For protected cables, lumped mass #1 is shielded from direct radiation from the fire – it will therefore begin to melt due to its temperature increase rather than burning due to the lack of critical heat flux. Lumped mass #2, however, experiences both a temperature increase as well as radiation on its interior face from lumped mass #1 and can eventually meet the conditions for combustion. In either case, it is assumed that if either lumped mass #1 or #2 starts to combust that both will burn simultaneously. When burning, an additional 61 kW/m^2 of direct flame radiation heat flux is applied to lumped masses #1 and #2 (minus a re-radiation of 15 kW/m^2 to the ambient environment), and their mass is reduced according to HDPE's published mass loss rate (Tewarson 2008). As the outer HDPE rapidly heats due to direct flame radiation, the strands in lumped mass #3 subsequently experience an increase in radiation. The large resulting temperature increase in lumped mass #3 eventually produces the conditions needed to trigger the combustion of the HDPE sleeves around the wire strands. As shown in Fig. 1c, the thin HDPE strand sheaths will combust rapidly and also apply an additional 61 kW/m^2 of direct flame radiation heat flux to the steel strands in lumped mass #3. Note that additional combustion of the grease or other lubricant within each strand's HDPE sheath is not considered. HDPE combustion progresses rapidly (usually taking 10-15 minutes to "burn off") until only the wire strands remain as shown in Fig. 1d. The fire radiation is then applied directly to the fire-exposed face of the strand bundle's approximate circumference, and the unexposed face is cooled via natural convection and radiation to the ambient environment.

The total heat transfer for the steel strands in each element along the length of the cable accounts for both the cross-sectional model shown in Figs. 1a through 1d as well as conduction between adjacent elements of along the cable length. Thermal conductivity, k (W/m-K), in the steel strands is temperature dependent and is calculated as an average value based on the temperature of the two adjacent elements. It is assumed that the cross-sectional areaand length of each elements are uniform along the length of the beam. The total heat transfer can then be used to calculate the temperature increase of the steel strands by accounting for material volume, density, and specific heat of the steel in that element. When making these calculations, all thermally dependent properties are calculated with a one-time-step lag (at t-1) – this approach has been used effectively for time steps of no more than one minute in previous lumped mass heat transfer studies (Quiel and Garlock 2010).



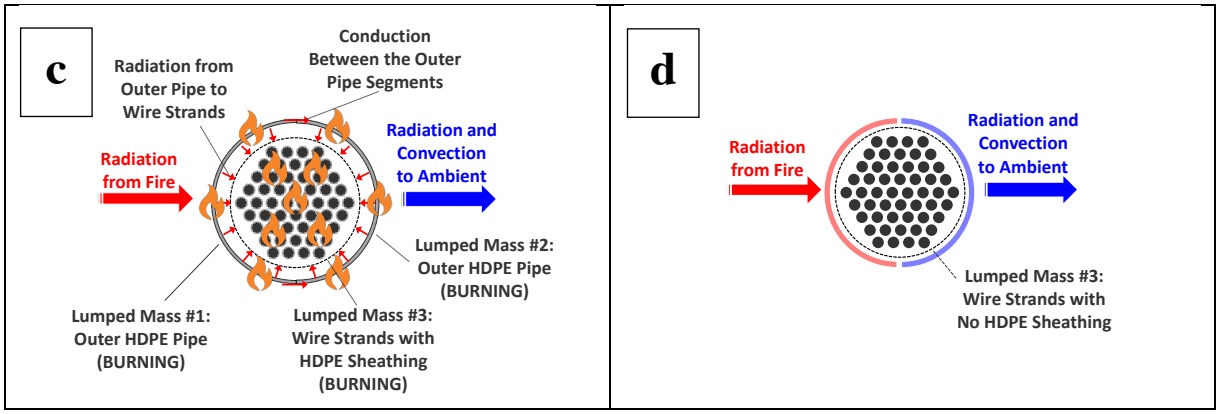


Figure 1- Four-step sequence (**a** through **d**) of HDPE combustion in the stay cable cross-section

Step 4: Modelling the Structural Response of the Stay Cable

The temperature change of the steel wire bundle in each cable element can be used to calculate the corresponding decrease in material strength and stiffness as well as thermal expansion. Time histories of these responses can then be used to evaluate structural behavior either via simple demand-vs-capacity comparisons or by mapping the results to a structural finite element model. In this paper, a design example will be examined using the calculated decrease of yield strength as a simplified indicator of potential collapse. Future research by the authors will examine the consequences of load redistribution in bridge structures due to the calculated effects of fire exposure that are obtained from this framework. The material deterioration model for cold-drawn steel wire according to Hertz (2004) is used for this study.

DESIGN EXAMPLE

The methodology outlined above is implemented for a case study of a generic prototype cable-stayed bridge shown in Fig. 2. The bridge spans 183 meters (600 feet) from the centreline of the concrete tower to the end of the longest cable, and two vertical planes of cables are attached to the edge of the deck at equidistant 12-meter (40-foot) spacing. Only one tower of the bridge is shown for simplicity, and the spans and cable layout on either side of the tower are symmetric. The deck is 30.5 meters (100 feet) wide and is assumed to accommodate two lanes of traffic plus a shoulder in both directions. The deck has a 2% lateral grade (cresting at it longitudinal centreline) and 1% longitudinal grade. The number of steel 7-wire strands increases from the shortest to the longest cable from 30 to 45 to 60 strands in groups of five each. The outer HDPE pipe has a slightly larger diameter for larger numbers of strands, ranging from 209 mm (9 inches) to 305 mm (12 inches). The outer HDPE pipe has a thickness of 8 mm (5/16inches), and the HDPE strand sleeves are 2 mm (1/16 inches) thick. It is assumed that the service load level for each stay cable at the time the fire starts is 50% MUTC, which is conservatively consistent with the recommended load level (45% MUTC) in the PTI testing protocol for stay cables under fire (PTI 2012).

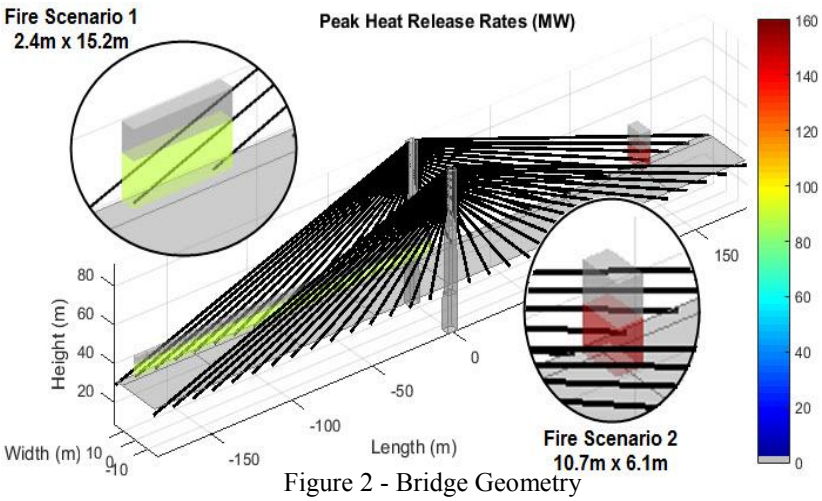

Figure 2 - Bridge Geometry

The design basis fire threat considered for this study is that of a tanker truck hauling 34000 liters (9000 gallons) of gasoline. The hazard scenario presumes that the tanker truck is involved in an accident or is sabotaged on the bridge deck, after which its contents start to combust.It is possible that the tanker truck fire could occur at any location along the length or width of the bridge. It is also possible that the fuel will either stay approximately contained within the tanker as it burns or spill onto the roadway as it leaks from the tanker. Due to the slope of the roadway, the spilled fuel will flow both laterally and longitudinally, with some percentage of its leaked

volume potentially draining into the nearby scuppers before it combusts. The potential for drainage of leaked fuel will be governed by the flow rate of fuel from the truck, the spacing and proximity of the scuppers, and the rate of fuel consumption by the fire.

Pool Fire Footprint: Controlling Cases

To simulate a realistic hazard scenario, the user must account for the significant uncertainty in the parameters regarding the location, footprint, and available fuel of the tanker truck fire. In practice, analysis could be performed to obtain estimates for the percentage of available fuel depending on the scupper design and placement relative to a range of fuel leak rates and fire locations. For this study, two hazard scenarios are considered as potentially controlling cases for fire severity and size:

(1) The fuel remains within the tanker, resulting in 100% consumption in an area approximately equal to the footprint of the tanker (50 feet long by 8 feet wide with its base at an 8-foot height). For this scenario, it is conservatively assumed the tanker is located in the shoulder (i.e. at the location nearest the cables).
(2) A moderate leak from the tanker, which is located in the left lane, allows the fuel to spill onto the roadway. The fuel will flow both laterally and longitudinally but will favor the larger lateral grade toward the curb. It is assumed that the leakage flow rate is larger than the fire's fuel consumption rate such that 25% of the total fuel volume will reach the curb and is drained from the area via the scuppers before it can be consumed. Though the actual shape of the fuel spill will be somewhat trapezoidal, the spill footprint for this scenario is simply representedas rectangular, spanning 35 feet laterally over both lanes and the shoulder as well as 20 feet longitudinally.

The spill footprint parameters of each fire scenario provide bounding cases for fire exposure and duration. The longer, thinner footprint of Scenario 1 (with a smaller overall area) provides greater exposure to a larger number of cables along the length of the bridge and will result in a longer fire duration than Scenario 2. Note that the HRR and fire height in Scenario 1 will be capped according to the aforementioned 2:1 aspect ratio provision. With a larger fire footprint and an aspect ratio less than two, Scenario 2 provides a larger fire height and a more severe HRR. Though the fire in Scenario 2 will be shorter in duration, it will have higher intensity and potentially affect more cables where they are significantly inclined (such as locations furthest from the towers) due to the increased fire height.The HRR time histories for both fire scenarios are plotted in Fig. 3.

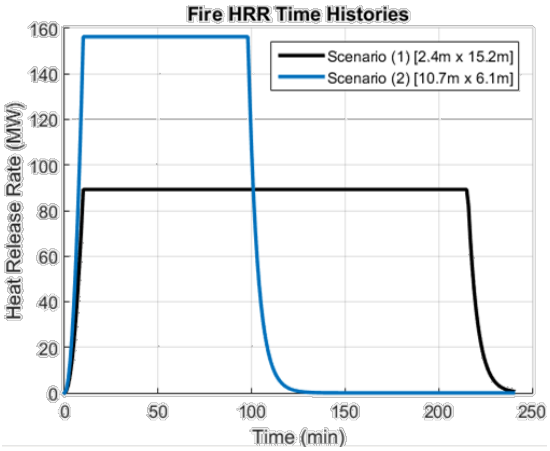

Figure 3 - Heat release rates for Scenarios 1 and 2

Determining the Extent and Amount of Mitigation

Acceptance criteria for fire-exposed performance must first be established before the extent and amount of stay cable fire protection needed to mitigate the effects of these fire scenarios can be determined. Based on the assumed service load for each stay cable, "failure" of a cable for this bridge is assumed when the 2% yield strength for cold drawn steel strand according to Hertz (2004) is reduced to 50% MUTC. Current stay cable bridges are typically designed with adequate redundancy to withstand the loss (i.e. "failure") of at least one stay cable (Zoli and Steinhouse 2008). This study will therefore consider the "failure" of two or more cables due to any fire scenario to produce an unacceptably high potential for total and/or progressive collapse of the bridge. For some cases, however, it may not be possible to provide a reasonably constructible amount of fire protection to prevent more than two cables from failing. For this study, it is assumed that firefighting efforts will be able to respond to the fire within 50 minutes of its ignition – if no more than one cable fails within the first 50 minutes of the fire duration, then the mitigation scheme will be considered to have successfully resisted that fire scenario.

To determine the required extent and amount of fire protection, the two aforementioned scenarios were analysed for a suite of locations along the length of the bridge. For the initial phase of analysis, the stay cables were modelled as unprotected. The fire was placed along the length of the bridge at 7.6-meter (25-foot) increments (Fig. 2).A critical fire location is selected based on the spatial distribution of the peak heat flux on the cables and their resulting strength loss. For the scenario 1 and scenario 2, the critical location is determined to be 137meters (450feet) and 130 meters (425 feet), respectively, from the tower (Fig. 4). Time histories of the heat flux

experienced by the stay cable as well as the resulting temperature increase and strength decrease are shown in Figs. 6 through 8 for the most severely affected cables in each case. These plots show a different spatial distribution and intensity of fire effects between the two scenarios, emphasizing the need for parametric analysis to determine the controlling locations and scenarios for the tanker truck fire on the bridge deck. A rapid burst of temperature increase (and corresponding strength decrease) is shown for the steel strand bundles in both fire scenarios during the rapid combustion of both the outer HDPE pipe and the HDPE strand sheaths (see Figs. 1b and 1c).

A closer look at the maximum height of 50% strength loss for all cables helps determine how high the cable protection must to reach to achieve the design objective. By allowing the loss of a single cable for any fire scenario, the critical protection height is governed by the cable that has a 50% strength reduction at the second highest elevation. For scenarios 1 and 2, this location occurs at 12.2 meters (40 feet) and 14.3 meters (47 feet), respectively, above the road surface.

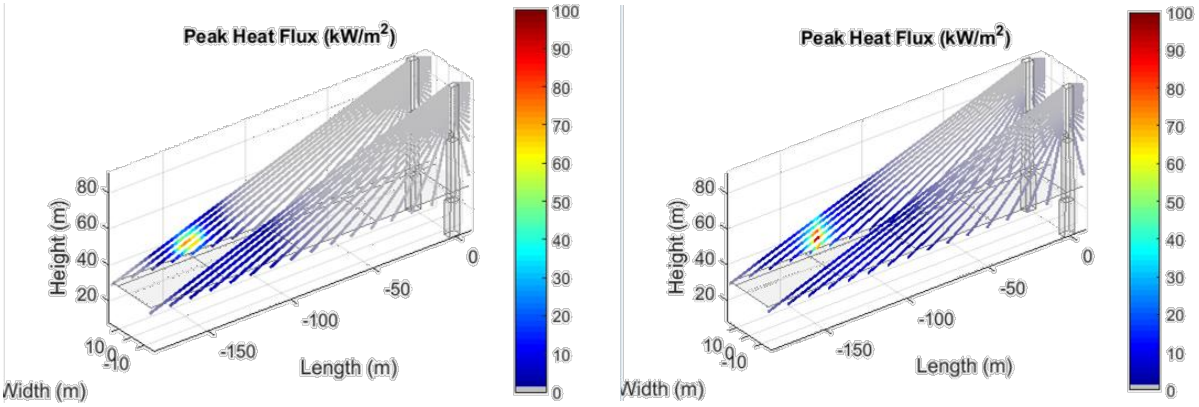

Figure 4 – Peak heat flux for Scenario 1 (L) and Scenario 2 (R)

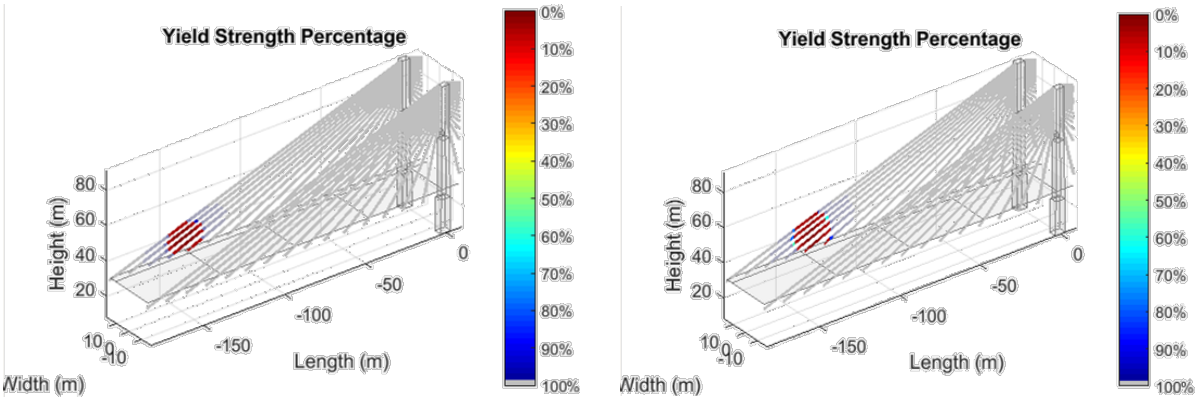

Figure 5–Resulting strength reductions for Scenario 1 (L) and Scenario 2 (R)

Subsequent suites of analyses were then performed to show the effects of aselected mitigation strategy. For these analyses, fire protection was applied to the exterior face of the outer HDPE pipe over a specified height of each cable (upward from the deck) to meet the aforementioned performance conditions. Fire resistance is based on the thicknesses of a commercially available spray-applied fire resistive material (SFRM) (Isolatek International 2015). As a simplification, the SFRM is modelled as having constant material properties (i.e. not as a function of temperature) using published values at room temperature. Note that SFRM is not an appropriate material for use on stay cables due to its high vulnerability to weathering and vibration, and other technologies such as concrete or steel encasement and intumescent paint would be realistically implemented to provide stay-cable fire protection. However, many of these technologies are proprietary, and material properties may be obtained only on a project-to-project basis. Rather, SFRM is used here to calculate a representative fire protection benchmark. SFRM thermal properties are publicly available for comparison, their performance can be easily correlated to prescriptive fire ratings, and analytical calculations for determining their fire resistance are well established (Buchanan 2002).

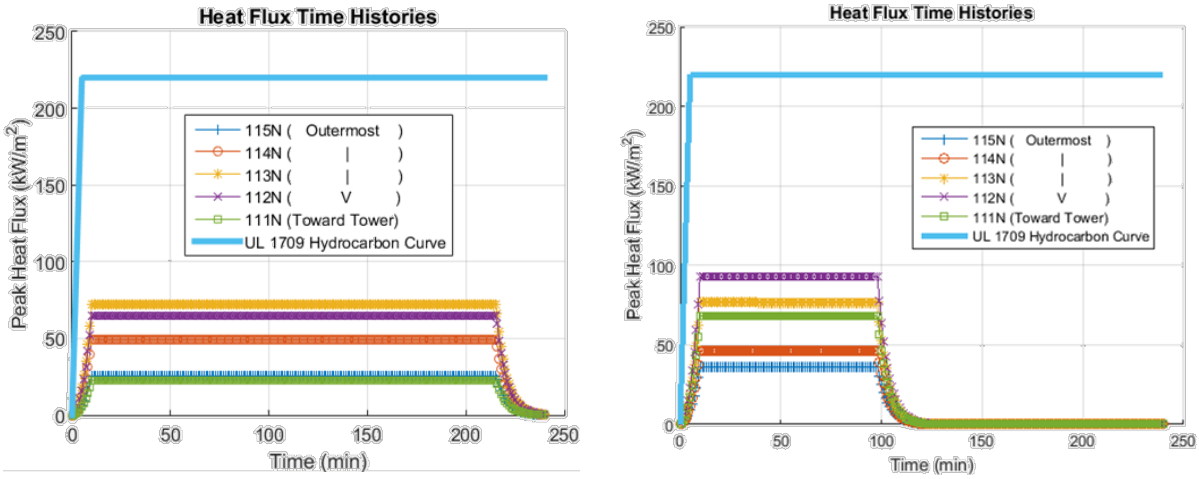

Figure 6 - Heat flux time histories for Scenario 1 (L) and Scenario 2 (R)

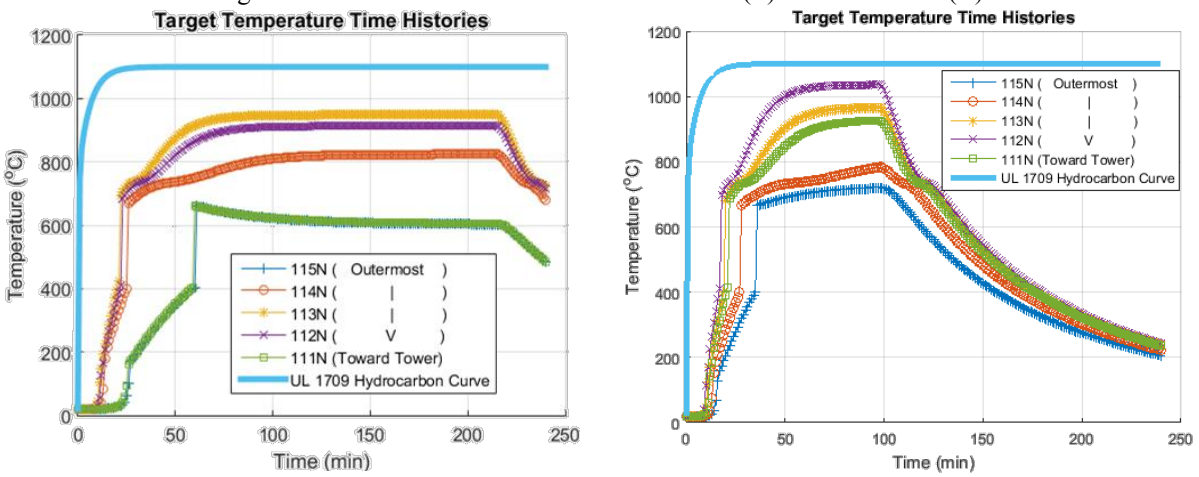

Figure 7 - Temperature time histories for Scenario 1 (L) and Scenario 2 (R)

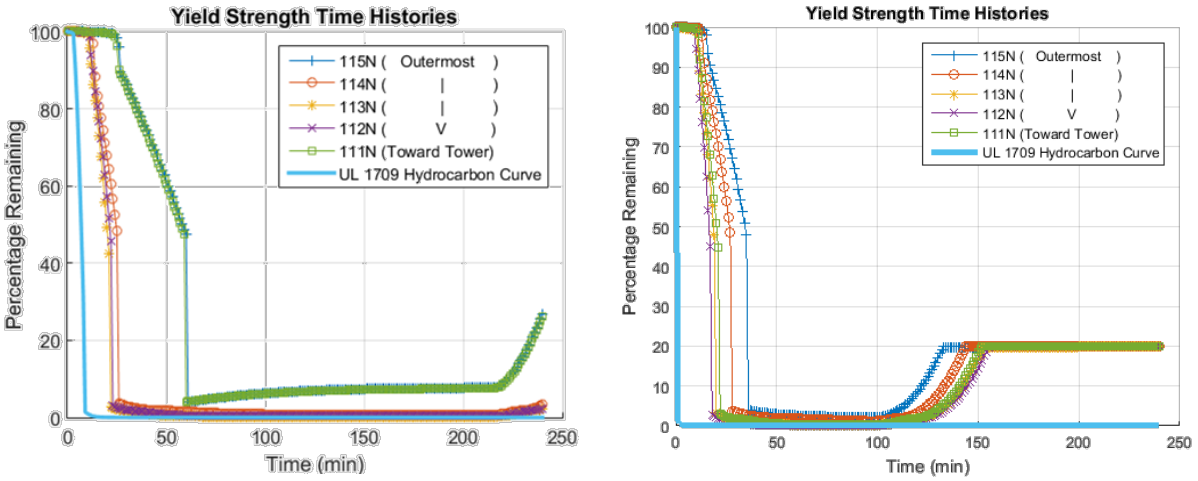

Figure 8 - Strength reduction time histories for Scenario 1(L) and Scenario 2 (R)

Fig. 9 shows the yield strength time history with fire protection applied on the second most critical cable for scenario 2. Note again that the most critical cable can be neglected because a single cable failure is acceptable. The cures in Fig. 9 show that the fire mitigation can delay the degradation of the steel strength for the critical second cable past the 50-minute mark, and meet the performance criteria set forth previously.

Comparisons with the UL 1709 Standard Fire

The UL 1709 hydrocarbon fire curve is typically used to obtain fire resistance ratings for a variety of construction products. UL 1709 has been referenced by bridge projects as the design fire load as a worst-case approximation. A major drawback in using the hydrocarbon curve is that it cannot be used to calculate the spatial distribution of fire effects nor the realistic variation in the magnitude of heat transfer to the structure. As shown in Figs. 6 thru 8, the UL 1709 curve provides a conservative time history for all cables for the scenarios examined; however, this high exposure magnitude may be overly conservative for most cases.

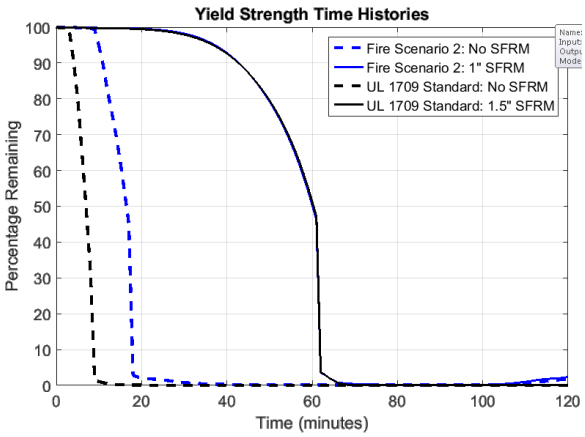

Figure 9 - Strength reduction time histories for protected and unprotected cables under Scenario 2 and UL1709

The major mitigation and cost savings of explicit modelling result from the ability to model the spatial effects of the fire and by limiting the height to which the mitigation needs to be applied. Mitigation and cost savings are also achieved by reducing the required SFRM thickness, as shown in Fig. 9.When the fire is explicitly modelled via the MDSF model, an SFRM thickness of 25 mm is needed to delay the failure of the second critical cable past 50 minutes, while the UL 1709 curve requires a thickness of 38 mm to achieve the same objective.

CONCLUSIONS

The authors have demonstrated the structural fire mitigation design process for a cable-stayed bridge by using a streamlined framework for calculating the effects of a tanker truck fire. Due to its efficiency, this approach was used to capture over 50 fire scenarios (2 fire footprints and 25 fire locations). Once the fire effects were enveloped and the governing design fire scenarios were identified, the spatial distribution of the fire protection as well as the thickness of fire protection were designed based on a set of performance criteria. The fire protection obtained via the streamlined framework was compared to the fire protection obtained using the UL1709 standard hydrocarbon fire curve. The results demonstrated that explicitly modeling the fire via the streamlined framework better quantifies the extent of fire effects on the cablesand reduces the required fire protection thickness.

ABSTRACT

The widespread use of structural timber in tall buildings is often inhibited because timber is a combustible material and is commonly perceived to behave poorly in fires. This research develops a simplified design approach for the fire performance of different types of prefabricated timber floors used in multi-storey buildings. The floor types under investigation include several different geometries of box-shaped and T-shaped timber floors made from Laminated Veneer Lumber (LVL). The investigations were carried out with numerical simulations and four experimental fire tests. A simplified design method to estimate the fire resistance of unprotected timber floor assemblies is proposed and calibrated against the numerical and experimental work. The method uses a bi-linear charring rate and the assumption of a zero strength layer in the timber. The method is compared to the experimental data from this research and others around the world, as well as charring rate methodologies from around the world.

KEYWORDS

Fire, timber, floors, furnace testing, design methods.

INTRODUCTION

Timber as a building material provides high levels of flexibility in terms of building design, and a freedom of architectural expression. It is aesthetically pleasing, making it an ideal material for use in environments where there is a desire to promote a sense of warmth and wellbeing, such as modern commercial and residential applications. As timber is also highly sustainable, it has distinct advantages over conventional building materials in an increasingly socially and environmentally conscious building environment. However as timber is combustible, the question of fire safety is paramount in the discussion of its application in large multi-storey buildings.

When considering the fire performance of timber structures in the built environment, restrictions are commonly placed on the allowable height of a building, to reduce the perceived risk of an unacceptable fire hazard stemming from the combustible nature of the material. This perceived risk can be broadly defined as the risk of catastrophic collapse or fire spread throughout the building and to other buildings, posing a threat to both the general public and property alike. This inhibits the widespread use of timber in large developments due to the perception of poor performance in fires. In reality, massive timber structures often exhibit excellent fire performance due to the inherent insulative properties of timber as a material. Timber assemblies have been demonstrated in the past to provide and maintain loadbearing and separating functions during prolonged periods of fire exposure. As many of the new timber technologies which are becoming prevalent in our markets have not yet been properly implemented into building codes, it is becoming increasingly important to provide evidence and guidance on their expected performance in fires to enable the correct use and implementation in the built environment.

Impetus of the Research

Floor systems provide the means for directly supporting the primary service loads of a building. In terms of fire, they also provide the separation between compartments. Most floors have large unprotected surfaces that are exposed to fires, and are thus regarded as critical elements in designing for the structural fire resistance. As timber is a combustible material its fire performance is complicated by the loss of its cross-section due to charring, the anisotropy of the material itself and the presence of connections. Thus adequate guidance and

design procedures are paramount to ensure that floor systems are appropriately designed and installed in modern buildings. In consideration of this, the impetus behind this research is to provide information and guidance on the estimation of fire resistance for standardised prefabricated timber floor assemblies used in multi-storey buildings. This work is based on experimental testing, numerical modelling, and studies of available design procedures to develop a simplified design method to estimate fire resistance of timber floors.

FLOOR TYPES STUDIED

The floor types under investigation include several different geometries of box-shaped and T-shaped timber floors made from Laminated Veneer Lumber (LVL), shown in Figure 1.

Figure 1 Illustration of composite box-shaped LVL floor (left) and composite T-shaped LVL floor (right)

The floors consist of LVL joists 200 mm to 600 mm deep, fixed to a continuous LVL slab system, with a fully rigid connection between the joists and slab components. Typically these floors range from 5 metres to 12 metres in length and are designed for normal service loads in office buildings and similar multi-storey buildings.

FURNACE TESTING

Floor Specimen Details

Four timber floor assemblies (two lightweight and two heavyweight variants) were tested in a full-scale furnace under controlled conditions at the Building Research Association of New Zealand (BRANZ), Wellington. These floors were sized to give approximately 30 and 90 minute fire resistance times, using generic LVL member sizes available from the manufacturer (Nelson Pine LVL 2012).

Specimens A and B were smaller T-shaped and box-shaped floors respectively, designed for 30 minutes fire resistance and 7 metre spans. Specimen A consisted of two 400 mm deep x 45 mm wide LVL joists glued in a pair under a 36 mm thick x 1200 mm wide cross-banded LVL slab. The joists were fixed together in pairs to reduce the area of timber exposed to fire thus increasing the expected fire resistance of the assembly. Specimen B consisted of a box section formed from 360 mm deep x 45 mm wide LVL joists and a 45 mm thick x 300 mm wide LVL bottom flange. This box section was fully fixed to a 36 mm thick x 1200 mm wide cross-banded LVL slab, similar to Specimen A.

Specimens C and D were larger T-shaped and box-shaped floors respectively, designed for 90 minutes fire resistance and 8 metre spans. Specimen C consisted of three pairs of 450 mm deep x 90 mm wide LVL joists glued under a 108 mm thick x 1200 mm wide cross-banded LVL slab which was made up of 3 layers of 36 mm thick cross-banded LVL glued together. Specimen D consisted of two box sections formed from 300 mm deep x 90 mm wide LVL joists and 90 mm thick x 400 mm wide LVL bottom flanges. The box sections were glued and screwed to a 108 mm thick x 1200 mm wide cross-banded LVL slab composed of three separate layers glued together. All floors were simply-supported, and the glue used to produce the LVL materials was a phenolic resorcinol adhesive which produced a Type A marine bond.

Loading and Fire test Protocol

The loads were applied to the specimens for 30 minutes prior to furnace testing in accordance with AS 1530.4 (2005) and ISO 834 (1999), and were held constant throughout each test until termination. Four point bending was simulated on the floors with a spreader bar approximately 1.6 metres in width located centrally on the specimens. The applied loads for the floor specimens were calculated based on normal office loading

characteristics from AS/NZS 1170.1 (2002), with a live load of 3.0 kPa and a superimposed dead load of 1.0 kPa plus the self-weight of the floors. The floors were subjected to the standard ISO 834 (1999) test fire for varying durations until runaway failure was observed and they were unloaded from the furnace for damage assessment.

Test Results

Char measurements were taken at quarter points throughout the length of the floor for each test, with the actual char depth observed to be remarkably uniform across each specimen indicating a relatively consistent level of combustion inside the furnace. The average calculated charring rates of each major surface of the floor specimens are shown in Table 1 with regards to the furnace testing duration and total burning time of each specimen. Note that there is a period of time from which the test is terminated until the test assembly can be disassembled and the test specimen extinguished, hence the total burning time is greater than the furnace testing duration.

Table 1 Calculated charring rates from furnace testing

Specimen	Test Duration (min)	Burning Time (min)	Calculated Charring Rate (mm/min)			
			Beam Sides	Beam Bottom	Slab Underside	Overall Average
A	30	36	0.69	0.83	0.69	0.74
B	41	-	-	-	-	-
C	105	113	0.66	0.86	0.84	0.79
D	105	113	0.68	0.71	0.84	0.74

The charring rates for the exposed surfaces of the floors ranged from 0.66 – 0.86 mm/min across all specimens. Charring rates for the vertical faces of the floors (sides of the beams) were all similar, ranging between 0.66 – 0.69 mm/min.

The T-shaped floors had much higher charring rates on the bottom of the beams due to the corner rounding effect where in the latter stages of burning the radii of charring on each corner of the beam intersect, compounding the vertical rate of char. This was observed in previous research on timber-concrete composite floors tested at BRANZ (O'Neill 2009). In contrast, this effect was not as pronounced for the box-shaped floors which experienced a greater relative degree of one-dimensional fire exposure, with a calculated charring rate on the underside of Specimen D of 0.71 mm/min.

The charring rate of the lightweight 36 mm thick timber slab was 0.69 mm/min in Test A, while the heavyweight 108 mm thick slab charred at 0.84 mm/min for Tests C and D. This higher rate can be attributed to the longer duration of burning where the furnace temperatures are comparably higher at this time. The temperature in the furnace was recorded as approximately 850°C at 30 minutes and reached temperatures over 1000°C after 80 minutes of exposure to the standard fire. As Specimen B was tested until failure at 41 minutes, no viable charring results could be obtained from the remaining specimen as it could not be retrieved from the furnace in adequate time. The uniformity of the charring is shown for Specimen D in Figure 2, before and after furnace testing (approximately 113 minutes burning time).

Figure 2 Underside of Specimen D before (left) and after furnace testing (right)

NUMERICAL MODELLING

Advanced numerical modelling is required when a problem is too complex to be solved by hand, and a greater understanding is required of the underlying principles and mechanisms involved in the analysis of the problem. Modelling is useful in fire engineering because it allows the investigation of parameters in the structural system while fire testing will only yield results for only one particular circumstance.

Numerical Modelling Conducted

A sequentially coupled thermo-stress analysis was conducted on each floor to determine the effects of fire on loaded floor assemblies using the software ABAQUS (2010). Firstly a two-dimensional thermal analysis was performed to track changes in the temperature profiles of the floor assemblies for the duration of the fire, and then a three-dimensional stress analysis (utilising solid continuum brick elements) was performed using the temperature profile as an input into the structural model. This procedure was used as the stress profile of a timber member is influenced by its temperature profile, but the converse is not true.

Potential Drawbacks

Sequential thermo-stress analysis of timber floor systems is difficult for many different reasons. It requires the definition of thermal, mechanical and physical properties. Mass transfer in timber members exposed to fire conditions is the fundamental process which governs many of these property changes. However, modelling any type of mass transfer is extremely difficult and time consuming; hence it is usually accounted for by taking effective values of other properties over a certain range. A review of some of the numerous models which incorporate some moisture movement is described by Janssens (2004). It highlights some of the difficulties and drawbacks of efforts in the past to model and predict charring behaviour by accounting for mass transfer, char oxidation, char contraction and modified properties. Although higher order effects such as these are important to understand, finding a method of reliably accounting for them without actually modelling the exact mechanisms taking place is difficult, and has been attempted in the past with varying degrees of success. As the thermal and structural effective properties presented in Eurocode 5 (CEN 2004) are able to model these effects well, an effective values approach is recommended for the numerical modelling of timber in fire.

Results Comparison

The ABAQUS simulations of load vs displacement data were compared with the results of experimental tests. It was found that the numerical model predicted the displacement response of the experimental floors very well, but was slightly under conservative when estimating failure times. Failure time comparisons from the numerical modelling effort and for the experimental tests conducted are shown in Table 2. Modifications to the effective material were proposed. These resulted in a closer approximation to the experiment, as shown in Figure 3.

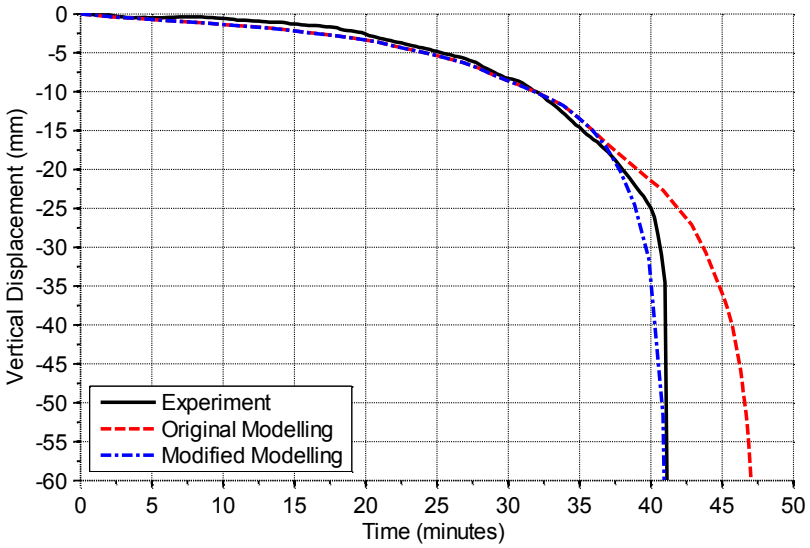

Figure 3 Load displacement response and corresponding numerical modelling of Specimen B

Table 2 Test durations and failure predictions

Specimen	Expected Failure Time from Experiment (minutes)	Failure Time from Numerical Modelling (minutes)
A	33 – 37	38
B	41	47
C	120 – 125	133
D	120 – 125	135

These modifications included varying the maximum tension strength reduction factor of the wood, based on a range of material properties data available in the literature. Sensitivity studies were conducted to determine the most influential parameters within the material model, including strength, modulus of elasticity, Poisson's ratio, and damage functions. Although the comparisons in Figure 3 highlights the importance of advanced calculations, simplified design methods are also needed for calculating the fire resistance, as a resource and time efficient method must also be available to facilitate everyday timber design calculations.

DESIGN METHOD

Simplified design methods are the backbone of current engineering practices in the modern environment. Although each structure and its expected hazards may be unique, a simplified approach and its supporting design methods allow the majority of these structures to be designed by engineers of varying skill levels while still attaining a minimum acceptable standard.

Current Practice

A number of simplified design methods exist for the prediction of timber member capacity in fire conditions, such as the reduced cross-section method or the reduced properties method. Although these methods have been developed to suit local design practices, there is consensus that charring rate methods are simpler to understand and apply as they reflect the physical changes a burning timber element undergoes. As such, this research proposes a charring rate methodology which is grounded in the basic acceptable practices from around the world. Although reduced properties methods are also available in some building codes, these methods are less intuitive, and less widely accepted and applied, hence are not investigated further in this research.

Generally accepted practice is to apply the above charring rate methods via Limit State Design or a similar means to determine the structural adequacy of a timber member or assembly. For fire conditions, short term loading durations are generally assumed, and the structural adequacy is checked under the Ultimate Limit State only. Fire design loading conditions are applied, which take into consideration the lower expected loading demand on the structure during this type of scenario. Loading factors vary between countries, however they generally consist of a gravity load factor of 1.0 and a live load factor of 0.5 or less. A full design procedure for the Australian and New Zealand design environment for timber assemblies is described by O'Neill (2013).

Failure Criteria

The standard measure of the fire resistance of an element is generally classified by three separate failure criteria, and are listed as follows:

- Stability – to prevent the structural collapse of the element,
- Integrity – to prevent the transmission of fire and smoke through the element,
- Insulation – to prevent an unacceptable amount of heat being transmitted through the element.

These criteria are generally abbreviated into a short form which is expressed in minutes as R/E/I. This represents the failure criteria fire resistances of stability, integrity and insulation respectively. This is known as the fire resistance level (FRL) of an element in Australia or fire resistance rating (FRR) in New Zealand, and has many similar abbreviations around the world.

Design Method for Structural Adequacy

The simplified method developed in this research is based on a reduced cross-section method that utilises notional charring rates to incorporate second order effects and the effect of corner rounding. This is because corner rounding often complicates what should in essence be simple hand calculations, and the impact of corner rounding is highly dependent on the exposure duration. Thus a residual section can be calculated for an entire

timber section by removing the expected char layer from all exposed faces of the section, including a zero-strength layer. The charring rate also incorporates bi-linearity, as the experimental results and other studies (Gardner and Syme 1991) have shown the rate of charring decreases significantly with increasing char thickness. The proposed bi-linear method is shown in Eq. 1.

$$d_{char} = \gamma\beta \times t + kd_0 \quad (1)$$

Where d_{char} is the char depth in mm, and t is the duration of burning in minutes. The bi-linear modification factor, γ, is defined as γ = 1.15 for $t < 45$, and γ = 0.90 for $t > 45$. The notional charring rate, β, is defined as 0.70 mm/min for softwoods and 0.55 mm/min for hardwoods, and d_0 is the zero strength layer, specified as 7 mm. These values were chosen as a good approximation to the experimental results in this research, and are also representative of a wide range of currently accepted codes such as in Australia (SA 2006) and Europe (CEN 2004) which specify similar values of nominal charring rate and zero strength layers. The k factor is calculated as $k = t / 20$ for $t < 20$, and $k = 1.0$ for $t > 20$, similar to the Eurocode (CEN 2004).

Design Method for Insulation and Integrity

The above charring methods are for calculating the expected resistance of a timber member or assembly, however they generally only provide information regarding the stability (or loadbearing) criterion of fire resistance. This may be acceptable for evaluating members such as columns and beams, however when dealing with assemblies such as floors or walls which are also required to provide a separating function, the insulation and integrity criteria must also be evaluated. Guidance from the codes is limited on the matter, with none of the above outlined codes providing any information or design procedures for evaluating the integrity or insulation criteria excluding Eurocode 5 (CEN 2004). It provides guidance on the separating function of wall and floor assemblies, with an additive method which accounts for the contribution of different layers of materials, their positioning in the assembly, and their location relative to joints. It has been shown to provide a conservative calculation of the separating function of wood decking (Janssens 1997). Further modifications and improvements to this method are given in the European Guidelines (Östmann 2010).

It is usual for an upper limit to be provided in terms of the allowable maximum temperature to be reached on the non-exposed cold face of the element, however accurately estimating the thermal penetration into a wood member requires a heat transfer analysis to be conducted, and is beyond the scope of simplified calculation procedures. A simplified approach to assessing both integrity and insulation is postulated in this research by which the insulation criterion, considering an unburnt thickness of wood is evaluated. As the remaining thickness of wood is assumed to be large enough to ensure the non-exposed face of the element does not undergo a significant rise in temperature, the integrity criterion is then also conservatively assumed to be satisfied with the insulation criterion.

It is estimated that an unburnt wood layer thickness ranging from 15 – 35 mm is appropriate to use for design, based on experimental testing and guidance from the literature (Buchanan 2001). Due to the insulative properties of timber the steepness of the temperature gradient is high, such that if timber is assumed to be converted to char at 200°C it may be assumed that the temperature of the non-exposed face of the timber separating element should be below 100°C. A value of 25 mm is suggested, based on the one-dimensional thermal modelling conducted by O'Neill (2013) and validated against experimental results incorporated into Eurocode 5 (König and Walleij 1999). Using this approach, a simple effective thickness calculation can be added to any charring rate method to evaluate the separating function for wood assemblies.

Building Code Comparison

As a comparison between currently used simplified methods, calculations of char depth are made for the bi-linear method compared with a selection of regulatory codes from around the world for a number of generic fire resistance times. The results are shown in Table 3, considering the effective charring depth (including zero strength layer approximations) of an unprotected segment of softwood timber under two-dimensional fire exposure. In comparison to the other code methods, the proposed bi-linear charring rate is notably more conservative for all exposures under two hours (excluding the two hour Eurocode 5-1-2 exposure). This is to be expected as the notional charring rate for the initial 45 minutes of exposure time is very high in comparison to other codes.

Table 3 Building code char depth calculation comparison

Calculation Method	Char Depth (mm)			
	30 min	60 min	90 min	120 min
NZS 3603	20	39	59	78
AFPA Technical Report 10	26	46	64	80
AS 1720.4	27	47	67	87
Eurocode 5-1-2	28	49	70	91
Proposed Bi-Linear Method	31	53	72	90

As these methods are all rooted in empirical findings of experimental tests, it is impossible to say which is the most appropriate for design without comparing the experiments themselves. Therefore common sense dictates the most robust testing regime, coupled with the most detailed analysis should take precedence over the others. However environmental factors may have also influenced the results, and hence each method may be appropriate to its specific region thus no definitive conclusions can be drawn in this sense. What is apparent from comparing the methods is that the assumption of a zero strength layer is common, as is accounting for the influence of the density of the wood. The application of each method is seen to be similar, however the assumption of a linear or non-linear charring rate, and the absolute charring rate value used can cause large discrepancies between the results.

Experimental Comparison

In order to gain an understanding of the spread of historic experimental data on measured charring rates around the world, the results of a number of experimental investigations have been summarised in Table 4. These results are readily available in the literature, and where reported the type of test assembly and wood species classification is given (with either hardwood or softwood denoted as "S" or "H"). Some of these results have been extracted from the research review work of Friquin (2010) and O'Neill (2013). The bi-linear calculation method has been applied to each historical test dataset for comparison.

Table 4 Experimental char depth comparison

Experimental Reference Source	Assembly Type	Species	Recorded Charring Rate (mm/min)	Bi-Linear Method (mm/min)
Collier (1992)	Wall Beam	S	0.53 – 0.93 0.57 – 0.63	0.88
Frangi and Fontana (2003)	Beam Slab	S	0.67 – 0.70 0.70	0.76 – 1.04
Frangi et al. (2008)	Wall Slab	S	0.64 – 0.78 0.99	0.85 – 1.01 1.06
Gardner and Syme (1991)	Beam	S H	0.50 – 0.94 0.40 – 0.63	0.75 – 0.88 0.60 – 0.71
König and Walleij (1999)	Slab	S	0.60 – 0.70	0.79 – 0.88
Lane (2005)	Beam	S	0.72	0.99
Lau et al. (2006)*	Beam	S	0.70	1.15
O'Neill (2009, 2013)	Beam	S	0.66 – 0.86	0.76 – 0.85
Osborne et al. (2012)	Slab Wall	S	0.64 – 0.65 0.65 – 0.80	0.71 – 0.86 0.76 – 0.89
Schaffer (1967)	Slab	S H	0.50 – 0.80 0.43 – 0.57	0.90 0.73
Tsai et al. (2010)	Beam	S	0.75 – 0.94	0.88
White (1988)	Slab	S H	0.50 – 0.86 0.55 – 0.97	0.83 – 0.96 0.68 – 0.81
*Only the experiments over 20 minutes in duration were collated.				

Note that the experimental results reported in Table 4 encompass both one and two-dimensional charring behaviour which is dependent on the test and assembly type. The timber elements are exposed to standard fires, and subjected to a wide range of loading regimes. All of these factors have an influence on the charring rates recorded. It can be seen from the wide range of data sourced that the spread of measured charring rates is large, with approximate charring rates for softwoods between 0.60 – 0.80 mm/min for the test exposures of beams, slabs and walls. The results for hardwoods are on average lower, being between 0.45 – 0.65 mm/min. The experimental test times for the data listed ranged from 20 – 120 minutes.

The proposed bi-linear method overestimates many of the average charring rate values recorded in the historical test dataset. This is due to a number of factors such as exposure time, the increased initial charring rate, and the inclusion of a zero strength layer for design. This has a magnified impact on very low test exposure times such that a high level of char is calculated, and the method is conservative overall in comparison to the test dataset. Variations in the zero-strength layer were not considered during the research, however if considered, it is expected to have a greater impact on values calculated for lower exposure times.

The work conducted by Gardner and Syme (1991) found that, comparing one and two hour fire exposure, the average charring rate for softwoods decreased from 0.79 to 0.65 mm/min. For hardwoods the decrease was much lower, decreasing from 0.55 to 0.52 mm/min on average. Post-fire investigations of actual buildings have found that without the presence of accelerants or specific design flaws such as large gaps in timber assemblies, charring rate values reported in the literature for fire resistance furnace tests are representative of real fires. Babrauskas (2004) concluded that charring rates between 0.50 – 0.80 mm/min are representative of severe post-flashover room fires.

In comparison to the experimental results and failure times predicted by the numerical modelling in this research, the expected fire resistance calculated by the bi-linear method for each floor specimen is shown in Table 5. This is calculated for stability failure only, as it is expected that in practice a lightweight non-structural concrete topping or other insulating membrane would be installed atop these floors for the purposes of better acoustic, insulation and durability properties. Thus the insulation and integrity criteria are not expected to govern the fire design of these floors. The calculation method was implemented in a spreadsheet as a quasi-steady state analysis in order to iteratively solve for the expected failure time of the floors to the nearest minute. A comparison with the Eurocode 5-1-2 method is also presented for the floors tested, as this method is widely used worldwide and gave the closest calculated char values to the proposed bi-linear method.

Table 5 Experimental failure time comparison

Specimen	Expected Failure Time from Experiment (minutes)	Failure Time from Numerical Modelling (minutes)	Failure Time for the Bi-Linear Method (minutes)	Failure Time for the Eurocode Method (minutes)
A	33 – 37	38	35	40
B	41	47	41	47
C	120 – 125	133	123	122
D	120 – 125	135	124	123

It can be seen that the bi-linear method is more conservative than the results of the numerical modelling, and predicts the failure time of the experiments well, which is expected. The Eurocode 5-1-2 method gives very similar results to the proposed bi-linear method for higher exposure times, however gives more conservative values at lower exposure times. This can result in the over prediction of expected failure times of up to 20% for some of the floor assemblies tested in this research.

It should be noted that the floor assemblies tested in this research may not perform in a similar manner when compared with other major structural assemblies such as walls, beams and columns. This may affect how the calculation method performs for these other assemblies. The load level, fire type, and surface fire exposure all play a critical role in determining the actual fire resistance of a timber assembly, and these factors can differ significantly between different types of assembly.

Despite this, the condition of the floors tested in this research should be representative of a wide range of flooring systems used in reality, in terms of load levels, cross-sectional geometries and span lengths. Thus, the bi-linear charring rate reduced cross-section method is generally applicable for these types of systems, and provides an excellent starting point for estimating their performance by hand calculation methods.

Designing for Redundancy

Care must be taken when using calculation methods to ensure that they are used appropriately for their intended purpose, and that other parts of the system which may be critical to the design are not ignored. Any other elements in the system which may cause premature failure or increased burning, such as the integrity of the connections, thin portions of slab, unprotected penetrations and holes drilled into floors, openings through wall cavities exposing more timber surface area, and any surface treatment or covering which could have an adverse

effect on the fire performance of the assembly. The effect of passive protection on timber assemblies should also be accounted for.

As such, a greater understanding of the global behaviour of the structure and any critical elements such as connection details must be appropriately designed for fire resistance to ensure the entire system performs as desired, and a premature failure does not occur in the event of a fire. Good construction practice is also paramount to ensuring that a structural assembly performs as intended.

CONCLUSIONS

In conclusion, this research has incrementally consisted of the experimental testing and numerical modelling of timber floor systems under fire conditions, culminating in a simplified charring method derived from the results of the research and grounded in generally accepted calculation methodologies from around the world. A bi-linear charring rate method is proposed, accounting for a zero strength layer and with provision for calculating a separating function.

As many of the new timber technologies which are becoming prevalent in our markets have not yet been properly implemented into building codes, it is becoming increasingly important to provide evidence and guidance on their expected performance in fires. This is not only to enable the correct use and implementation of these systems in the built environment, but to allow for informed and reasoned justification behind any restrictions placed on timber systems which may form the basis of modern building codes.

ABSTRACT

Tall timber building designs have utilized cross-laminated timber (CLT) significantly over the past decade due the sustainable nature of timber and the many advantages of using an engineered mass timber product. Several design methods have been established to account for the composite action between the orthogonally adhered timber plies. These methods assume perfect bonding of the adjacent plies by the adhesive. CLT designs methods for timber in fire have also been formulated. These methods rely on the relatively constant charring rate of timber to calculate a sacrificial layer to be added onto the cross-sectional area. While these methods focus on the timber failure mode of reduced cross section by charring, the failure mode of ply delamination is often overlooked and understudied. Due to the reduction of shear and normal strength in the adhesive, the perfect bond assumption can be questioned and a deeper look into the mechanics of CLT composite action and interfacial stress needs be conducted. This paper seeks to highlight the various design methods for CLT design and identify the failure mode of delamination not present in the current design codes.

Charring, Fire, Cross-Laminated Timber, Adhesive, Delamination, Failure Modes, Thermal Penetration Depth.

INTRODUCTION

The design and construction of tall timber buildings have increased in recent years. The Murray Grove Tower (29 m) in London and the Forté Building (32 meters) in Melbourne are currently the tallest two buildings in the world (Timmer 2011, Wells 2011, Wheeldon 2012). The Treet Building under construction in Bergen, Norway will be 49 m tall when completed (Abrahamsen and Malo 2014). Research into the feasibility of even taller designs has progressed as well. A report from mgb ARCHITECTURE + DESIGN demonstrated designs for 32 to 96 meter tall buildings (Green 2012). Skidmore, Ownings, & Merrill LLP (SOM) have produced the tallest design to date at approximately 120 meters (Skidmore Ownings & Merrill LLP 2013). In each of the designs, engineered mass timber products provide member sizes with the required structural strength and stiffness.

Engineered mass timber products rely on the composite action between two adjacent timber plies and the glue adhering them together for structural strength. Adhering multiple plies together offers many advantages over solid timber cross sections. The biggest benefit is the elimination of growth and other defects. The resulting cross section is structural stronger than solid timber and the resulting strength more reliable. Larger members capable of spanning longer distances are now possible where solid timber was incapable. The benefits of engineering mass timber are fully realized in cross-laminated timber.

Cross-laminated timber (CLT) is an engineered mass timber product where adjacent timber plies are glued orthogonal to one another. Cross laminating timber not only eliminates timber defects as in other glued timbers but also prevents dimensional expansion due to moisture. CLT has the capability of spanning in two directions (Gagnon, Bilek et al. 2013) allowing floors, slabs, and walls to be highly optimized and more economical.

SOM's tall timber design even used CLT as part of the shear walls and cores to provide increase lateral stability against wind and earthquake loads (Skidmore Ownings & Merrill LLP 2013). As the market increases the use of CLT in structural frames, the number and accuracy of design methods developed as well.

METHODS OF CLT DESIGN

Currently, three different design methods are commonly used throughout the world. These and other methods are based on analytical and experimental solutions.

Mechanically Jointed Beams Theory

The Mechanically Jointed Beams Theory (Gamma Method) by Karl Möhler was originally developed for beams mechanically fastened by connections with a fixed stiffness *K* spaced *s* distance apart. The plies of the beam were oriented parallel with adjacent layers. The resulting beam had an effective stiffness of EI_{eff} which was dependent on the efficiency of the connection, γ (Eqs 1 and 2). Completely glued connections received a γ of one and non-glued connections had a γ equal to zero. This allowed the stiffness of the member to bedependent on the amount of slip in the connection(Gagnon and Popovski 2011). This methodology for glued beams can be found in Annex B of EN 1995-1-1:2004 (European Committee for Standardization 2004).

$$EI_{eff} = \sum_{i=1}^{n}(E_i I_i + \gamma_i E_i A_i a_i^2) \quad (1)$$

$$\gamma_i = [1 + \frac{\pi^2 E_i A_i s_i}{K_i l^2}]^{-1} \quad (2)$$

where:

i = layer number
E_i = Modulus of Elasticity
I_i = Moment of Inertia
A_i = Area
a_i = distance from centroid of each layer to the neutral axis of the cross section
l = span length

$$0 \leq \gamma \leq 1$$

Since CLT has orthogonally oriented timber plies, several corrections and assumptions had to be made to the Gamma Method. The first assumption was that layer oriented perpendicular to the direction of the span would carry no load. The perpendicular layers could be applied as fasteners to the longitudinal layers and the rolling shear stiffness, G_R, would act as the fastener stiffness between load carrying layers (Eq.3).

$$\frac{s}{K_i} = \frac{\bar{h}_i}{G_R b} \quad (3)$$

where:

$\bar{h}_i$ =thickness of ply
G_R = Rolling shear stiffness
b = width of panel

The maximum bending stress (σ_{max}), ply 1, can therefore found by equating both the local and global bending stresses in Eq. 4. Other stresses such as axial and shear can be found as well.

$$\sigma_{max} = \frac{ME_1}{(EI)_{eff}}(\gamma_1 a_1 + 0.5h_1) \quad (4)$$

where:

M = applied moment

Composite Theory

The composite theory, otherwise known as the k-theory, as in the Gamma Theory uses an effective stiffness but in the form of composition factors which account for loading configurations and each individual layer's properties. The main assumptions are linear stress strain relationship and Bernoulli's hypothesis of plane sections. Each composition factor (Eq 5) is multiplied with each strength value and compared with the maximum stress applied. A list of composition factors can be found in (Blass and Fellmoser 2004, Gagnon and Popovski 2011). Shear deformations are not accounted for in this method.

$$\sigma_{max} \leq f_{b,0}k \tag{5}$$

where:

$f_{b,0}$ = bending strength
k = composition factor

Shear Analogy Method

The shear analogy method accounts for shear deformations and is the most precise CLT design method according to Blass and Fellmoser(Blass and Fellmoser 2004). The bending and shear stress both incorporate the properties of each layer. The rolling shear stiffness is incorporated in the maximum deflection of a CLT slab by the introduction of the second term in Eq 6 (Gagnon and Popovski 2011).

$$u_{max} = \frac{5}{384} \cdot \frac{qL^4}{(EI)_{eff}} \cdot \left(1 + \frac{48(EI)_{eff}k}{5(GA)_{eff}L^3}\right) \tag{6}$$

where:

k = shear coefficient form factor
q = distributed load
L = span length
$(EI)_{eff}$ = effective bending stiffness
$(GA)_{eff}$ =effective shear stiffness

While each of the methods besides the k-method, assumes a degree of shear deformation, the shear is isolated in the plies themselves. All the methods assume complete bond adherence and no slip between the plies.

METHODS OF CLT DESIGN FOR FIRE

In the design of timber buildings, the structural components need to be designed against fire loads due to the combustible nature of timber. As timber increases in temperature, the wood slowly starts to decompose in a process known as pyrolysis. The wood breaks down into two major by-products: combustible gases and char. The char layer which increases in thickness as the timber burns builds to around a constant thickness of 25mm and insulates the rest of the cross section from the heat of the fire. Current methods of designing CLT for fire utilize the almost constant rate of charring to add a sacrificial layer of timber to the structural members.

EN1995-1-2

EN 1995-1-2 defines the distance from the exposed surface of char to the char line, where pyrolysis occurs, as the charring depth. The char line is typically taken as the 300°C isotherm. The char depth is defined by Eq 7 for both one-dimensional charring and charring accounting for corner rounding(CEN 2004).

$$d_{char,0} = \beta t \tag{7}$$

where:

β = β_0(one-dimensional charring rate) or β_n(notional charring rate accounting for corner rounding)
t = fire exposure time

To calculate the strength of a timber structural member, EN 1995-1-2 allows two calculation methods: the Reduced Properties Method (RPM) and the Reduced Cross-Section Method (RCSM). Both methods use the charring depth and assume the char contributes no strength to the structural capacity of the member. Both methods use a modification factor to account for the thermal penetration depth, the thickness of the member at temperature above ambient but below the pyrolysis temperature. Where the methods differ is that the RPM modifies the modulus of elasticity and the bending, tensile, and compressive strength of timber in the overall structural calculations. The RCSM specifies a "zero-strength" layer to be added to the char layer. This increased char layer is termed the effective char depth (d_{ef}) and accounts for the reduction in structural properties by eliminating a certain portion of the thermal penetration depth (Eq. 8). The remaining amount of the cross section is used to calculate the strength of the member assuming ambient temperature strength.

$$d_{ef} = d_{char,n} + k_0 d_0 \tag{8}$$

where:
$d_0 = 7mm$

$$k_0 = \begin{cases} \frac{t}{20}; t < 20\ min \\ 1\ ; t \geq 20\ min \end{cases}$$

If the structural member protection, such as gypsum board, falls off the charring rate doubles until the char layer re-increases to 25mm (Fig 1). The solid line in Figure 1 represents timber which chars at a constant rate. The dashed line represents a newly unprotected timber member which chars at double the rate until a charring depth of 25 mm is achieved. While EN1995-1-2 does not explicit mention CLT, char and ply delamination of CLT acts in a similar manner to protection fall off (Frangi, Fontana et al. 2006, Dagenals, White et al. 2013, Inghelbrecht 2014). The EN 1995-1-2 method of accounting for fire loads is purely a charring method and does not specify when char or ply fall-off occurs.

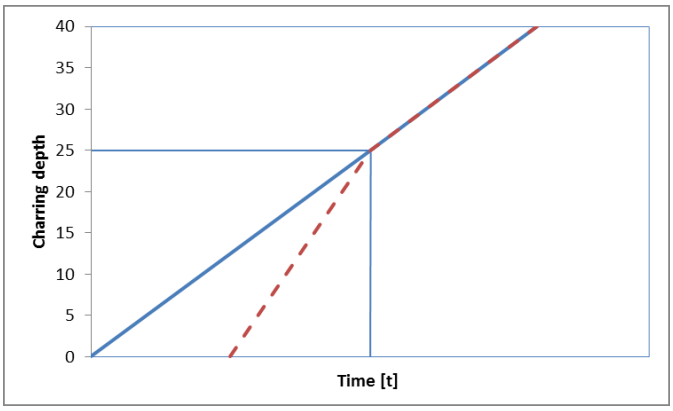

Figure 1: Charring depth of Protected and Unprotected Timber

National Design Specification

The National Design Specification (NDS) methodology for structural performance of timber in fire uses an effect charring depth as specified in Eq. 9(Dagenals, White et al. 2013).

$$d_{ef} = \frac{\beta_n t}{t^{0.187}} \tag{9}$$

where:
t = fire exposure
β_n = notional charring rate

NDS adds twenty percent to Equation 9 as its zero-strength layer. Unlike EN1995-1-2, the zero-strength layer is variable and depends on the actual char depth. While the maximum zero-strength layer for EN1995-1-2 is 7mm, the NDS zero strength layer increases beyond that (find out).

The NDS accounts for char and ply delamination by assuming the CLT layer falls off once the temperature of the adhesive reaches 300°C. Once the ply has fallen off, the char layer grows from zero thickness again. Aguanno(Aguanno 2013) recommended based on medium and full-scale tests to have ply fall-off be when the 300°C isotherm reached 12mm from the bond line.

SP Model

The last model to account for structural deterioration of timber and CLT due to fire is the SP Technical Research Institute of Sweden (SP) model(SP Technical Research Institute of Sweden 2010). The charring model recommended accounts for the char layer plus a compensating layer for the thermal penetration depth into the uncharred portion of the cross section. The charring depth recommended is shown in Eq. 10 and is based on a compensating layer factor, s_o. The compensating layer is dependent on the following factors:

- Number of CLT plies
- Overall member thickness
- Stress orientation of fire-exposed side
- Thermal penetration temperature gradient

$$d_{ef} = d_{char,n/0} + k_0 s_0 \quad (10)$$

where:

$d_{char,\ n/0}$ = notional or one-dimensional charring depth

$k_0 = \frac{t}{20}$ for unprotected members. Increases linearly from 0 to 1 then remains constant.

s_0 = compensating layer

Char and ply fall off are calculated the same manner as in the EN1995-1-2 and NDS methods. Each of the methods described above accounts for structural deterioration of timber due to fire through the use of a charring method. Two of methods, NDS and SP, accounts for the thermal penetration depth through the use of a compensating factor and assume that failure of the bond line of CLT occurs at 300°C.

CLT COMPOSITE ACTION MECHANICS

Both the design of CLT for ambient and fire conditions consider the bond line to never fail until the char layer (300°C isotherm) has reached the bond line. Since timber has no strength above 300°C, the assumption of these methods is that the strength of the glue is adequate enough for failure to occur in the timber and not in the bond line. Bond line failure of CLT is a failure of the engineered mass timber products overall design. Failure of CLT should occur in the weakest portion, namely, the timber.

In order to properly understand the mechanics behind CLT ply interaction and the role the glue plays in the composite action, the interfacial shear ($\tau(x)$)and normal stresses ($\sigma(x)$) need to be understood. Fig. 2 shows the breakdown of the forces between two plies and the adhesive layer between them.

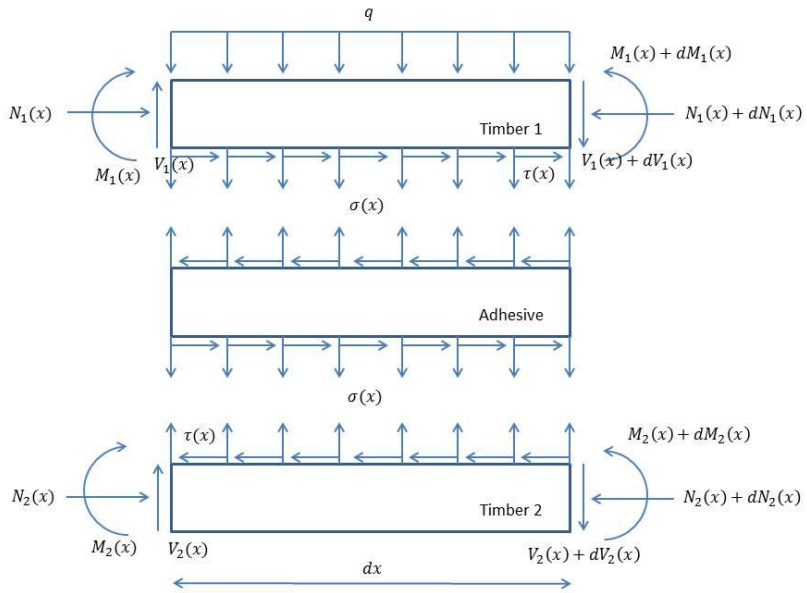

Figure 2: Interfacial and normal stresses (adapted from (Smith and Teng 2001)

As shown in Fig. 2, the adhesive needs to resist both shear and normal stresses and based on the assumptions from the charring models the glue should resist all stresses below 300°C. Current research shows that this assumption may not be entire accurate. Two studies were conducted on the shear strength of popular adhesives used to bond CLT. Frangi, Fontana et al. (2004) performed shear tests on glue laminated timber at temperature ranging from 20 to 170°C. Resorcinol-formaldehyde (R-F), one-component polyurethane (1K-PUR) and epoxy

were used. The blocks heated in an oven to the desired temperature and loaded until failure. The studied revealed that the shear strength of the varied significantly even among the same type of glue and that the shear strength reduced to between 25-75% of the ambient strength. Table 1 shows the temperature at which cohesion failure dominated. The second study was conducted by Clauß, Joscak et al. (2011) on the thermal stability of adhesive under shearing loads at temperatures up to 220°C. The conclusion from this study were same as Frangi, Fontana et al. (2004).

Table 1: Temperature of Cohesion Failure (Frangi, Fontana et al. 2004)

Kauresin 460 (R-F)	>170°C
Kauranat 970 (1K-PUR)	180-190°C
Balcotan 107 TR (1K-PUR)	50-60°C
Balcotan 60 190(1K-PUR)	190-200°C
Purbond HB 110(1K-PUR)	60-70°C
Purbond VN 1033(1K-PUR)	150-160°C
Araldite AW 136 H (epoxy)	50-60°C

Based on these tests and the force diagram in Fig.2, the importance of the adhesive is clearly demonstrated. Not only will the CLT failure be predominately in the adhesive above approximately 150°C but also the adhesive loses significant strength above 100°C. As the temperature increases, the adhesive will slip and deform and the overall CLT section will have greater deflection. Failure of the section by delamination will be gradual and not sudden. Failure of plies will occur before visual fall off. Several studies have noted fall off in furnace tests on CLT. Craft, Desjardins et al. (2012) conducted vertically oriented CLT tests and noted delamination when the thermocouples at the bond line measured 300°C. Osborne, Dagenals et al. (2012) had several tests exhibit delamination. The temperatures at the bond lines reached 200°C. This was repeated and confirmed by Aguanno (2013). These tests all relied on visual observations to detect delamination and comparisons with thermocouple data.

DISCUSSION

The CLT failure mode of delamination has been identified which current design models do not account. As the thickness of the thermal penetration depth has been measured between 25 to 50 mm (Frangi and Fontana 2003) multiple bond lines of CLT could be above ambient temperatures as the char line progresses through a structural member. The shear and normal strength of the adhesive is an integral part of the composite action design of CLT and they both deteriorate at temperatures above ambient. Complete cohesion failure of the adhesive is between 70°C and 190°C. The extent delamination affects the structural mechanics of CLT has yet to be studied in depth, and proper quantification is necessary to gain an understanding of this failure mode.

ACKNOWLEDGMENTS

The authors would like to thank Dr. Dilum Fernando for his advice and discussion on the various topics relating to the structural mechanics of composite structural members and interfacial stresses.

ABSTRACT

Delivering structures that achieve their specified fire resistance is a key component of ensuring that the built environment is adequately resilient. The failure of buildings that are tall often has collateral consequences way beyond that of the immediate structural collapse. This paper describes the need for effective performance based structural fire engineering of tall or unusual buildings where the fire safety measures required to pass the standard fire resistance test do not necessarily deliver an appropriate level of safety. The case study of inclined columns in a tall building is used to illustrate this behaviour, and it is demonstrated that sufficient knowledge already exists for engineers to mitigate many possible failure modes. The columns are analysed when subject to a range of different heating conditions, and an analytical formulation is presented which can be used to improve the design of fire tall or unusual structure with inclined columns.

KEYWORDS

Composite steel structures; fire resistance; geometrically bi-linear columns; design.

INTRODUCTION

Modern structural engineering techniques require a range of analysis techniques of varying complexity to deliver the architectural goals of a project while simultaneously balancing cost and structural efficiency. Innovation is frequently required to deliver the services and architecture that, in a lower rise building, could be derived from the application of prescription or standardised methods.

Where systems are regularly required for the ongoing day-to-day operation of the building (for example, mechanical services, or serviceability loading) any inadequacy in a solution is readily highlighted. Conversely, where systems are required only for extreme events (for example, fire safety systems or earthquake resistance) any deficiencies in a proposed solution are more difficult to recognise prior to the event. This is the case for the structural fire resistance of a building – which is required where other redundancies are not effective (e.g. failure of active fire suppression).

Consequently, when designing for extreme events it is necessary to carefully examine the fundamental assumptions within the design methodologies used to develop a solution to ensure that these are valid for the proposed application.

Although standard fire resistance testing has been conducted for nearly a century to assess the performance of structures, there remain fundamental deficiencies in its facility to assess the interaction of multiple elements (Buchanan, 2006). Where a structure is composed of more than one element, the standard furnace test does not represent this effectively.

INCLINED AND GEOMETRICALLY BILINEAR COLUMNS

Geometrically bi-linear columns (GBCs) are those where the orientation of one or more of the columns above or below the storey level is not orthogonal to the floorplate. These types of columns feature on a number of existing and proposed buildings including: the WalkieTalkie, 52 Lime Street, 100 Bishopgate, and One Blackfriers.

To maintain equilibrium under ambient conditions, GBCs require a force to be applied at the bifurcation point. This force is provided by the beam that is connected to the column. The force may be tensile or compressive, depending on the angle of the column and whether the inclined section is above or below the floorplate. Conversely, the forces in the floorplate associated with inclined columns are limited to those associated with the resolved shear force from the floorplate. These columns are shown in Figure 1.

BASE CASE MODELS

To describe mechanics, different structural models were created. The structural design was in accordance with BS EN 1993-1-1 and BS EN 1994-1-1. The common properties of each of thefloors were as follows: 4m floor to floor height;120mm flat soffit slab; S355 steel; 25MPa concrete; composite steel beams; H section columns.

To describe mechanics, different structural models were created. The structural design was in accordance with BS EN 1993-1-1 and BS EN 1994-1-1. The common properties of each of the floors were as follows: 4m floor to floor height; 120mm flat soffit slab; S355 steel; 25MPa concrete; composite steel beams; H section columns.

The design approaches were incorporated into an algorithm that selected the sections based on the applied loads (axial force, shear, and moment) and the target utilisation. A beam size was selected that achieved utilisation within 1% of the target value.

Once the structural design was developed, the critical temperature for each element was defined based on the guidance of BS EN 1993-1-2 (2005) and BS EN 1994-1-2 (2005). The critical temperature tables provided in the UK National Annex to these documents were adopted for columns. Once the critical temperature was calculated, the sections were allocated a thickness of fire protection in order to achieve exactly 120 minutes fire resistance. It was assumed that a uniform protection thickness was applied to the section (as is currently standard design practice)

This study purposefully remains within the paradigm of the standard heating curve. Throughout this paper the duration that any structural assembly is able to resist exposure to the standard temperature time curve is termed “fire resistance”; strictly, this is not a correct definition as fire resistance can only be defined in terms of the test setup and performance metrics associated with the relevant testing standard; nevertheless, to maintain simplicity this terminology is adopted herein.

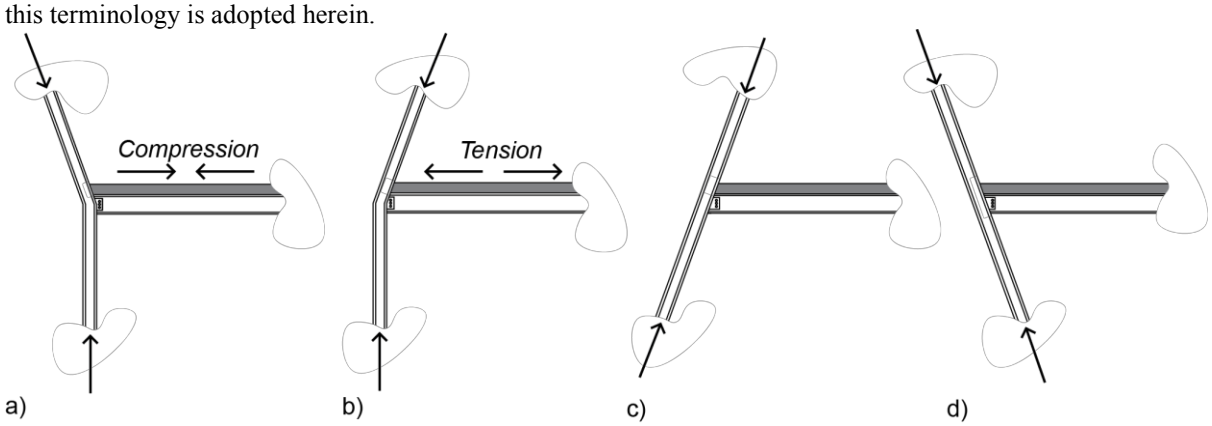

Figure 1a) GBC *compression*; b) GBC *tension*; c) Inclined *positive*; d) Inclined *negative*

Finite Element Representation

To facilitate the analysis of the structural arrangement, a finite element model was created of the GBC and the adjoining composite beam. The model was analysed in the finite element software LS-DYNA; key modelling assumptions were that: Hughes-Lui elements were used for the beams, and Belytschko-Tsay elements were used for the slab (LS-DYNA, 2012); composite action was assumed to be 100% throughout the analysis; beam to column connections were assumed to be pinned; Eurocode material properties within LS-DYNA were implemented (LS-DYNA, 2012).

In the finite element analysis (unlike the design case, where critical temperatures were defined in accordance with the Eurocode), a heat transfer analysis was conducted for each structural arrangement. Heat transfer in the beams was conducted in accordance with the lumped mass approach described in BS EN 1993-1-2. The temperature development in the web and flanges were considered individually.

To represent the thermal bowing and expansion of the slab, the heat transfer in the concrete slab was conducted using a one-dimensional finite difference method. The convective heat transfer co-efficient and emissivity were assumed in accordance with EN 1992-1-2; it was assumed that that concrete had 0% moisture content.

Results

Analysis of the base case models showed that the vertical and inclined columns exhibited similar behaviours, while the geometrically bi-linear columns show substantial differences. This can be observed both in term of time until failure when the assemblies were subject to standard heating, and the changes in deflection associated with different locations in the models.

The results from each of the base case models are illustrated in Figure 2.

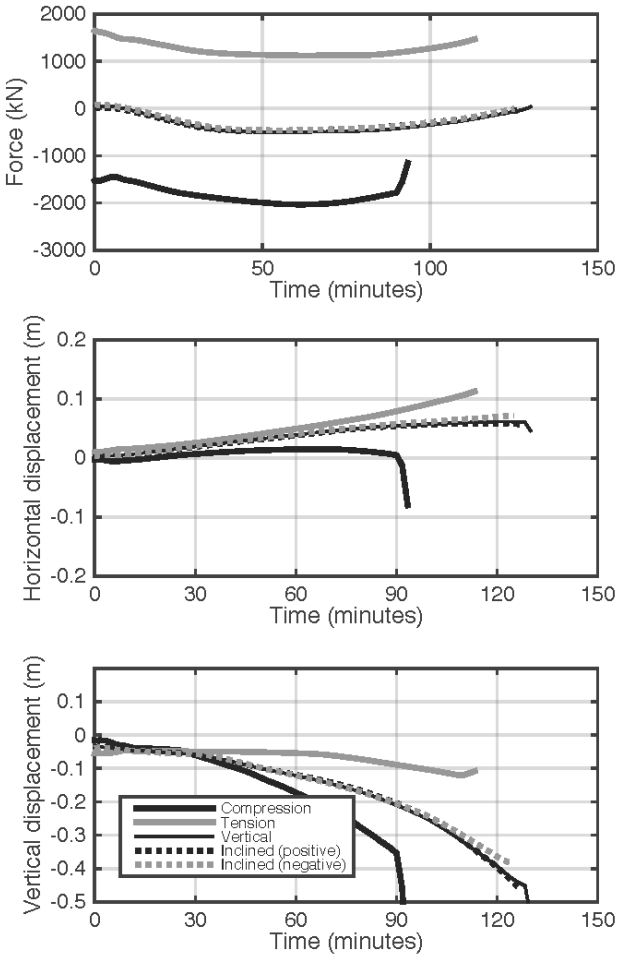

Figure 2a) Axial force in beam; b) horizontal displacement at column; c) vertical displacement in composite beam.

Discussion

The difference between the inclined/vertical columns and the geometrically bi-linear columns is due to the high forces induced in the composite beam in ambient conditions. Under fire conditions these cause dramatically different behaviours to occur. Since the behaviour of inclined and vertical columns is fundamentally very similar, inclined columns will not be discussed further in this paper.

Where compression is induced in the composite beam at ambient, the sagging associated with thermal bowing and loss of stiffness at high temperature results in an increased moment within the beam due to the P-delta effect. This results in the formation of a plastic hinge in the beam and then failure of the perimeter column. Conversely, where tension is induced in the composite beam at ambient, the deflection in the composite beam is significantly reduced. However, the expansion of the floorplate leads to an increase in horizontal expansion at the perimeter column, (and therefore a corresponding increase in column moment). Ultimately this leads to failure within the perimeter column. These are illustrated in Figure 3.

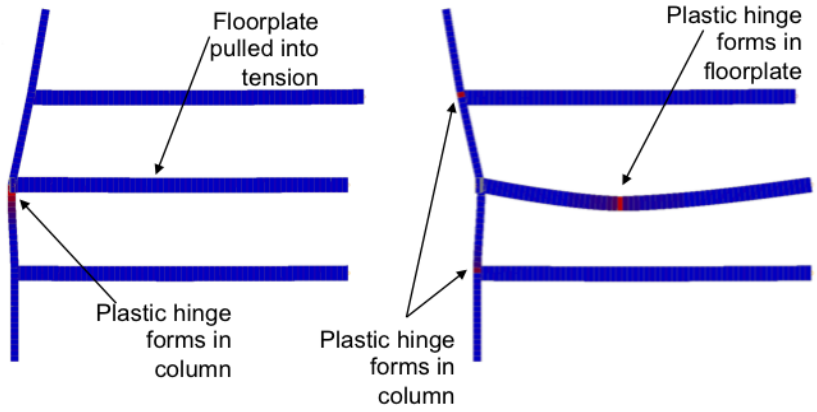

Figure 3Failure modes for geometrically bi-linear columns

SENSITIVITY

The sensitivity of the geometrically bi-linear columns to a range of parameters were assessed. These were as follows:

- Span. The span was varied between 10m and 20m at intervals of 2.5m. This range of values is representative of the span lengths that are typically use in contemporary construction.
- Angle of inclination. The angle of inclination was varied between -15 degrees and +15 degrees at intervals of 5 degrees. This range of angles was informed by previous studies by the authors (Law et al., 2015) and was found to encompass a wide range of different structural behaviours.
- Number of stories. The number of storeys above the fire floor was varied between 10 and 50 at intervals of 10 storeys. This significantly affects the magnitude of the axial force that is transferred into the floorplate.
- Utilisation. Section utilisation (in terms of maximum mode of loading) was varied from 75% to 95% at 5 percentage point intervals. This represents the range of utilisations that are frequently adopted as designs develop from concept to final.

The results are shown in Figure 4 and are expressed in terms of duration that stability is maintained when the assembly is subject to standard heating. These results clearly demonstrate that the fire resistance of a GBC assembly can be significantly lower than both: the specified fire resistance for the individual members; and the fire resistance achieved by an assembly with a vertical column. It was found that:

- Angle of inclination had a relatively strong influence on the behaviour – particularly for compression arrangements. A variation of -15° caused a maximum reduction in fire resistance of ~40%; a variation of +15° caused a maximum reduction in fire resistance of ~20%.
- Span had a relatively strong influence on behaviour. Doubling the beam length resulted in a maximum ~35% reduction in fire resistance.
- Target ambient utilisation had a relatively weak influence on behaviour. A 20% increase in utilisation resulted in a ~10% reduction in fire resistance period.
- A variation from 10-50 storeys induced a reduction ~20% reduction in fire resistance.

The GBC “compression” cases induced the worst case behaviour due to the run-away failure associated with the developing moment in the composite beam. The P-delta effect associated with the compression case is compounded by increasing span; increasing number of storeys; and to a lesser extent increasing utilisation.

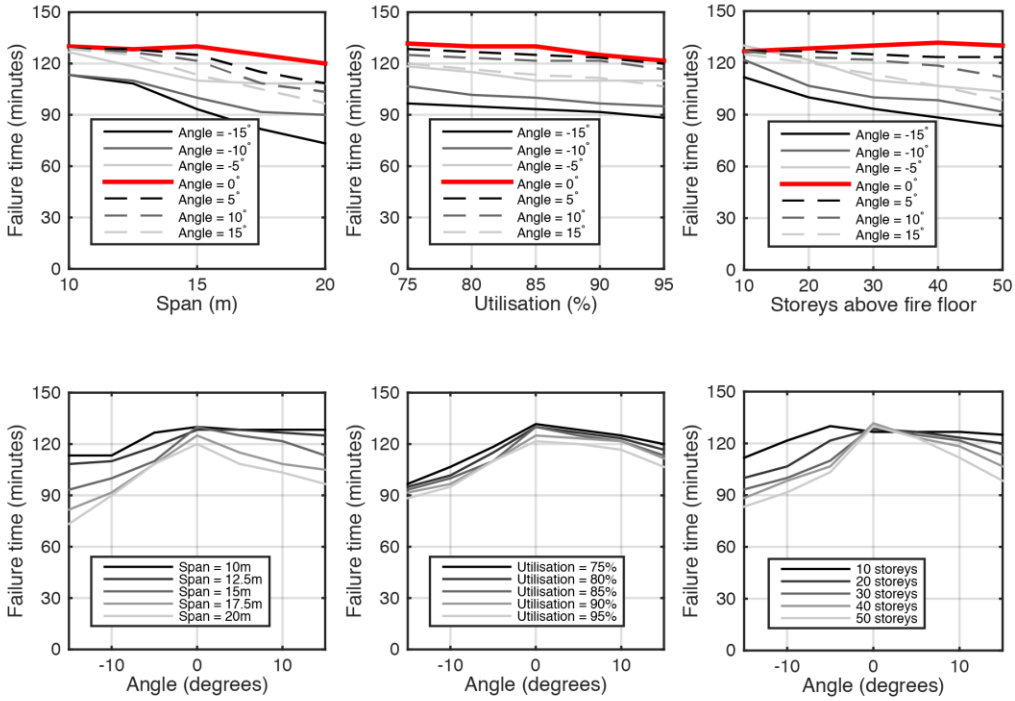

Figure 4Results of sensitivity study – expressed in terms of time to failure when exposed to the standard heating curve

MITIGATION

Many of the GBCs described above perform very poorly when compared against straight vertical columns. They do not achieve the specified fire resistance because the structural arrangements and their interaction during fire are outside the scope of standard furnace testing and associated guidance.

It is the authors' view that, during design, a structural fire engineering review must be undertaken to address the increased likelihood of failure associated with such columns.

There are several options available for mitigating the behaviours that have been observed. Any of the above parameters may be adjusted to "design out" the observed failure modes. Alternatively (or where redesign is not possible), the critical temperature of the individual elements could be adjusted to reflect the interactions that occur during a fire. This is termed and *assembly critical temperature*.

In the event that the structural design is fixed, one of the more effective methods for mitigating the behaviours that have been observed is to reduce the temperature in the main beam. This effect is threefold:

1. It reduces the thermal expansion and therefore the destabilising forces associated with column pull-out;
2. It increases the stiffness within the main beam, and therefore reduces the extent to which the column is pulled in; and
3. It reduces the overall deflection in the main beam and therefore minimises the P-delta effect associate with the failures described above.

The critical temperatures for each element are a function of the specific structural arrangements. Therefore to conduct an exhaustive quantitative analysis using a finite element model of all the possible arrangements is prohibitive. To verify that any design is appropriate, a finite model similar to that described above – but based on the proposed structural design – is likely to be required. For the compression analyses, it is also possible to create a simpler design methodologies founded on basic structural mechanics.

The following section develops a series of formulations that can be applied in design as a first pass to estimate the critical temperature for the main elements for the compression case. The results can then be checked and refined using a more detailed finite element modelling.

Compression Formulation

Previous work by Lange et al. (Lange et al., 2012) developed a series of equations to describe beam failure under fire conditions. In the formulation for a weak floor failure mechanism developed by Lange et al., failure occurred in an unheated floor plate; in the GBC compression scenarios, the beam failure occurs on the fire floor. Consequently, to apply these equations, they must be extended to accommodate the effect of heating on the failure floor.

The total moment in the beam is the sum of the moment due to the applied vertical loads on the beam (M_ω) and the moment due to the applied load (M_N). For the purpose of this study, it will be assumed that the applied load is uniformly distributed.

$$M_{net} = M_N + M_\omega \tag{1}$$

The moment due to the applied load (N_x) is a function of the deflection of the beam (equation 2); where δ_y is the deflection generated by the applied axial load, and d is the deflection due to the distributed load, and thermal curvature.

$$M_N = N_x(\delta_y + d) \tag{2}$$

Following Lange et al. (Lange et al., 2012), this can be formulated as follows:

$$\delta_y = \frac{Cd}{1-C} \tag{3}$$

Where:

$$C = 0.3183\frac{L^2 N_x}{\pi K_{net}} \tag{4}$$

And

$$d = \frac{5\omega L^4}{384K_{net}} + \partial_T \tag{5}$$

In equation 5,K_{net} is the effective stiffness of the composite beam and may be approximated (for the fire limit state) following Arya (Arya, 2009). This results in:

$$K_{net} = E_\theta\left(I_g + \frac{B_e D_s^3}{12\alpha_e} + \frac{AB_e D_S\ (D_S+D)^2}{4(\alpha_e A+B_e D_S\ )}\right) \tag{6}$$

where E_θ is the temperature dependent stiffness of steel; I_g is the second moment of area of the steel section; B_e is the effective breadth of the slab; of the concrete section, D_s is the depth of the concrete; α_e is the of the concrete; A is the area of steel and D is the depth of the steel section. It should be noted that in calculating temperature dependent stiffness, $\alpha_e$is temperature dependent (i.e. dependant on the relative temperature of the concrete and steel). This formulation is visualised in Figure 5.

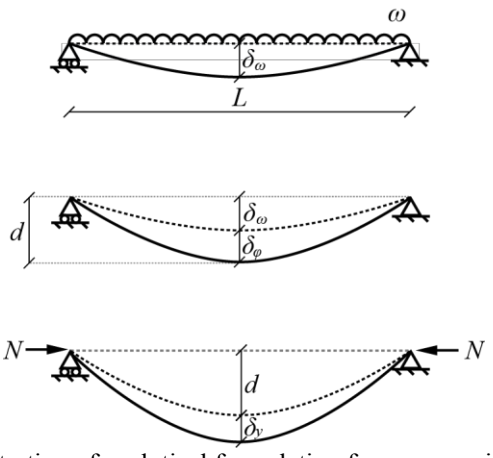

Figure 5Illustration of analytical formulation for compression assembly

In equation 6, the term δ_T has been added to account for the effect of curvature due to thermal expansion. Assuming uniform curvature along the length of the beam, this can be calculated as described as:

$$\partial_T = \frac{1}{\phi}\left(1 - \cos\left(\frac{\phi L}{2}\right)\right) \tag{7}$$

where L is the length of the beam, and ϕ is the thermal curvature. For a composite section, thermal curvature is difficult to define simply – as it is a function of both the temperature time history of the thermal exposure, and the thermal properties of the section. Nevertheless, it may be approximated and the formulation described by Usmani (Usmani et al., 2001) is adopted in this paper as follows:

$$\phi = \alpha\left(\frac{T_2 - T_1}{d}\right) \tag{8}$$

To reflect the fact that there is a non-uniform gradient, T_2 was taken as the temperature of the steel and T_1 was assumed to be ambient; d was assumed to be the difference from the centre of the beam to the centre of the slab.

Sectional Capacity

The above is sufficient to provide a crude estimate the moment in the beam due to the applied loads and thermal conditions. However, to be useful in design, the results must be linked to a prediction of moment capacity. This calculation must be completed to incorporate M/N effects, as these are significant. An approach for calculating the M/N capacity was implemented in accordance with BS EN 1994-1-2 (and therefore the design assumptions outlined in section 3).

Comparison

Implementation of this approach allows both the loading and capacity during heating to be estimated. Each value is calculated as a function of temperature, the point at which the applied loading exceeds the moment capacity is therefore the critical temperature. As all the results are simply a function of temperature, there is no direct link to duration of fire exposure.

To permit a comparison between the finite element analyses above, the predicted assembly critical temperature and the observed temperature at failure in the finite element model may be compared. The failure temperature is measured in the bottom flange of the beam. Results for compression models are provided in Figure 6.

The comparison shows that most of the data falls within ±10% of agreement. A best-fit line plotted through the origin records a gradient of 1.0 and an R^2 value of 0.9; a best fit line minimising R^2 records a gradient of 0.8. As such, lower predicted failure temperatures lead to over-conservative results, and higher predicted failure temperatures lead to under-conservative results. Where the predicted temperatures were found to be unconservative, there was consistently less than 10% error.

The strong correlation in Figure 6 indicates that for the compression case the temperature of the lower flange of the composite beam controls both the level of loading and the capacity of the composite beam. Consequently, lower flange temperature controls the failure time of the assembly.

Figure 6a) Comparison of predicted failure temperature (finite element model), and predicted failure temperature (analytical model) ; b)Comparison of predicted failure temperature (finite element model), and predicted failure temperature (analytical model).

APPLICATION

This paper has demonstrated that GBCs may not deliver their specified performance if additional measures are not taken to mitigate the effects associated with assembly behaviour during fire.

It has been proposed that the critical temperature of individual elements in the assembly may be adjusted in order to increase the overall fire resistance achieved by the structural assembly. To demonstrate the efficacy of this protection strategy, it was implemented within the same structural arrangements described above.

The critical temperature for the compression models were estimated based on the results from the analytical model described above and the critical temperature for the beam and the column in the tension assemblies were defined based on the temperature at failure in the original finite element model.

Figure 6b shows a comparison of the fire resistance achieved for *compression* assemblies before and after the *assembly critical temperature* approach was implemented. Figure 7 is split into several regions. These are described below:

- Region A represents assemblies where the *assembly critical temperatures* approach increased the fire resistance achieved from <120 minutes to ≥120 minutes. These data represent a successful protection strategy; ~87% of the data fell into this category.
- Region B represents assemblies that achieved ≥120 minutes both the original and modified design. These data represent a successful protection strategy; ~9% of the data fell into this category.
- Region C represents assemblies that originally achieved ≥120 minutes FR, but following the proposed modified design achieved <120 minutes. Data in this region would represent a failure of the fire protection strategy – no data were recorded in this region.
- Region D represents assemblies that originally achieved <120 minutes, and following the *assembly critical temperatures* approach achieved even lower fire resistance – no data were recorded in this region.
- Region E represents assemblies that originally achieve <120 minutes, and following the *assembly critical temperatures* approach delivered improved fire resistance. ~4% of the data fell into this category.

These results show that the strategy for improving the performance of the compression assemblies is highly successful – with all but two of the models delivering in excess of the specified 120 minutes fire resistance.

CONCLUSIONS

The conclusions of this study are:

- For vertical and inclined columns, the existing Eurocode single element critical temperature approach delivers an assembly that fails at a time roughly equivalent to the specified fire resistance;
- For geometrically bi-linear column assemblies, the existing Eurocode single element critical temperature approach frequently delivers a structure that (when subject to standard heating) fails at a time substantially before the specified fire resistance;
- The failure of geometrically bi-linear column compression assemblies is governed by the temperature of the lower flange of the composite beam;
- A calculation approach has been developed to allow the failure temperature of geometrically bi-linear column compression assemblies to be defined;
- Geometrically bi-linear column tension assemblies are more complex and require consideration of column stiffness as part of any formulation to define the *assembly critical temperature*.

ABSTRACT

This paper presents a case study into the use of advanced finite element analysis as part of a performance based structural fire engineering design for a multi-storey steel framed building in New Zealand. The building is a multi-storey steel framed building with long span cellular beams supporting composite concrete floor slabs. As part of the building design, the secondary steel beams and composite columns of the structure are proposed to be unprotected. A series of advanced finite element analysis using the SAFIR finite element programis carried out to test the robustness of structure without passive fire protection for the secondary beams and composite columns. The numerical modelling features thermal modelling of the structural elements and 3D structural modelling of the heated elements to test the behaviour of the long span beams under realistic compartment fires. The analysis utilizes non-linear temperature dependent materials to consider realistic behaviour of the structural response under a fully developed compartment fire, including the rapid thermal loading during flashover and the cooling phase of the fire. The analysis is able to consider the different realistic structural responses during the course of the fire including contraction during the cooling phase and lateral buckling of the cellular beams in fire. This paper shows how such an analysis can be applied by consulting engineers on a realistic building design to demonstrate a robust design for a steel framed building with unprotected structural elements whilst providing savings with reduced amount of fire protection to the structure.

KEYWORDS

Concrete filled steel tubes, cellular beams, composite construction, finite element analysis, fire, structural fire engineering, steel.

INTRODUCTION

Fire resistance in steel framed structures is conventionally achieved through the application of passive fire protection to the structural elements. The purpose of the insulating passive protection is to prevent high temperatures from forming within the structural element which will compromise its load bearing capacity. Until the 1990s, it was generally perceived that unless fully protected, an entire steel structure could suffer significant or catastrophic damage in a fire.

Part of this perception originates from standard fire testing in furnaces for structural elements which showed the poor behaviour of unprotected steel elements tested in isolation. These furnace tests, originally developed in the early 1900's, are useful for providing a benchmark of structural fire behaviour of individual elements under laboratory conditions. The standard fire was established based on what the American Society of Testing Materials described as a worst-case time-temperature relationship to be expected during a fire. The curve has remained essentially unchanged since and has been adopted by numerous countries around the world (ASCE 2009).

Such furnace tests are only useful for benchmarking the performance of isolated structural elements of limited size. However, these tests do not provide an accurate representation of how structural elements within a real building respond under a realistic fire. For example, the test furnace structural supports do not represent those found in modern real buildings and the tested specimens are usually shorter than the beam and column spans that are built in modern structures. The furnace tests also do not consider the cooling phase of real fires which is important at these can result in high contraction forces when the elements, particularly beams, cool down.

STEEL STRUCTURES IN FIRES

Since the 1990's, significant experimental and analytical research has been undertaken in Europe (SCI 2000, Nadjai et al 2011) and Australia (Proe et al, 1994) into the structural fire performance of whole steel buildings under real fire conditions. This research showed that, if designed to mobilise multiple redundant load paths and other forms of load resisting mechanism, composite steel structural frames do not need to be fully fire protected and that some of the elements, such as the secondary beams, can be unprotected.

ADVANCED NUMERICAL METHODS

The research in Europe in the 1990's has also led to the development of advanced numerical models for analysing the highly complex nature of structural fire behaviour (Huang et al 1996, Gillie et al 2001, Izzuddin et al 2002). These numerical models, based on the finite element method, have provided engineers and researchers with better insights into the physics of structural behaviour in fires.

These programs consist of either bespoke finite element programs such as SAFIR (Franssen 2005) or Vulcan (Huang et al 2004), which have been developed specifically for analysing structures in fire, or commercial general purpose finite element programs such as *ABAQUS* or *ANSYS*, which have been modified for this purpose. These programs can consider the highly non-linear behaviour of structures in fire, including large displacements and non-linear temperature dependent material properties, as well as the thermal expansion and contraction of the structural elements at elevated temperatures. The programs can consider the loss of strength and stiffness in materials, damage, and recovery of strength and stiffness when the materials cool down.

Such programs have progressively become numerically more stable and robust, and coupled with increasing computing power, have provided consulting engineers with the ability to apply such analysis on commercial building and infrastructure projects.

Using advanced analyses, the inherent fire resistance provided by the building as a whole can be analysed, considering the actual structural design of the building, and the fire and structural loading conditions. Using such tools, consulting engineers can test the robustness of the structure in fire conditions. The outcomes of the analysis can give insights into the performance of a structure in fire conditions, which would normally not be possible with standard prescriptive designs or with simpler analysis methods. For example, such programs can include the effect of significant compression restraint forces which form during the heating phase as well as tension forces during the cooling phase. These forces can cause premature failure of the structural elements and the ability to detect such forces allows engineers to be able to improve their designs to mitigate failure. Such insights provide project stakeholders (Certifying authorities, architects, insurers) with better understanding of the true structural fire performance rather than a piecemeal approach to achieving fire resistance.

The application of such analyses also has other significant benefits for optimising or eliminating fire protection in steel framed buildings. This provides better building aesthetics by having exposed steel elements. This also reduces waste of materials and time through the reduction of unnecessary fire protection and also results in significantly less capital and life cycle costs, and shorter construction period. Advanced analysis has also been applied to concrete structures to reduce and optimise the thicknesses of reinforced concrete slabs, to quantify the residual strength of fire damaged structures and to design the structural elements for resisting high challenge fires such as hydrocarbon fires.

APPLICATION OF STRUCTURAL FIRE ENGINEERING

An advanced analysis was undertaken for the new Christchurch Justice and Emergency Services Precinct in New Zealand. The Precinct consists of three buildings, a Justice building, an Emergency Services building and a parking building for operational vehicles. The Justice and Emergency Services Building is a five storey building, consisting of four moment-resisting steel framed structures that are built on a large podium structure (Figure 1). The moment resisting frames consist of concrete filled steel CHS columns and I-Beams. The structural frame also features long span cellular beams and I-beams arranged in a regular grid, which in turn support concrete-metal deck floors.

The precinct has stringent requirements for structural robustness for seismic and fire resistance, due to the Emergency Operations Centre located in the Emergency Services Building, which will be a centre for emergency response and coordination in the event of a natural disaster. The structural elements are required to achieve a 60 minute fire resistance rating. Conventionally, all the columns and beams would need to be protected with a fire

resisting protection material such as intumescent paint or SFRM (Sprayed Fire-Resistive Material) to achieve this fire rating. However, an alternative design was proposed where the secondary steel beams and the composite columns were not protected with passive fire protection.

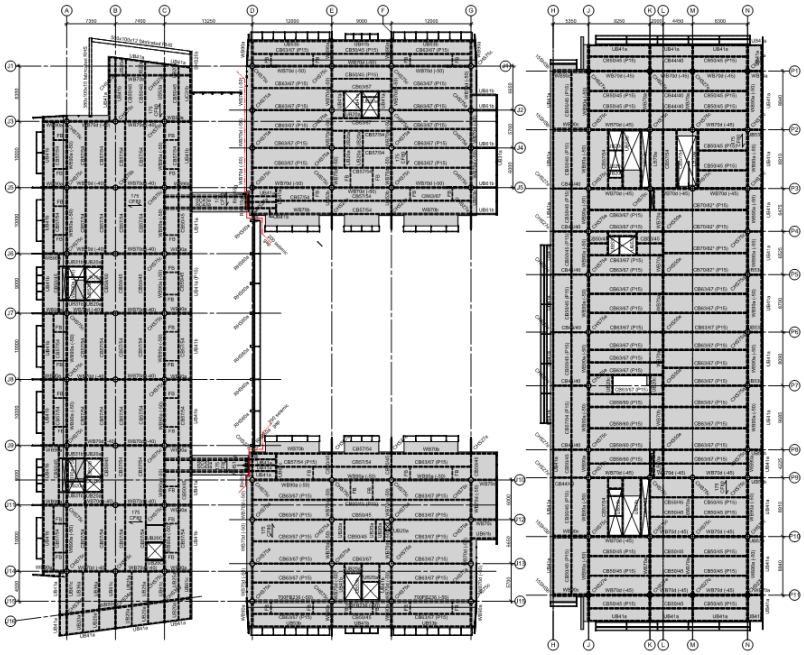

Figure 1: Beam layout on typical floor.

METHODOLOGY

A series of analyses using non-linear finite element analysis was carried out to test the robustness and stability of the structure in fire conditions and to quantify if the steel hollow section columns and the secondary cellular beams could be unprotected. The analysis consisted of detailed heat transfer analysis of the structural components under exposure of a realistic fire and 3D structural modelling of the frame to determine the structural response. The numerical analysis was undertaken using the SAFIR finite element program.

SAFIR (Franssen 2005, 2012) is a bespoke non-linear finite element program that has been developed at the University of Liege, Belgium, for the thermal and structural analysis of concrete, steel and composite structures in fire conditions. The program considers large displacement behaviour, non-linear temperature dependant material properties, and thermal expansion and contraction of materials at elevated temperatures. The program incorporates pre-defined non-linear material properties, based on the Eurocodes, but also allows user-defined material properties for the analyses. The program contains a range of structural finite elements, such as beam elements and shell elements, for modelling civil engineering problems. The structural finite elements can consider non-linear temperature distributions across the cross section of the structural elements (e.g.: across beams, columns and slabs).

DESIGN FIRE

A realistic fully developed office fire was considered for the structural fire analysis. The temperature-time fire curve was defined based on the Eurocode 1 Parametric Fire (BSI 2009) definitions. The Parametric Fire represents a fully developed fire, whereby the rate of the fire growth, peak temperature and burning duration are considered through the amount of ventilation, compartment linings and the expected fuel load. The significance in using a realistic fire is that it provides a more realistic representation of the peak temperatures and duration of a fire in the building. In addition, the cooling of the elements during the decay phase of the fire would impose axial tension forces on the beams and the connections; this is a key structural phenomena which needs to be considered to check the adequacy of the beam connections. The design fire is shown in Figure 2 which is based on an office occupancy.

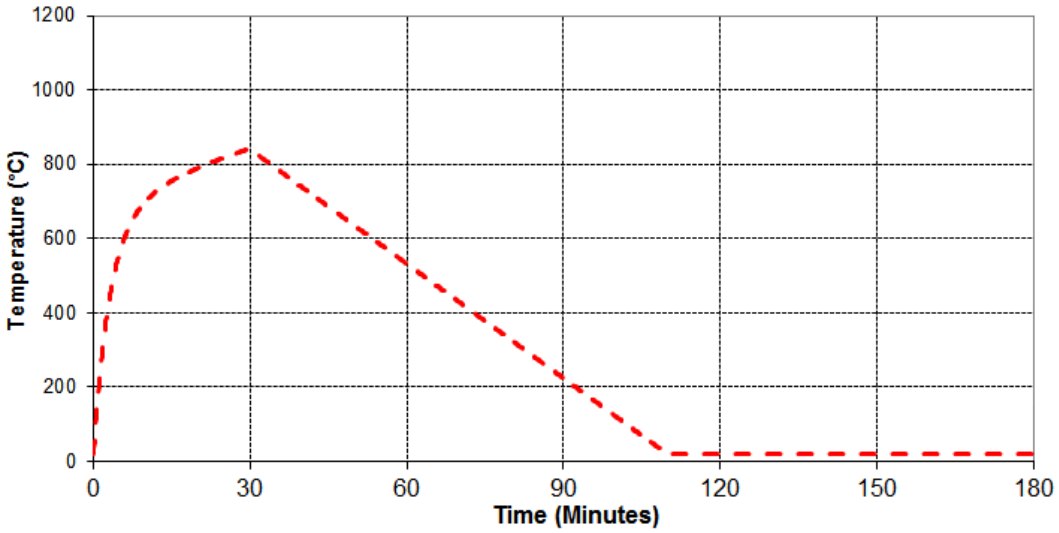

Figure 2: Design fire for office

Heat Transfer Analysis

Using the defined design fire, specific heat transfer analysis is undertaken for all the structural elements (Figure 3), including the protected and unprotected beams, floor slab and composite columns. The cross section of each heated structural element is discretised into finite elements, as shown in Figure 3. Each finite element within the cross section is assigned with its specific material property.

The heat transfer utilises the convective and conduction coefficients based on Eurocode 1 (BSI 2009). The heat transfer analysis calculates the temperature distribution across and thermal gradients across the structural section as a function of time. Non-uniform temperature gradients in the elements can result in deflections and bending moments forming in the beams and slabs, so an accurate thermal analysis is needed to be able to accurately determine the structural fire behaviour. The results of the heat transfer analysis are used to determine the strength and stiffness degradation in the elements during the implementation of the structural analysis.

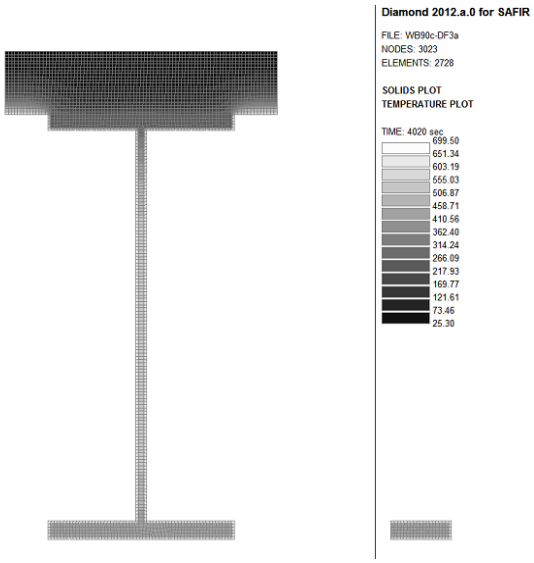

Figure 3: Typical heat transfer calculations undertaken in SAFIR for a composite beam.

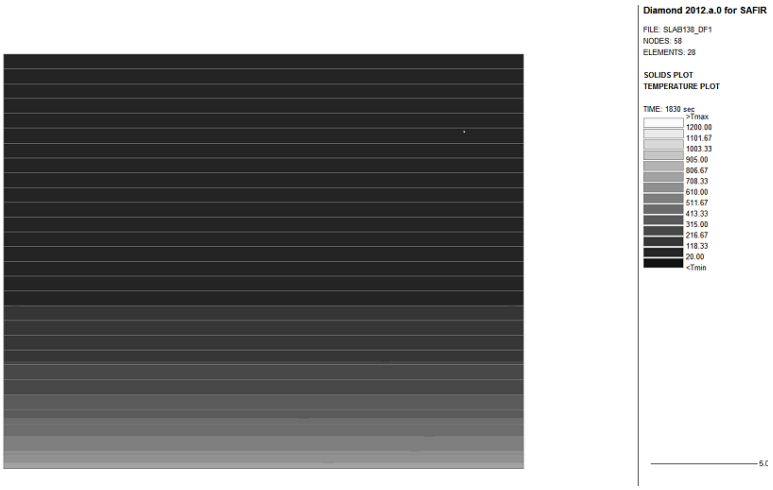

Figure 4: Temperature profile across equivalent 138mm flat slab at 30mins (Peak fire temperature).

The composite floor construction is modelled as a reinforced concrete flat slab with an effective thickness of 138mm, for simplification of the structural analysis. The effective thickness of the slab is determined in accordance with Eurocode 4 Part 1-2:2005 (BSI 2005). The flat slab is still able to represent the structural fire behaviour of the composite floor because under fire exposure, the metal deck will have negligible strength and stiffness and the composite floor will behave similarly to that of a reinforced concrete flat slab.

Figure 4 shows a finite element heat transfer model and the temperatures across the equivalent flat slab at 30 minutes into the design fire, which corresponds to the peak fire temperature. The temperatures across the section of the slab at various stages of the fire are shown in Figure 5. The cross section of the flat slab is represented as a rectangular slice across the slab thickness. The slab is modelled using rectangular solid finite elements. The thickness of each of the solid elements is approximately 5mm thick.

The thermal properties of the concrete are based on normal weight siliceous aggregate concrete based on EN1992-1-2 (BSI 2009), which is referenced in NZS3101 for assessing fire resistance. Spalling of the concrete, resulting in the loss of concrete cover, is not modelled. However, the provision of the metal deck, is expected to mitigate loss of cover due to spalling.

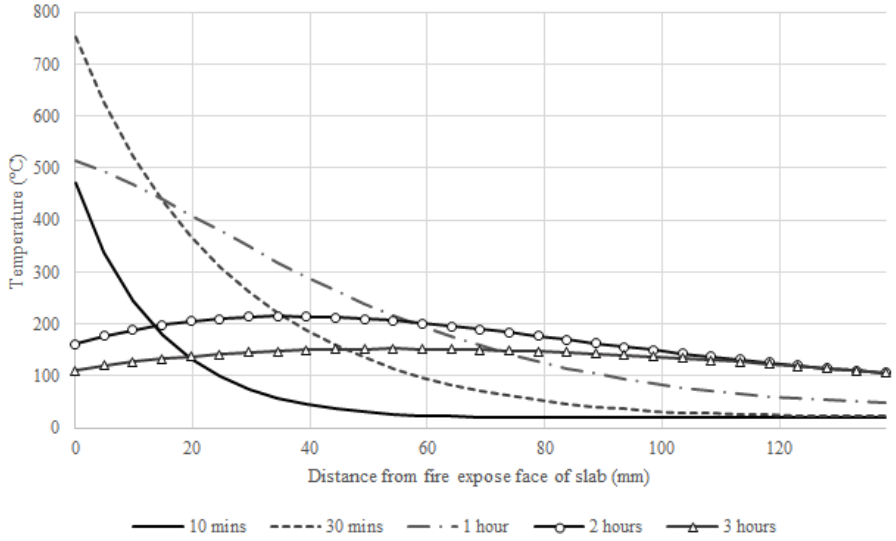

Figure 5: Temperature distribution across the flat slab under various stages of the design fire

STRUCTURAL ANALYSIS

The structural analysis of the frame is carried out based on the thermal analysis results of the members, incorporating the physical loads on the structure. The structural analysis calculates the structural response, including the thermal expansion strains, deflections and forces of the heated structural elements based on the outputs of the thermal analyses. It considers the loss of strength and stiffness, and thermal expansion and contraction of the elements as a result of high temperatures. For this project, different sub-models were analysed, instead of a large single structural model which covers all the conditions; this is to reduce the analysis time as this approach is more efficient for delivering results relevant to the design.

Figure 6 shows the plan view of one of the structural subassemblies which were modelled using the SAFIR structural fire analysis. The purpose of this model is to assess the structural fire performance of a typical structural configuration with the unprotected secondary beams and composite columns.

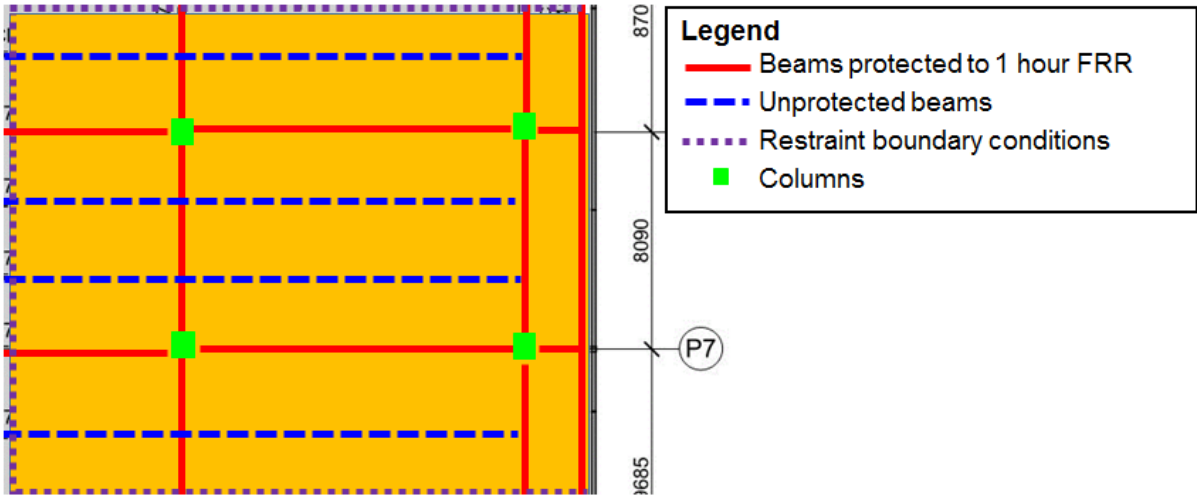

Figure 6: Plan view showing the extent of a structural model

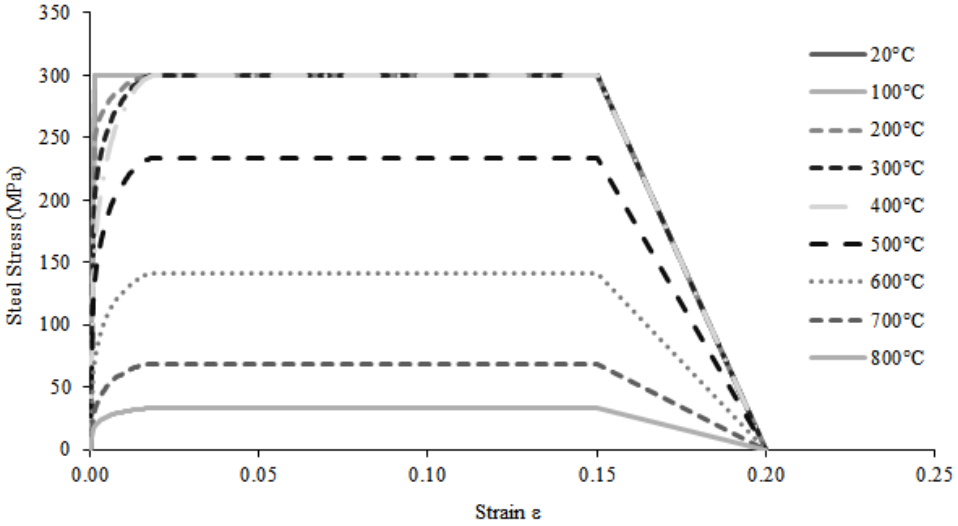

Figure 7: Stress Strain Curve for Structural Steel at Elevated Temperatures

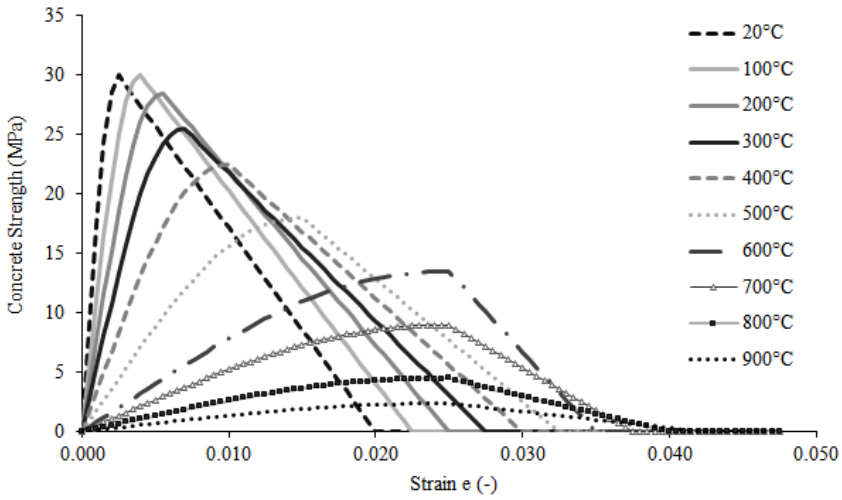

Figure 8: Stress Strain Curve for Concrete at Elevated Temperatures

Non-linear temperature dependant material properties are used in the structural analysis. Figure 7 and Figure 8show the typical temperature dependent stress-strain curves of the steel and concrete (in compression) that have been utilized in the calculations. These properties are based on Eurocode 3 (BSI 2005) and Eurocode 2 (BSI 2004), respectively. The effect of cracking of concrete on the stiffness of the structural elements is considered in the structural fire analysis. Cracking in the concrete elements are modelled based on the smeared crack model.

To simulate the effects of lateral buckling of unprotected long span cellular beams in fire, a modified material property is used for the bottom tee of the cellular beams. The material has the same properties as structural steel (based on Eurocode 3) up to 500°C but loses its material properties between 500°C and 600°C. This modified material has been used by Gernay and Franssen (2010, 2013) in SAFIR to simulate unprotected long span cellular beams in fire and has shown good agreement when compared to full scale experimental fire tests.

The modelling of the lateral buckling of the bottom tee, and the associated loss of stiffness and strength contribution of the bottom tee is critical. If this phenomena is not taken into account, the strength and stiffness of the floor system would be overpredicted, resulting in unconservative results.

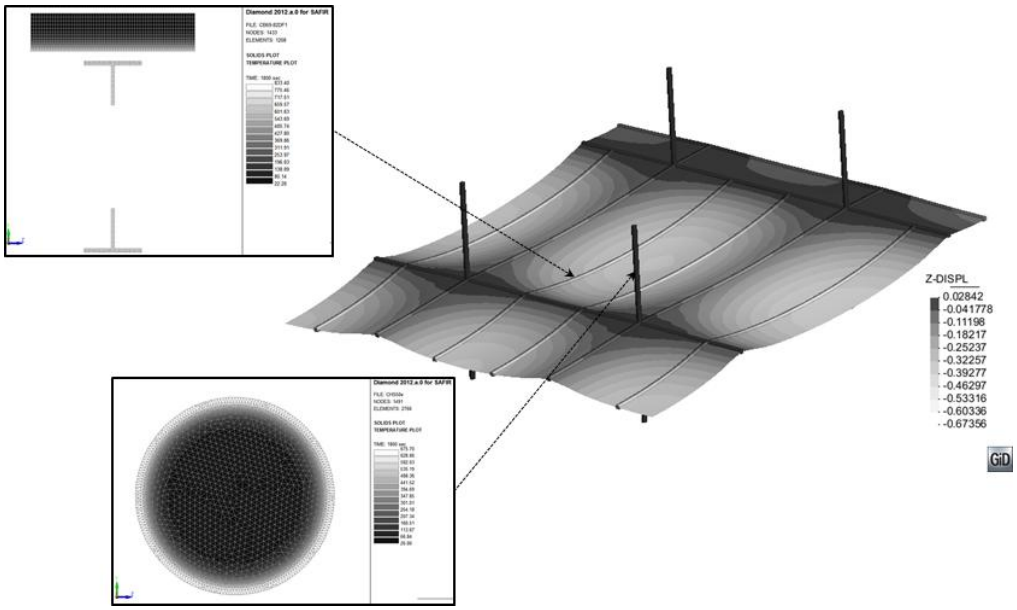

Figure 9: Deflection contour results of the 3D analysis of the structural steel frame with unprotected long span secondary cellular beams and composite columns shown at the peak fire temperature (30 minutes).

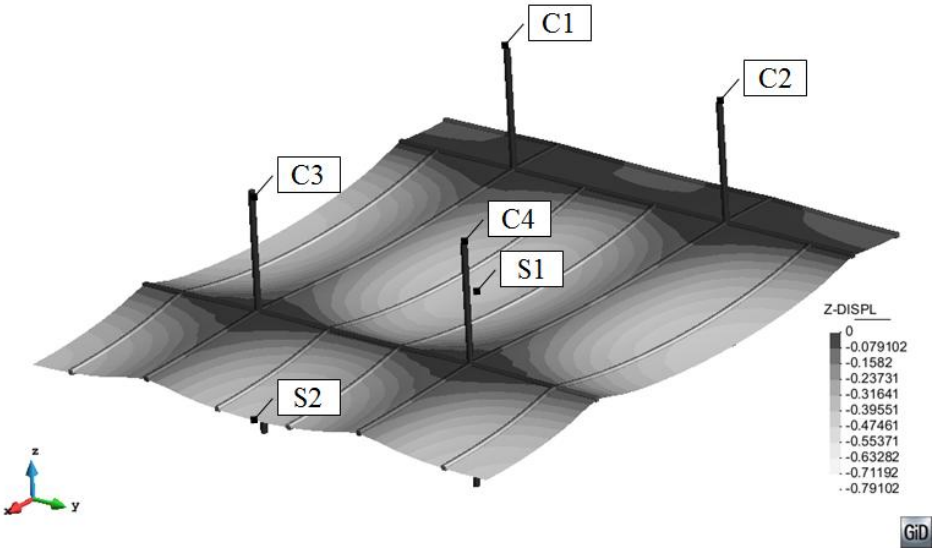

Figure 10: Deflection contour results of the 3D analysis of the structural steel frame at the end of the analysis (3 hours).

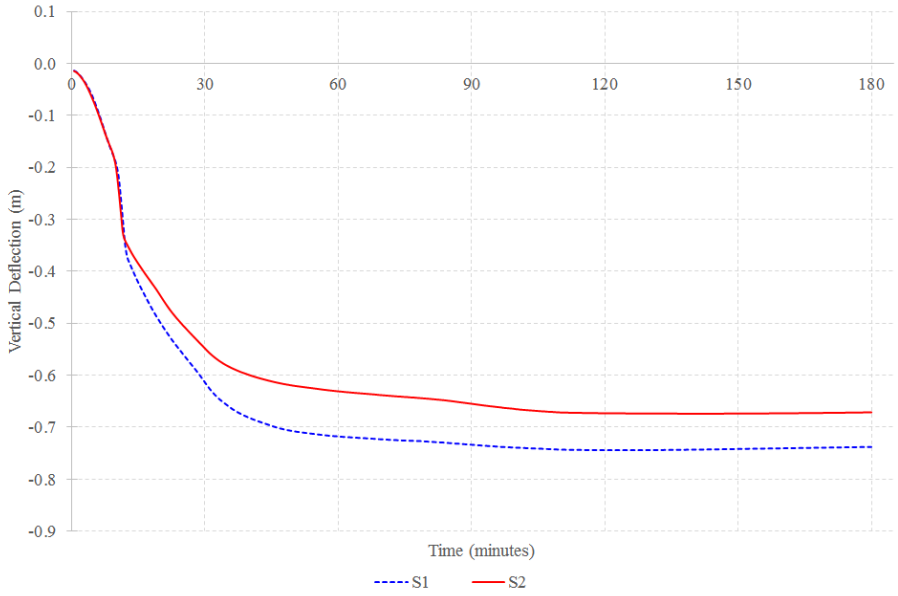

Figure 11 Variation of midspan vertical deflections with time at midspan locations S1 and S2 (Refer to Figure 10 for locations)

Figure 9 and Figure 10 shows the vertical deflections of the structure at the peak of the fire temperature (30 minutes) and at 3 hours, when the simulation was terminated. The analysis was performed for up to 3 hours, even though the fire had fully decayed after 2 hours, to capture the cooling of the structural elements. At the end of the simulation, the beams do not recover to their initial undeformed state due to permanent plastic deformations in the unprotected beams and the slab (See Figure 11). However, the analysis results show that the structure remained stable despite the large deflections in the floor structure. The results indicate that there was no runaway failure of any part of the structure. The stability of the structure is also depicted by the relatively small axial movements of the columns, as shown in Figure 12. The difference in the amount of axial movement of the columns is attributed the amount of axial load applied to the columns.

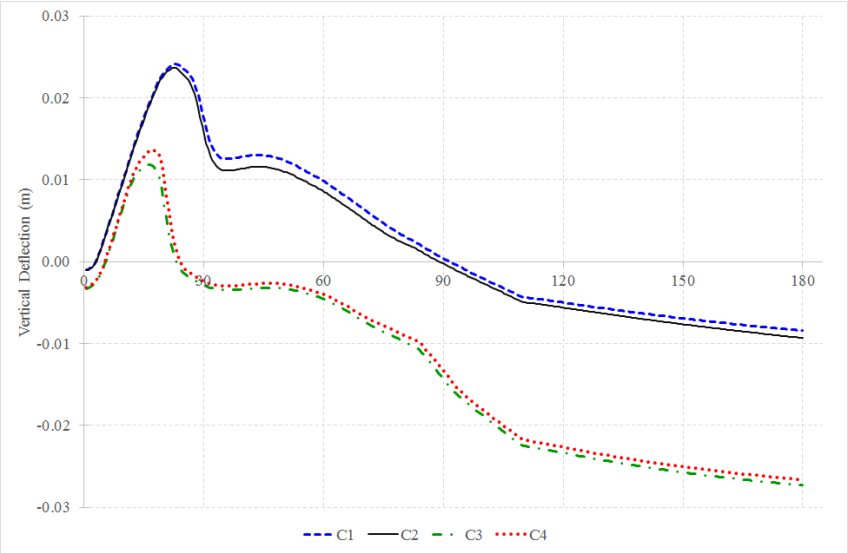

Figure 12Variation of vertical deflections with time at the top of columns (Refer to Figure 10 for locations)

Connector elements were also modelled at the ends of the unprotected secondary beams. The connector elements were modelled with temperature dependent axial capacities with a failure limit of 20mm, corresponding to the deformation limit of the bolts in the connections. The analyses showed that the axial capacities of the connections was reached, however, the axial deformations did not exceed the connection deformation limits.

The ability of the floor construction with the unprotected secondary beams to resist the applied loads and the design fire is due to tensile membrane action forming in the slab. This behaviour has been demonstrated experimentally in fire tests (SCI 2000, Nadjai et al 2011). The loads on the floor are resisted by the slab reinforcing in the central (tension) region, which is balanced by the compression ring around the edges of the rigid structural bay. This mechanism allows the floor structure to remain stable even when the unprotected secondary steel beams within the bays have lost significant bending strength and stiffness. Figure 13 shows the distribution of membrane forces in the slab, forming tensile membrane action. The tension forces (light coloured lines) in the middle of the bays are resisted by the compression forces (dark coloured lines)forming around the perimeter of each bay. This is pattern of forces is consistent with the findings of numerical analyses by numerous researchers (Huang et al 1999, Lim et al 2004).

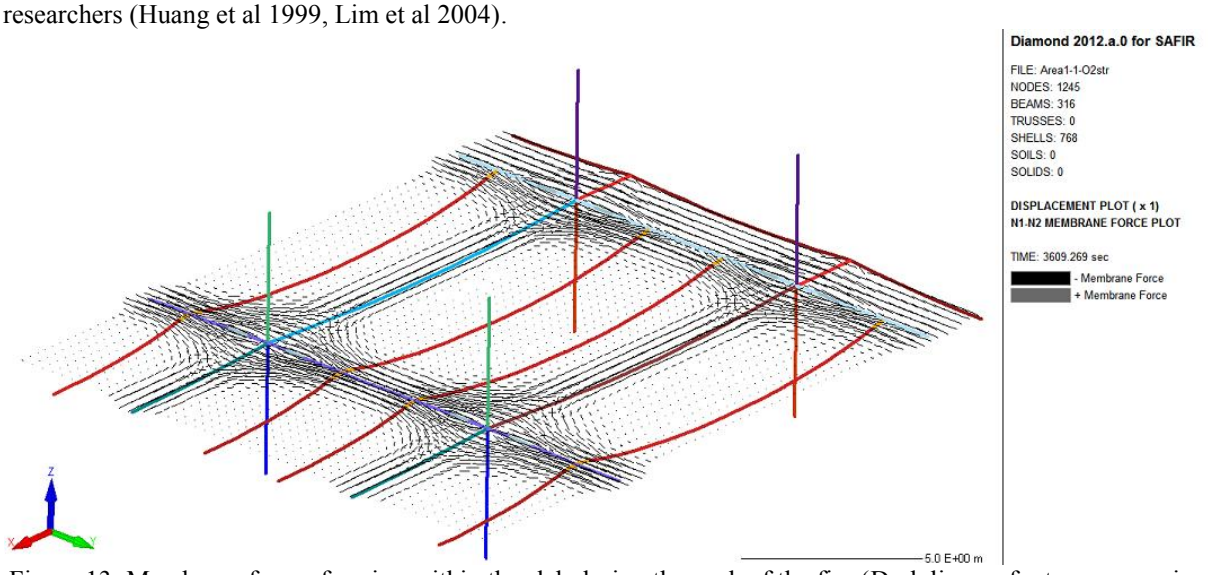

Figure 13: Membrane forces forming within the slab during the peak of the fire (Dark lines refer to compression membrane forces, light lines are tensile membrane forces).

This analysis demonstrated how a performance based analysis can be applied on a commercial project to provide a robust design by identifying structural weaknesses, but also enabled the structural design to be safely optimised, whilst avoiding over-design. The 3D modelling enabled different load resisting mechanisms to be included in the analysis, such as tensile membrane action, which would typically not be considered with simpler

calculation methods. The application of such an analysis provided cost savings to the project through the reduction of passive fire protection to the secondary beams and columns.

CONCLUSIONS

The ability to quantify the fire behaviour of structures has improved significantly over the two decades with the development of advanced numerical models. Such numerical models can now be utilised by engineers on projects to demonstrate a robust and optimised design. As shown in the case study in this article, the outcomes of applying advanced analyses on commercial projects have resulted in designs which achieve robustness as a whole structural system, and providing savings in fire protection and building materials and improved building aesthetics.

ABSTRACT

Sepiolite is a natural clay mineral consisting of magnesium hydrosilicate. High surface area and micropores which form micro structure of sepiolite play an important role for the sepiolite to be used as a binder in the construction sector. The adsorbed water molecules, which are located in the chemical composition of sepiolite, move away from the structure while temperature goes up. When the temperature reaches 950°C chemical structure of sepiolite becomes impaired. This behavior under high temperature of sepiolite supports the use in the construction industry. Pozzolans such as sepiolite have little binding effect on their own. Therefore lime or cement is used together. The use of lime and sepiolite together in the repair mortars for restoration of historic buildings is one of the recent studies. However authors didn't encounter a study on high temperature resistance of mortars added with sepiolite. In this study to determine the behavior of mortars at high temperature, mixtures are designed at different rates of sand/binder and sepiolite/hydraulic lime. Specimens were exposed to 400°C and 700°C. The effect of high temperature on the lime mortar was determined, with respect to the loss in unit weight, ultrasonic pulse velocity, compressive strength and bending strength. At the end of the test results, there wasn't any significant change in physical and mechanical properties of mortars up to 400°C. However above 400°C, negative effects were observed.

KEYWORDS

Sepiolite, hydraulic lime, high temperature, physical and mechanical properties.

INTRODUCTION

Sepiolite is a natural clay mineral consisting of magnesium hidrosilicate, belonging to the group of phyllosilicates (layered silicates). Slick-looking, fine-grained, earthy and layered sepiolite may be usually in white, cream, gray or pink color. Depending on its organic content, it can also be dark brown or nearly black (Sabah & Celik, 1999). The chemical formula of sepiolite, according to the model of Nagy and Bradley is $Si_{12}Mg_9O_{30}(OH)_6(OH_2)_46H_2O$ according to the model of Brauner and Preisinger is $Si_{12}Mg_8O_{30}(OH)_4(OH_2)_4$-$8H_2O$ (Karakaş, 2006). Sepiolite has a crystalline structure, comprising the Si-O tetrahedron and octahedral layers. Si-O tetrahedron is arranged up or down from the base plane of oxygen. The crystal structure of sepiolite is given in Figure 1 (Galan, 1996).

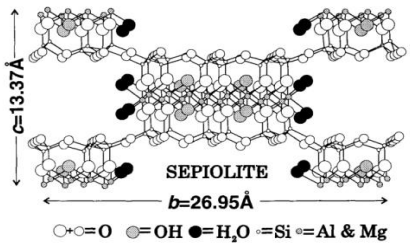

Figure 1 Structure of sepiolite (Galan, 1996)

Spain ranks first in the world in the production of sedimentary sepiolite. Sepiolite reserves of this country are between 15 and 20 million tones. Besides, in PRC economic sepiolite deposits are known to exist. Also in Turkey and in the United States sepiolite clay mining is done in small tonnages. Industrial or layered type sepiolite deposits which can be regarded as commercial product in Turkey are located in Eskisehir, Izmir, Bursa, Kütahya and Isparta. Layered sepiolite reserves in Eskisehir are around 57 million tons (Sabah & Celik, 1999; Tekin, 2004). High surface area and micropores and the zeolitic channels which form micro structure of sepiolite play an important role for the sepiolite to be used as supporting material in various sectors. The adsorbed and the zeolitic water molecules which are located in the chemical composition of sepiolite, move away from the

structure while temperature increases. When the temperature reaches to 900-950°C destruction occurs in the chemical structure of sepiolite (Martinez-Ramirez, Puertas, & Blanco-Varela, 1995; Pinilla Melo, Sepulcre Aguilar, & Hernández Olivares, 2014). The chemical composition of sepiolite is given in Table 1.

Table 1 Chemical composition of sepiolite (Sabah & Celik, 1999)

Composition (%)	Turkey	Spain	Japan	Madagascar	Australia	USA
SiO_2	**55.97**	**60.60**	**52.05**	**52.50**	**52.43**	**50.80**
Al_2O_3	**1.56**	**1.73**	**1.03**	**0.60**	**7.05**	**0.66**
Fe_2O3	**0.77**	**0.62**	**0.04**	**2.99**	**2.24**	**1.05**
MgO	22.81	22.45	23.74	21.31	15.08	16.18
Na_2O	0.12	0.16		-	-	8.16
K_2O	0.27	0.58		-	-	-
FeO			0.01	0.70	2.40	1.51
MnO	0.02			-	-	-
TiO_2	0.12			-	-	-
CaO	0.57	0.40	0.51	0.47	-	0.12

Pozzolans such as sepiolite have little binding effect on their own. Therefore lime or cement are used together. Especially prior to the discovery of cement, lime is known to be a widely used construction material (Martinez-Ramirez et al., 1995). CaO is obtained by calcination of limestone. CaO reacts with the water and $Ca(OH)_2$ is transformed (Böke, Akkurt, & İpekoğlu, 2004). Lime can be classified into three groups; lime putty, hydrated lime and hydraulic lime. Characteristic that distinguish Hydraulic lime from other limes is that its structure comprises a high percentage of silica. Hydraulic lime can be classified into two groups; natural hydraulic lime and hydraulic lime. Natural hydraulic lime is produced from limestone that contains a high percentage of siliceous materials. This kind of limestone is composed of CaO, MgO and alumina, iron and silica and several other foreign matters. When the limestone, which contains a high percentage of silica and clay materials, used as raw material for the production of lime, these foreign matters are reacted with quicklime during the high temperature calcinations and calcium aluminates and silicates are produced. Pure hydraulic limes harden under water. Therefore, this type of lime is used as binders for mortar in the construction of bridges, drainage systems, water cisterns, foundations etc. Hydraulic lime is produced by the addition of the pure silicate into the powder limestone (clay minerals) and this mixture is heated at a temperature from 950°C to 1250°C. While non-hydraulic lime hardens only with CO_2, the hydraulic limes harden with water as well as CO_2 gas (Toprak, 2007). When hydraulic lime is quenched it turns into slaked lime $Ca(OH)_2$ and the main mixed oxide of cement $2CaO.SiO_2$ (Akman, 2003). The calcium aluminate silicates are formed calcium silicate hydrate and calcium aluminate hydrates with water and lime is converted to calcium carbonate. Therefore the strength of the hydraulic mortar is greater than the strength of the non-hydraulic mortar (Böke et al., 2004).

Table 2 Chemical analysis of hydraulic lime(Lanas, Pérez Bernal, Bello, & Alvarez Galindo, 2004)

Lime	I.L. (%)	SiO_2 (%)	CaO (%)	MgO (%)	Al_2O_3 (%)	Fe_2O_3 (%)	SO_3 (%)	Na_2O (%)	K_2O (%)
Hidraulic Lime	15.00	12.57	54.26	7.65	5.42	1.16	2.13	0.34	1.35

There are a few, studies about the behavior of hydraulic lime based mortars and concretes in the literature. It has been proved that sepiolite slows down the rate of carbonation process in the lime mortars due to its capacity of water adsorption without affecting the mechanical behavior of the mortars. However, it has been observed that sepiolite influenced the development of the microstructure of mortar. On the other hand, the weak surface load of sepiolite, together with the absence of swelling and the needle shape of its particles, confers a singular rheological behavior on this material (Martinez-Ramirez et al., 1995).

Table 3 The chemical analysis of sand, lime and sepiolite (Martinez-Ramirez et al., 1995)

	SiO_2	MgO	Al_2O_3	CaO	Fe_2O_3	SO_3	PF	IR
Sand	98.92	0.28	0.18	0.00	0.06	0.00	0.05	0.40
Lime	0.39	1.10	73.82	0.20	0.00	0.00	24.45	0.02
Sepiolite	55.10	19.43	5.91	5.13	1.96	0.00	12.02	0.10

The use of lime and sepiolite together in the repair mortars for restoration of historic buildings is one of the recent studies. Various researches has been done to determine the behavior of lime mortars containing sepiolite under various conditions and to determine the optimum mixture ratio. It has been observed that adding sepiolite 5% by weight of lime mortar did positive changes in the final properties (Martinez-Ramirez, Puertas, Blanco-Varela, & Thompson, 1998; Pinilla Melo et al., 2014).

In most of the studies the mechanical properties and physical characteristics were evaluated of sepiolite mortars and concrete, however the studies are limited for durability. When reinforced concrete elements exposed to high temperature, changes are seen in its physical and mechanical properties. Such as, decrease in the compressive strength and modulus of elasticity of concrete, formation of cracks, fragmentation and disintegration, decrease in yield strength, ductility and tensile strength of steel. It has been observed that when temperature reaches 600°C the concrete loses 50% of its strength when it reaches 800°C it loses approximately 80% of its compressive strength (Kızılkanat & Yüzer, 2008). Limestone's thermal conductivity depends upon the nature and status of its pores. As temperature increases, the thermal conductivity decreases. Specific heat is another feature which varies with temperature. The changes of specific heat of limestone with temperature are given below in Table 4. All types of limestone are converted to oxides before they melt. The melting point of CaO is 2800°C. Calcitic and dolomitic limestones are chemically the most stable substances. They certainly do not decompose at temperatures up to 600°C and they are not affected by water which does not contain CO_2. Limestone decomposes at higher temperatures is converted to calcium oxide (Parlakyıldız, 2008).

Table 4 The changes of specific heat of limestone with temperature (Parlakyıldız, 2008)

Temperature, °C	Specific heat (cal/g°C)
0	0.191
200	0.239
400	0.270
600	0.296
800	0.322

The objective of this work is to determine the features of the mortars which used sepiolite together with lime as a binder. Especially the mortar used in the external environment is open to various physical and chemical effects. For any reason, if the water reaches the sepiolite-lime mortar hydraulic lime was used to protect. Different sepiolite-lime mortar binder-sand ratios were produced and specimens were subjected to high temperature such as 20, 400, 700°C. With experiments such as the unit weight, ultrasonic pulse velocity, compressive strength loss was determined as a result of high temperatures.

EXPERIMENTAL STUDIES

Materials

Sepiolite: In this study, the sepiolite from Kaymaz region of Eskisehir was used. The surface area of sepiolite is 300 m^2 and its density is about 2.3 kg/m^3. Sepiolite has a porous structure and the average micro pore diameter is 1.5 nm. The chemical composition of sepiolite is given in Table 5.

Table 5 The chemical analysis of sepiolite and hydraulic lime

	Na2O	MgO	Al2O3	SiO2	SO3	K2O	CaO	Fe2O3
Sepiolite [2]	0.09	22.28	1.36	13.24	0.03	0.15	23.18	0.51
Hidraulic Lime [16]	0.34	7.65	5.42	12.57	2.13	1.35	54.26	1.16

Hydraulic lime: In this study, pure hydraulic lime produced by Tekno firm was used. Hydraulic lime properties are shown in Table 6. The chemical composition of hydraulic lime is given in Table 5.

Table 6 Properties of hydraulic lime

Bending Strength, MPa	Compressive Strength, MPa	Unit Weight, kg/dm3	Color
1	3.7	0.75	Ecru

Aggregate: The standard sand named RILEM Cembureau prepared by Trakya Cement Set Cement Industry and Trade Inc. suitable for TSE EN 196-1 was used.

Water: Eskisehir tap water was used as mixture water. The contents of water were 45 mg/l sulfate, 57 mg/l calcium, 83 mg/l magnesium, 49 mg/l chloride, 438 mg/l evaporation balance and pH was 6.75.

Method

Mortar series were created using Sand/Binder and Sepiolite/Hydraulic Lime at different rates. In Table 7 the different compositions of prepared hydraulic lime mortars are shown.

Table 7 Lime Mortar Compositions

Sand/Binder (S/B)	0			1/3			1		
Sepiolite/Hydraulic Lime (S/L)	1/3	1	3	1/3	1	3	1/3	1	3

The required ratio of water was determined as the consistency of each mixture will be the same. The Flow Test used for the determination of consistency is given in the Figure 2.

Figure 2 Flow test

From the produced mortar 4x4x16cm sized specimens were taken as shown in Figure 3. The specimens were kept 28 days in standard curing conditions. These mortars were exposed to 20, 400 and 700°C temperatures for 3 hours. Specimens were cooled down to room temperature in air. The unit weight and ultrasonic tests as nondestructive testing method were done on the specimens. Destructive test methods as the bending and compression experiments were made. The effect of high temperature on the lime mortar was determined, with respect to the loss in unit weight, ultrasonic pulse velocity (UPV), compressive strength and bending strength.

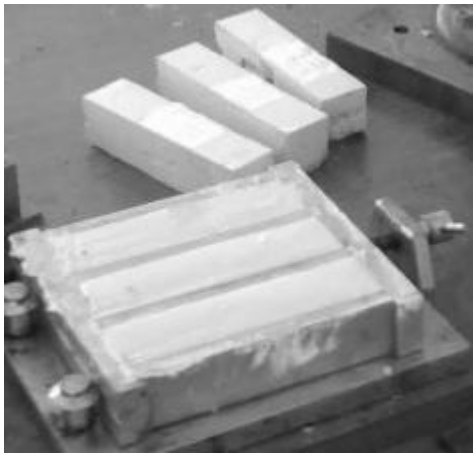

Figure 3 Produced Specimens

RESULTS AND DISCUSSIONS

In Figure 4, the change of the unit weight of the produced materials with respect to temperature is given. Unit weight values were changed in the range of 0.8-1.7 kg/dm^3. Generally the decrease of unit weight of the produced mortar series with increasing temperature reached at 20%. As the S/B ratio increases, the unit weights of the produced mortars increased at rates up to 30% at 20°C and 40% at 400°C, 50% at 700°C. The specific weight of the sand is greater than the specific weight of sepiolite. Therefore, as the S/B ratio increased, the unit weights of the specimens were increased. Especially, in sand-free specimens, after 400 degrees the cracks occur in the structure as a result of increase in the volume, therefore unit weight loss was found to be more than the other specimens.

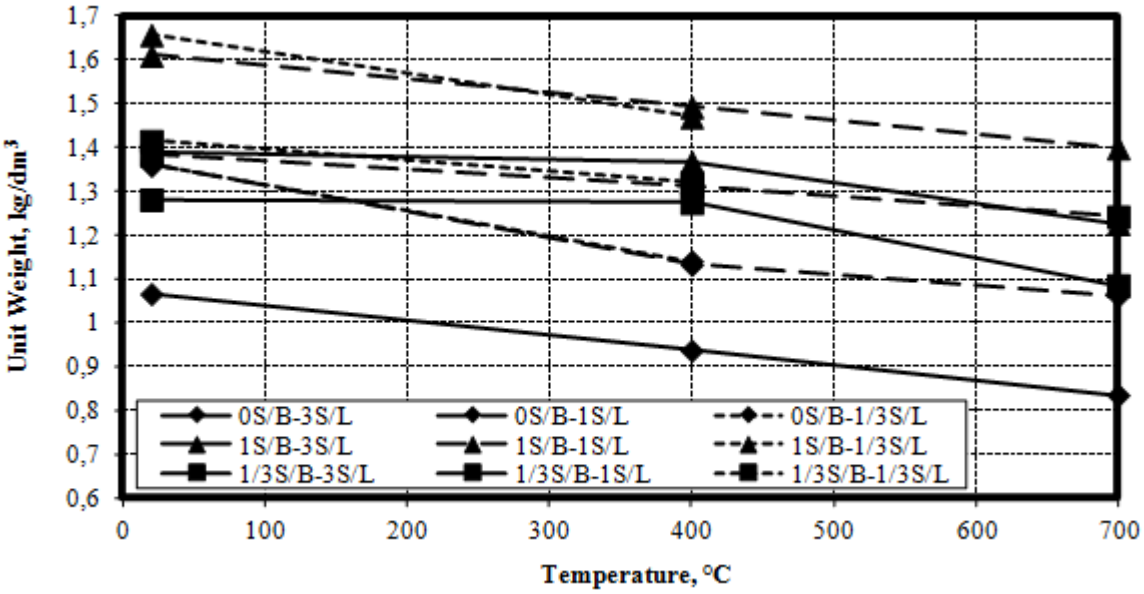

Figure 4 Unit weight versus temperature for different compositions of mortars

Mortar specimens including sand is prone to shrinkage due to water loss. On the contrary, aggregate resists this shrinkage. Therefore, in the micro structure the cracks are formed resulting from arising stress. Generally it has been seen that the unit weight loss was more significant in the 400°C and before. As the S/L ratio increases, unit weights of the control specimens have been decreasing at rates up to 20% at 400°C and 15% at 700°C. The specimens which have 1/3 S/L ratio disintegrated at 700 degrees. Therefore the measurements couldn't be made. When the sepiolite amount increases the unit weight of the specimens are decreased. The reduction in unit weights of the specimens which have the highest sepiolite ratio was less and more regular. This is because when the mortars are exposed to high temperatures the lime volume changes more than sepiolite. Even more the dissolution was observed in the mortar specimens which has more lime ratio, 1/3 S/L, at high temperatures.

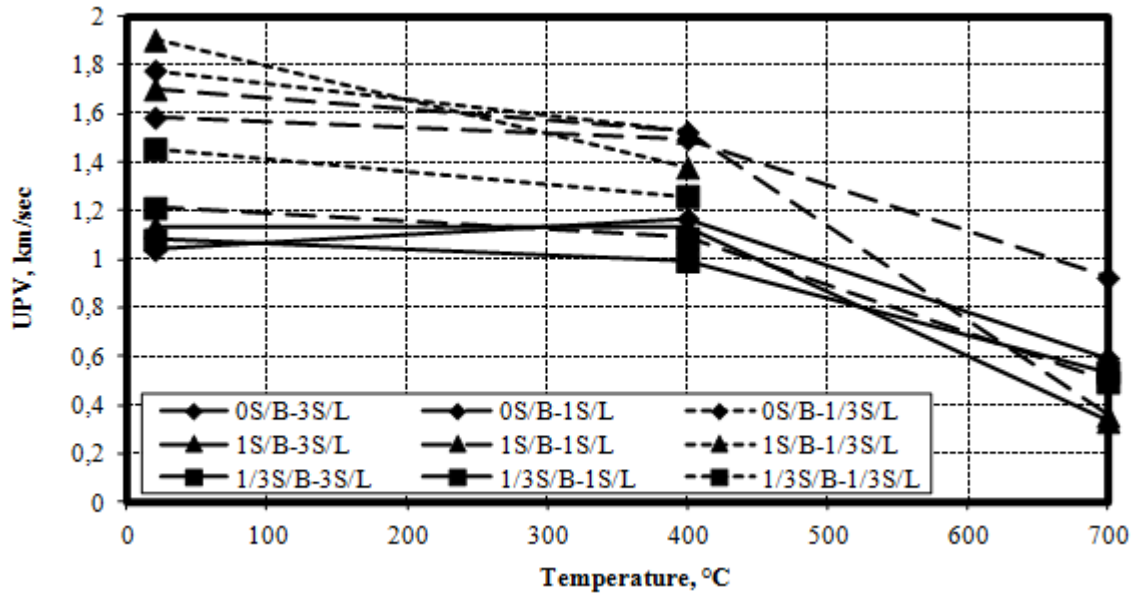

Figure 5 UPV versus temperature for different compositions of mortars

Ultrasonic pulse velocity (UPV) test is a practical non-destructive method which used to measure the quality of the specimens depending on the amount of cavity of the specimens. In Figure 5, the calculated ultrasonic pulse velocity for each specimen which has been exposed to 20, 400 and 700 degrees temperatures were shown. UPV values were changed in the range of 1.9-0.3. Generally, the calculated UPV values of the mortar series have decreased with the temperature increase. When the temperature increases, in the mortars the water loss and shrinkage occurs. The cracks, which have been as a result of this shrinkage, cause a reduction in the UPV values.

As S/B ratio increases, firstly UPV values of the produced mortars have been decreasing at rates up to 20%. When the S/B ratio is 1, generally UPV values have been increasing at rates up to 10%. It has been considered that the reason for this increase is due to the UPV of the binder dough is lower than the UPV of the sand. As the S/B ratio increases, unit weights of the produced mortars have been decreasing at rates up to 20% at 400°C and 65% at 700°C. At 570°C the cracks occur in the micro structure of the quartz sand due to polymorphic transformation. Thus, as the S/B ratio increases a significant decrease occurs at 700°C. If we look at the increase in S/L ratio, the reduction in the UPV's of the mortars can be seen as 40% at 20°C, 25% at 400°C, 40% at 700°C. As the sepiolite rate increases the UPV values are decreased. The volume change that occurs at high temperatures in the micro structure of sepiolite reduces UPV values. When the specimens which have maximum sepiolite ratio are exposed to higher temperatures, the UPV values increased when temperature reaches up to 400°C. After 400°C it has become a more regular decrease.

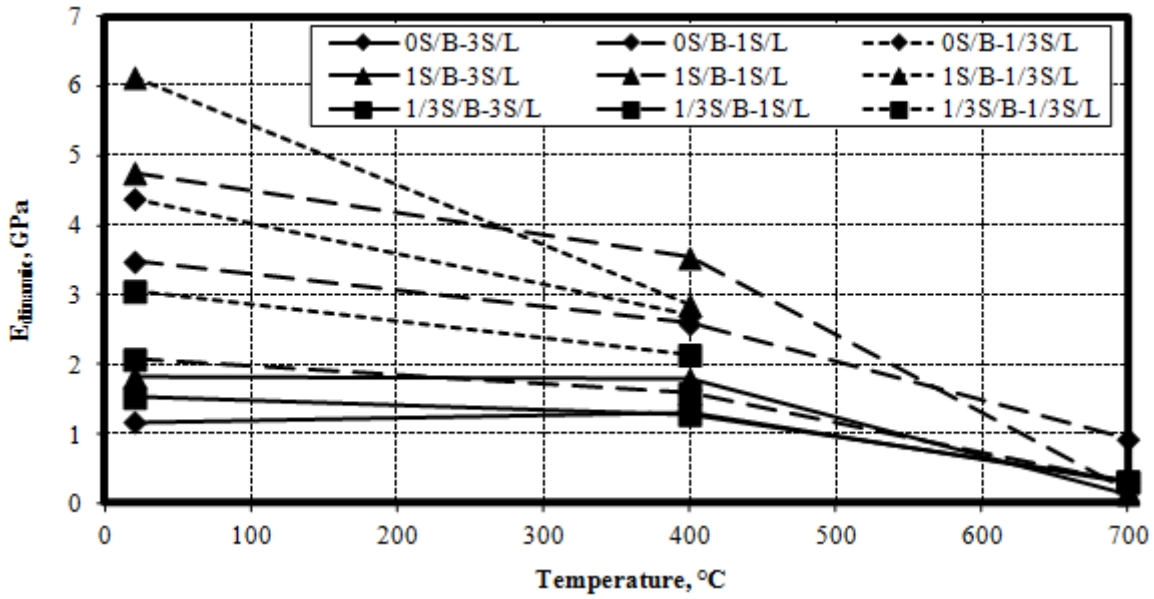

Figure 6 $E_{dinamic}$ versus temperature for different compositions of mortars

Dynamic modulus of elasticity is calculated depending on the square of the UPV and the unit weight. In Figure 6, the changes of the dynamic elasticity modulus of the produced materials with respect to temperature are given. Overall, the dynamic elasticity modulus decreased as the temperature increased. Dynamic modulus of elasticity has values between 0.1 and 6. As the S/B ratio increases, till it reaches 1, the values of the dynamic elasticity modulus are decreased. After that the values of the dynamic elasticity modulus were increased as the S/B ratio increases. Dynamic elasticity modulus have been increasing at rates up to 40% at 20°C and 35% at 400°C, while it has been decreasing up to 70% at 700°C. There are many factors those affect the elasticity modulus of mortars, such as properties of the used materials, porosity, moisture conditions of the specimens and loading conditions. Dynamic elasticity modulus is directly proportional to the square of UPV and the unit weight. Therefore, the change in dynamic elasticity modulus with S / B ratio is similar to the changes in UPV values. When considering the increase in S/L ratio it is observed that dynamic elasticity modulus has decreased at rates up to 80% at 20°C, 35% at 400°C, and 90% at 700°C. The increase in the sepiolite ratio has made decrease in the dynamic elasticity modulus values. This decrease has been faster after 400 degrees, and after 700 degrees the dynamic elasticity modulus has been decreased down to zero. This reduction is a result of crack propagation which occurs in the micro structure of the specimen under the influence of high temperatures.

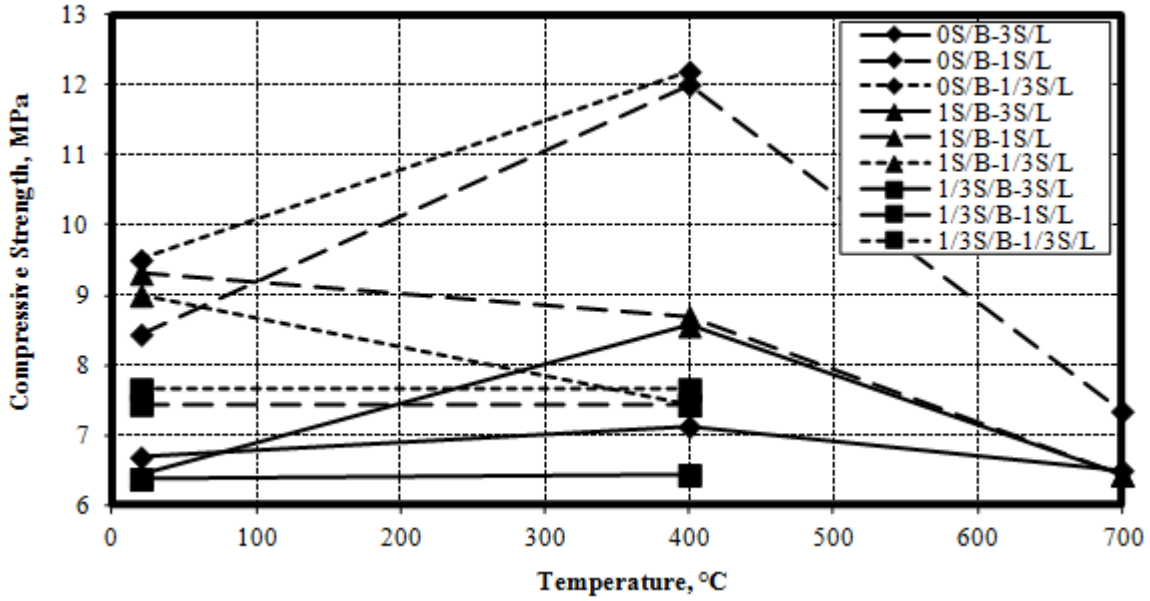

Figure 7 Compressive strength versus temperature for different compositions of mortars

The change of the compressive strength of the produced mortars with respect to temperature is given in Figure 7. The compressive strength of the mortar series ranged from 6 MPa to 12 MPa. In general, the compressive strength of the specimens remained stable up to 400 degrees. It can be clearly seen from the chart that, after 400 degrees, the compressive strength of the mortar series has decreased dramatically. The increase in the S/B ratio reduces the compressive strength in general. Reduction of binder ratio caused a decrease in compressive strength. This reduction in compressive strength of the mortar series reached up to 15% at 200°C, 25% at 400°C and 10% at 700°C. It is observed that the compressive strength of sand-free specimens increased up to 12 MPa. Different thermal expansion of the sand and binder phase caused a decrease in compressive strength of the specimen containing sand. In specimens containing a low content of sepiolite, the compressive strength was not obtained at 700°C. Increasing binder ratio used in the construction of mortar also increases compressive strength.

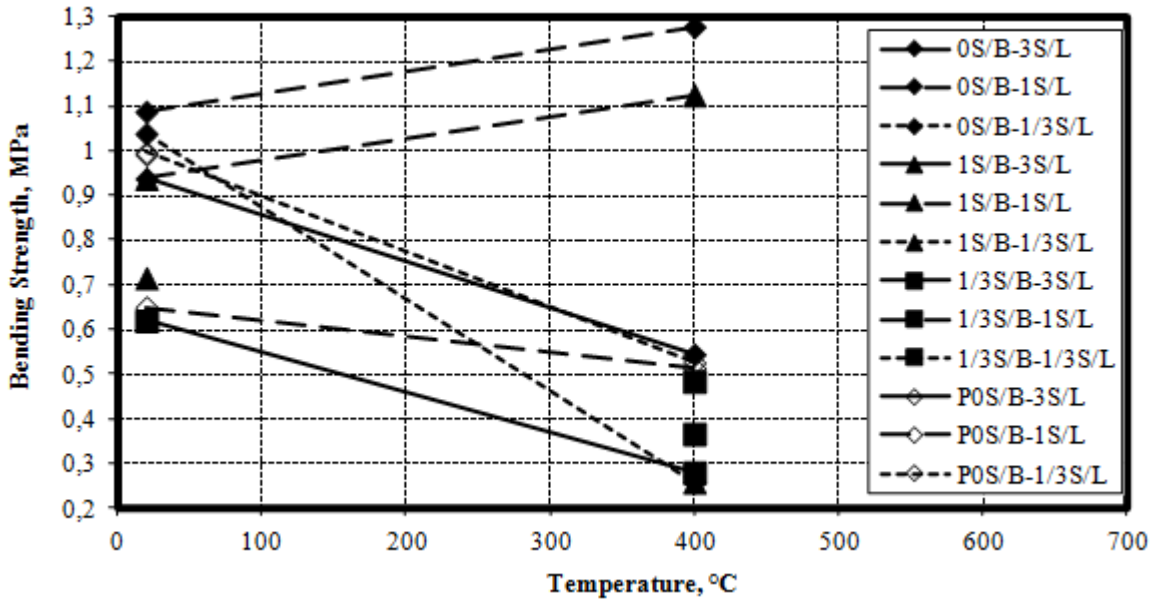

Figure 8 Bending strength versus temperature for different compositions of mortars

The results of the bending tests conducted on the specimens at 20°C, 400°C, and 700°C are shown in Figure 8. Bending strength of mortar series ranged from 0 to 1.3 MPa. Generally under high temperature the bending strength of the mortar series of S/L ratio of 1 has increased while others bending strength decreased. It was thought that the fibrous structure of sepiolite increased the strength of the clay binder and this increased the

bending strength of the mortar. The reason for the reduction in the bending strength of the mortars of S/L ratio is greater than 1 could be shown as the loss of the hydraulic lime which is the actual binder. It is observed that as the S/B ratio increases the bending strength of the mortar series has increased until the S/B ratio is 1. As S/B ratio increases, firstly the bending strength of the mortars has been decreasing as well. When the S/B ratio is 1, although a slight increase is observed they did not reach the bending resistance possessed by the sand-free specimens. Depending on the temperature as the S / B ratio increased the bending strength decreased at rates up to 90% at 20°C, 70% at 400°C. The reason for the reduction of the bending strength under increasing sand ratio could be shown as the strength of the binder paste is higher than the sand strength. Overall, the amount of sepiolite in a certain ratio (S/L = 1) showed a positive effect on the bending strength of the mortar series exposed to high temperature. However, increased sepiolite ratio reduces the bending strength.

CONCLUSIONS

The conclusions of the study are summarized as follows:

1. With the increasing content of sepiolite in prepared mortars the unit weight decreased overall. As a result of less volume changes of sepiolite compared to lime, the reduction in unit weight at high temperatures in specimens with more sepiolite content was observed to be lower and more regular. As the S/B ratio increases the unit weight of mortar series are increased. With the increasing volume as a result of micro cracks the unit weight of specimens, without sand, decreased especially after 400°C.

2. Because of the volume changes in sepiolite at high temperatures, as the sepiolite ratio increases it has been observed that UPV values of the mortars were decreased. Even though increasing sand ratio has improved the UPV values around 10%, under high temperatures especially after 700°C decrease was observed up to 65% in those values. At about 570°C, sand loses its polymorphic structure, and volume expansions occur. Therefore the UPV values were decreased. There is also a similar behavior in the Dynamic elasticity modulus as in the UPV values.

3. As a result of being directly proportional to the mixture water requirement with sepiolite content, increasing sepiolite ratio reduces the compressive strength of specimens under high temperatures. Increased sand content decreased the compressive strength of the mortar specimens.

4. Under high temperature the flexural strength of mortar specimens with S/L ratio=1 showed a favorable behavior, but increasing sepiolite ratio has reduced the flexural strength of those specimens.

Consequently, it was determined that use of sepiolite as a binding material with hydraulic lime for mortars doesn't have adverse effect on the mechanical properties of mortar. Also it may be advisable that the addition of sepiolite with the rate of S/L=1 to reduce the unit weight of the mortars and for use in bending members. Considering the versatility of sepiolite, more research should be done on the mortars those contains sepiolite for the use in repair mortars in countries which have high reserves of sepiolite.

ABSTRACT

The outbreak of fire in a concrete infrastructure can have disastrous consequences, including severe structural damage, total loss of contents, and loss of life. Adequate structural fire design is therefore critical. Despite significant past studies, our understanding of concrete performance in fire remains inadequate. This paper will first highlight major limitations of conventional testing and accordingly of resulting constitutive models for concrete at elevated temperatures. The paper will then detail results of a thermal-stress coupling analysis as part of an ongoing research at The University of Queensland that aims to develop more realistic constitutive models through studying performance of concrete cylinders subject to known consistent heat flux boundary conditions. It is clearly shown that (i) Different levels of incident heat flux causes significantly different evolution of temperature and stress profiles within the specimen; and (ii) Such profiles and their nature may be considerably modified by mechanical loading. Accordingly, heat flux, and temperature gradient by extension, may have non-negligible influence on thermal and structural behaviour of concrete and concrete structures – Such influence has not been captured in currently available models.

KEYWORDS

Concrete, elevated temperature, fire, temperature gradient, heat transfer.

INTRODUCTION

The outbreak of fire in buildings and civil engineering structures can have disastrous consequences, including severe structural damage, significant loss of contents, and possible loss of life. Adequate design for fire is thus an essential requirement in the design process. Accordingly, knowledge of concrete performance in fire is critical.

Despite extensive research in the past decades, our current knowledge of fundamental properties of concrete at elevated temperatures remains largely based on data from conventional tests in which the thermal loading experienced by concrete specimens is very difficult to be consistently controlled (Cristian Maluk et al., 2014; C. Maluk et al., 2012; J. L. Torero, 2014). As a result, the effect of temperature gradients within concrete on its fire performance has not been adequately investigated. Accordingly, the influence of critical processes linked with temperature gradients, including thermal stresses, moisture transport, and pore pressures, has not been properly addressed. This knowledge gap is critical considering the likely significant temperature gradients within concrete in fires. As a result, revised knowledge of fundamental properties of concrete at elevated temperatures is required.

This paper will briefly highlight the limitation of thermal boundary condition in conventional test. On that basis, this paper will present some initial results of numerical modelling of concrete specimen (Φ100 × 200 mm) in fire condition that aims to study the effects of temperature and temperature gradient in concrete material/structural levels.

LIMITATIONS IN CONVENTIONAL TESTS AND THEIR EFFECTS

The increase of temperature in a test specimen depends on the heat flux imposed on the specimen. When conventional furnace/oven is used, the temperature evolution of the gases in the furnace is controlled if thermocouples are used and the heat-flux to a plate if a plate thermometer is used. In conventional furnace/oven, the imposed heat flux results from a combination of different forms of heat transfer (radiation, convection and conduction) between the furnace (gases/furnace walls/other test specimens) and the test specimen. Through consideration of energy balance at the cylinder surface, $q_s^{"}$ can be approximated as:

$$q_s^{"} = \varepsilon.q_{inc}^{"} - \varepsilon.\sigma.T_S^4 + h(T_H - T_S) \quad (1)$$

where ε: thermal emissivity; T_H, T_S: temperature of gas and of specimen surface; σ: Stefan-Boltzmann constant; q''_{inc}: incident radiative heat flux (from gases, furnace walls and other test specimens).

The evolution of q''_s in time and space is thus highly complex, and accordingly very difficult to be controlled accurately and consistently. (In furnace/oven, the temperature evolution of the gases in the furnace is controlled if thermocouples are used and the heat-flux to a plate if a plate thermometer is used.) This inconsistent thermal loading imposed on test specimens has serious implications for the case of concrete with Biot number close to 1 (Figure 1b), where proper characterisation of thermal boundary conditions is required (J. Torero, 2014). On the other hand, for the case of plasterboard with Biot number much greater than 1, T_S approximates T_H - enabling the simple adoption of the monitored gas temperature (T_H) as T_S on the specimen surface. For steel with Biot number much smaller than 1, a single temperature can be assumed for specimen, also significantly simplifying the problem.

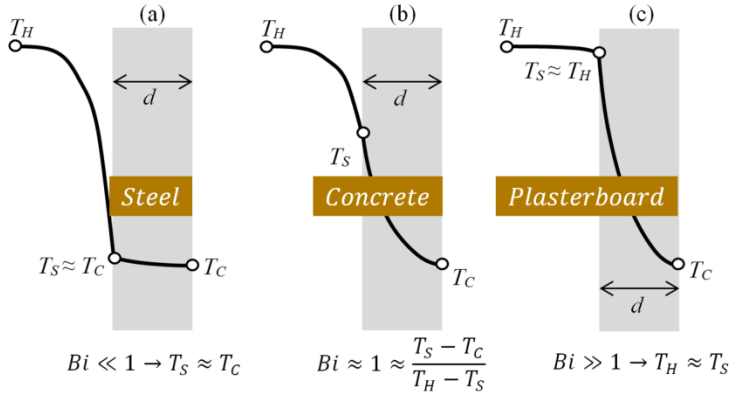

Figure 1 Typical temperature distributions for different materials.

The inconsistent q''_s means reliable control of the temperature evolution/gradient in test specimens is rather challenging, if not impossible, in furnace tests. This has caused, at least partly, the following:

a. Currently available constitutive models have been predominantly derived from "standardized" tests where temperature gradient within concrete test specimens is generally purposely minimized (Cheng et al., 2004; Phan, 1996). Limitations of these models include:
   - Mass transfer processes affected by heat are very different from typical real fire situations (with typically significant temperature gradients) because the very slow heating rates do not only allow dissipation of heat through the sample but also slow dissipation of water vapour with minimal pore pressure increase.
   - The temperature gradients while small remain undefined: Proper characterization of in-depth temperatures implies intrusive measurements that if introduced in sufficient quantity would affect the mechanical properties of the test specimen, and is thus normally not carried out.
   - Components of the model linked with temperature gradients have not been properly addressed. Neither have the couplings between different processes related to temperature gradients (including moisture transport, vapour pressure, and thermal gradient induced stresses).

b. Significant variation in test results regarding both strength deterioration and spalling of concrete upon heating (Khoury et al., 1984; Phan, 1996): Though small, different heating rates adopted have resulted in different heating histories for and thus variations in response of test specimens. These histories, however, are complex and generally undefined due to poor thermocouple/sensor resolution.

The above-discussed shortcomings can be effectively addressed if known heat fluxes representative of real fire scenarios can be consistently applied onto test specimens. A major research program is thus ongoing at The University of Queensland to carry out tests under well-defined and controlled conditions as subsequently outlined.

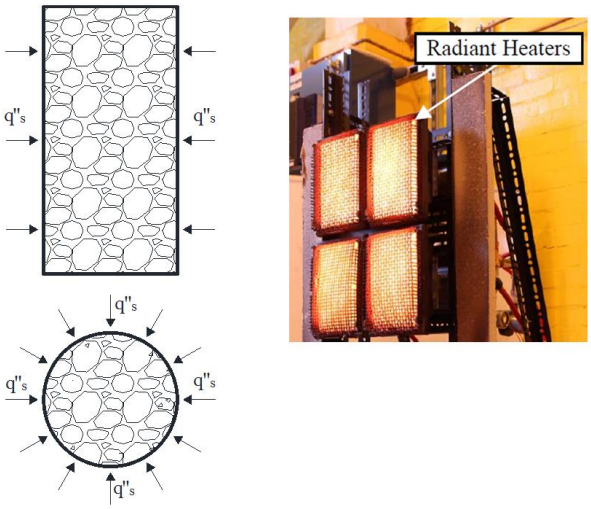

Figure 2 Novel fire test using radiant panels.

NUMERICAL MODEL FOR COUPLED THERMAL-STRESS ANALYSIS

There are essentially two different approaches for coupled thermal-stress analysis, namely (i) sequentially coupled analysis, and (ii) fully coupled analysis. Sequentially coupled thermal-stress analysis is performed by first solving the pure heat transfer problem, then reading the temperature solution into the structural model as a predefined field (Figure 3): The temperature field is thus assumed unaffected by the stress analysis solution. In fully coupled thermal-stress analysis, however, the coupling is two-way with iteration between thermal and stress analysis solutions.

In this study, the modification of the temperature field within the test cylinder specimen due to stress is deemed negligible. Accordingly, the sequentially coupled thermal-stress analysis – being simpler and less time-consuming than full coupling – is adopted.

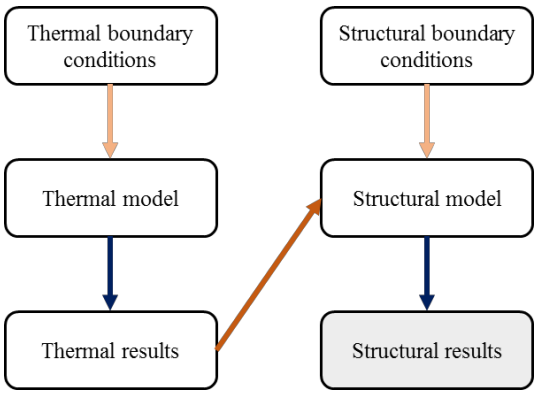

Figure 3 Sequentially coupled thermal-stress analysis.

To carry out such sequential coupling thermal-stress analysis, ANSYS is chosen due to its versatility and strong foundation for multi-physics. Within ANSYS, two models are performed:

- A thermal model to calculate nodal temperature evolution over time within concrete specimen under a specific thermal boundary condition – a known, uniform, and consistent incident heat flux;
- A structural model to determine the mechanical response corresponding to the input thermal and structural boundary conditions. The evolution of the temperature field from the thermal model is read into the structural model as inputs.

In the thermal analysis, a 3D eight nodes, SOLID70, was used to determine temperature distribution via heat conduction, while SOLID65 element was chosen to model the behaviour of concrete under thermal and structural loading. Figures 4 and 5 show the geometry of SOLID70 and SOLID65 in ANSYS, and Table 1 shows the details information of these two elements.

Due to the symmetry of thermal and structural boundary condition as well as the geometry symmetry of concrete, a quarter of the cylinder specimen is modelled, as in Figure 4. To facilitate the coupling, identical solid mesh systems are used for both thermal and structural analysis.

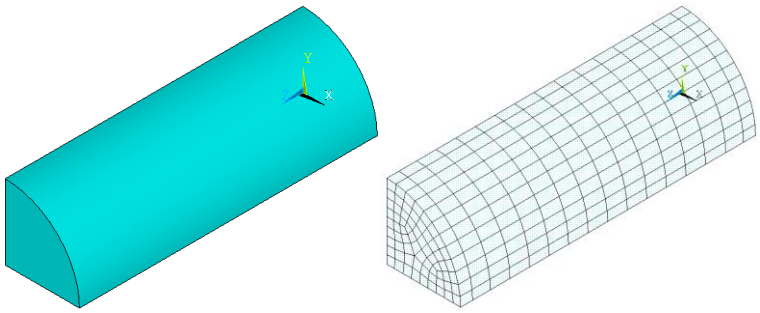

Figure 4 Physical and finite element models.

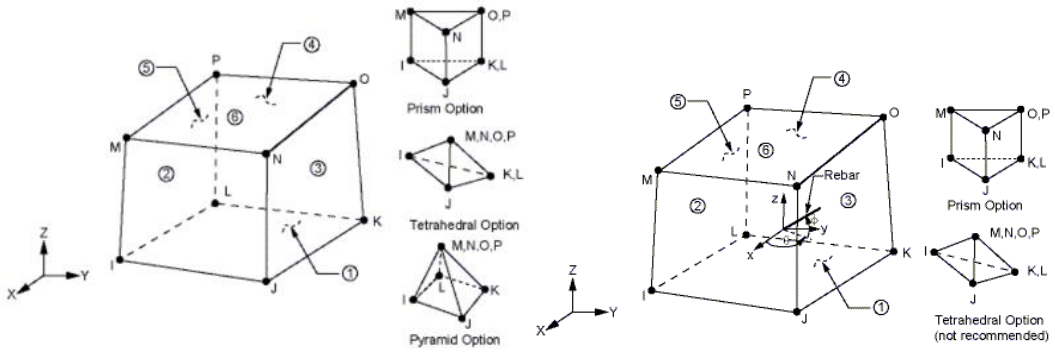

Figure 5 Thermal and structural elements, SOLID70 and SOLID65 (ANSYS® Academic Research, 2009).

Table 1 Properties of thermal and structural elements.

	Thermal analysis	*Structural analysis*
Element	SOLID70	SOLID65
Nodes	8 nodes	8 nodes
Degrees of freedom (DOF)	1 (TEMP)	3 (UX, UY, UZ)
Material properties	Thermal conductivity, density, specific heat	Young's modulus, thermal expansion coefficient, Poisson's ratio, density
Loading	Surface loads, body loads	Surface loads, body loads
Output data	Nodal temperatures	Nodal displacements, Stresses, Strains

The developed model is then used to determine the temperature and stress in a concrete cylinder of 50mm in radius. The boundary conditions, thermal and mechanical properties, and some notable results are presented as follows.

THERMAL ANALYSIS

Thermal Initial and Boundary Conditions

The cylinder has an initial temperature of T_o of 25°C and is subject to a uniform heat flux ($q_s^{"}$) around the curve surface (Figure 6). There is no heat transfer through the two end faces and no internal heat generation. To model the heat transfer within concrete specimen under heat flux boundary condition together with heat loss, surface element SURF152 was used; the heat flux and convection loss were assigned to these two SURF152 elements.

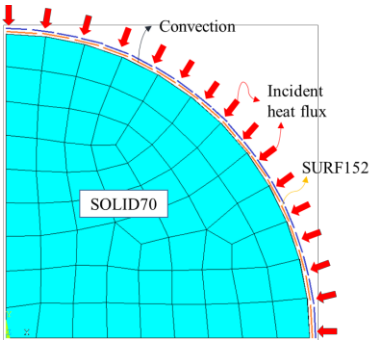

Figure 6 Model the heat transfer in the concrete specimen.

The initial and boundary conditions of concrete specimen are as follows:

$$T\big|_{t=0} = T_O \tag{2}$$

$$k\frac{\partial T}{\partial r}\bigg|_{r=a} = q_s^{"} \tag{3}$$

$$k\frac{\partial T}{\partial r}\bigg|_{r=0} = 0 \tag{4}$$

where k: thermal conductivity of concrete; T: temperature; t: time; r: radial distance from specimen's centreline axis; and T_0 : initial temperature of the whole concrete specimen. Appropriate symmetric conditions are assigned to Line L3 and Surfaces S2, S3 (Figure 7).

For the pupose of this paper, concrete specimen was subjected to two levels of incident heat flux of 10 and 30 kW/m^2 to investigate the difference in temperature and stress response of the cylinder due to temperature gradient. The cylinder specimen had uniform initial temperature of 25°C and was then heated to an average target temperature of 400 °C. The evolution of temperature distribution over time was obtained using transient thermal analysis.

Thermal Properties of Concrete

Thermal properties of concrete - including thermal conductivity, specific heat, and concrete density (mass loss) – were assumed as functions of temperature, as suggested in (Kodur et al., 2003).

Weighted Average Temperature and Its Location

During heating, the temperature distribution is not uniform across the cross-section of the test specimen. The higher the heating rate, the more significant such non-uniformity. The temperature gradients are also dependent on the specimen geometry and thermal properties of concrete. The specimen thus generally does not possess a single temperature at any given time during heating but a temperature range. For practical purpose, it is desirable to represent a given temperature profile by its weighted average value. Analytical and numerical solutions for such a value were reported in (Khoury et al., 1984) for the case of concrete cylinder subject to uniform temperature on the boundary. Similar solutions were given in (Le et al., 2015) when concrete cylinder is subjected to heat flux boundary conditions. Interestingly, in both cases, the location of the weighted average temperature on a cross-section of concrete cylinder is at 0.58 times the cylinder radius from its centreline. Accordingly, the temperature at this location is taken as representative for the cylinder and used to determine whether a predetermined target temperature level has been reached.

STRUCTURAL ANALYSIS

Structural Initial and Boundary Conditions

The structural boundary conditions are as summarised in Table 2: The two end faces are restrained from axial displacement along Z-direction. The position of lines (L1 to L3) and surfaces (S1 to S4) of the physical model are given in Figure 7.

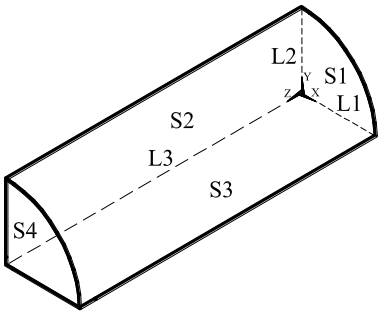

Figure 7 The position of lines and surfaces of the physical model.

Table 2. The constraints of lines and areas in the structural model.

Lines/Areas	*Constraints*
L1	*UY = 0; UX ≠ 0*
L2	*UX = 0; UY ≠ 0*
S1, S4	*UZ = 0*
S2	*Symmetric*
S3	*Symmetric*

Mechanical Properties of Concrete

Mechanical properties of concrete at elevated temperatures required include compressive strength, Young's modulus, compressive strain at peak stress, thermal expansion coefficient, Poisson's ratio, and general stress-strain relationship. Models for the above properties are chosen on the basis of their simplicity and generality and detailed as follows.

Stress-strain relationship of concrete at temperature T is as proposed by Lie et al. (1985):

$$\sigma_{cT} = f'_{cT}.\left[1-\left(\frac{\varepsilon_{oT}-\varepsilon_{cT}}{\varepsilon_{oT}}\right)^2\right] \qquad \varepsilon_{cT} \le \varepsilon_{oT} \tag{5}$$

where: σ_{cT} and f'_{cT} are compressive stress and compressive strength of concrete, respectively; ε_{oT} is strain at maximum stress of concrete; and ε_{cT} is concrete strain. These concrete properties are determined using a model proposed in (Li et al., 2005):

$$f'_{cT} = f'_c\left[0.00165.\left(\frac{T}{100}\right)^3 - 0.03.\left(\frac{T}{100}\right)^2 + 0.025.\left(\frac{T}{100}\right) + 1.002\right] \tag{6}$$

$$\varepsilon_{oT} = \frac{2.f'_c}{E_{ci}} + 0.21\times10^{-4}.(T-20) - 0.9\times10^{-8}.(T-20)^2 \tag{7}$$

where: f'_c and E_{ci} are concrete compressive strength and Young's modulus at ambient temperature, respectively. Ascending branch of the resulting stress-strain curves at different target temperatures are plotted in Figure 8.

The coefficient of thermal expansion (α), assuming concrete using calcareous aggregates, was defined using Kodur's model (Kodur & Sultan, 2003):

- For $0 \le T \le 450$ °C
$$\alpha = -0.0002 + 0.000008\times T \tag{8}$$
- For $450 < T \le 920$ °C
$$\alpha = -0.0061 + 0.000021\times T \tag{9}$$

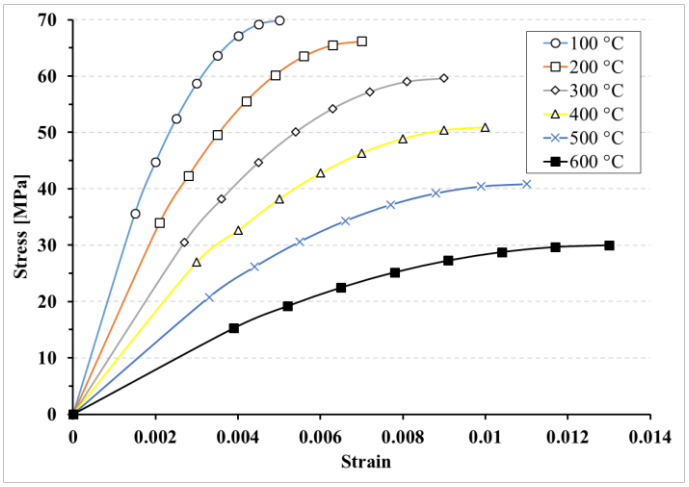

Figure 8 Stress-strain curves of concrete at different target temperatures.

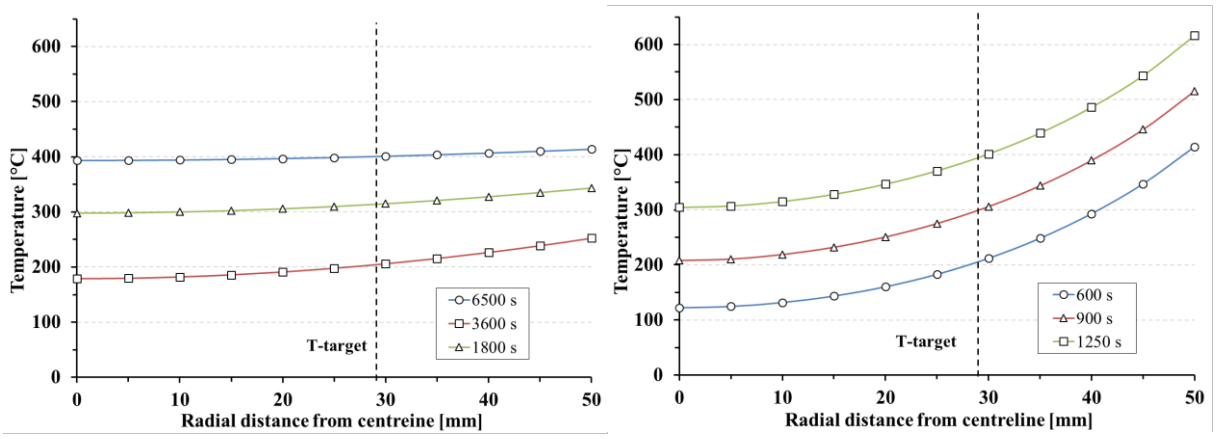
RESULTS AND DISCUSSION

To investigate the effect of temperature gradient, the temperature and stress in the concrete cylinder when subjected to two different levels of incident heat flux (q''_{inc}) of 10 kW/m^2 and of 30 kW/m^2 are studied. The cylinder, being fixed longitudinally at both end surfaces, is first subject to the imposed incident heat flux until the target temperature of 400 ^{o}C is reached at 29 mm (being 0.58R where R is 50 mm (Le et al., 2015)) from the centreline of the cylinder. Once the target temperature is reached, a specified displacement (chosen as 0.5 mm, 1 mm and 2 mm) is imposed onto one end surface of the cylinder.

Evolution of Temperature Profiles

The evolution of temperature profile along a radius when the concrete cylinder is subject to an incident heat flux (q''_{inc}) of 10 kW/m^2 and of 30 kW/m^2 is shown in Figure 9. The following can be observed:

- The temperature profiles given by the numerical model are found to agree very well with the analytical solution (Le et al., 2015), suggesting both analytical and numerical models are appropriate.
- The time taken to reach the target temperature of 400 ^{o}C is shorter for the case of an increased heat flux of 30 kW/m^2, compared to that of 10 kW/m^2; as expected.
- When subject to a given level of incident heat flux, the temperature gradient may change during the heating process. This is a result of the heat losses due to radiation and convection (Equation 1). Should a constant temperature gradient be required, the q''_s in Equation 1 can be kept essentially constant by manipulation of q''_{inc} through changing either the radiant intensity or position of the radiant panel system.



(a) (b)

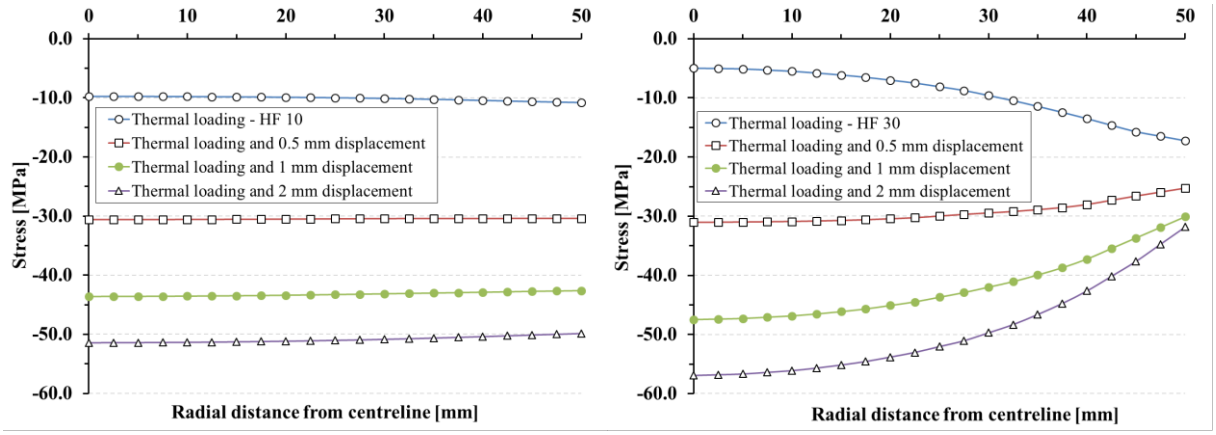
Figure 9 Temperature profiles in concrete at the different heating time of 10 and 30 kW/m^2 incident heat flux.

Stress Profiles due to combined Thermal and Mechanical Loading

As the cylinder is constrained at the two end surfaces, the different temperature distributions due to varied imposed heat fluxes in Figure 9 result in different stress profiles in the specimen, as clearly evidenced in Figure

10 ("*Thermal loading – HF10*" in (a) versus "*Thermal loading – HF 30*" in (b)): The higher the applied heat flux, the higher the compressive stress in concrete at the surface compared to that at the centre.

However, upon application of the imposed displacement, the stress distribution along a radius changes: The larger the imposed displacement and the higher the applied heat flux, the more significant the change. For the case of incident heat flux of 30 kW/m^2, the concrete stress at the surface become significantly less than that at the centre when the cylinder is subject to 2 mm imposed displacement.



(a) (b)

Figure 10 Stress profiles due to thermal loading combined with different levels of imposed displacement.

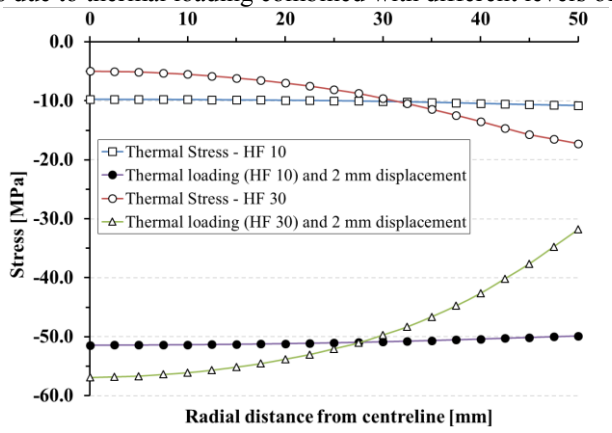


Figure 11 Illustration of stress profiles due to different applied heat fluxes.

The stress profiles along a radius due to different combinations of thermal and mechanical loadings are presented in Figure 11. It is clearly evidenced that for the same level of mechanical loading and at the same target temperature, different levels of incident heat flux may cause significantly different stress profiles, and thus potentially considerably different thermal and structural behaviour. However, such effect of heat flux, and of temperature gradient by extension, has not been captured in currently available models.

The temperature and stress profiles given by the numerical model presented in this paper will be compared to those to be obtained experimentally soon. Through such comparison, the model will be modified as appropriate. The better understanding of concrete performance in fire and improved numerical models would support the needed further transition to performance-based structural fire engineering.

SUMMARY AND CONCLUSIONS

This paper has first highlighted major limitations of conventional testing of concrete: (i) Thermal loading experienced by concrete specimens in conventional tests is very difficult to be accurately and independently controlled; and (ii) Currently available constitutive models have been primarily derived from tests with purposely-minimized temperature gradients, typically much lower than those experienced by concrete in real fires. Accordingly, the effect of temperature gradients within concrete on its fire performance has not been properly addressed – Neither has the influence of critical processes linked with temperature gradients, including thermal stresses, moisture transport, and pore pressures.

An ongoing research program at The University of Queensland thus aims to develop more realistic constitutive models through studying performance of concrete cylinders subject to known consistent heat flux boundary conditions. The numerical work for coupled thermal-stress analysis of concrete cylinder is subsequently presented in the paper. It is clearly shown that (i) Different levels of incident heat flux causes significantly different evolution of temperature and stress profiles within the specimen; and (ii) Such profiles and their nature may be considerably modified by mechanical loading. Accordingly, heat flux, and temperature gradient by extension, may have non-negligible influence on thermal and structural behaviour of concrete and concrete structures – Such influence has not been captured in currently available models.

ABSTRACT

To simulate a fire inside large compartments, there is a pioneering method called 'traveling fire'. As steel structures are vulnerable to high temperatures, they are normally fireproofed by insulation materials appropriate for a specific duration of time. An investigation is performed here to examine the robustness of a generic four-story moment-resisting steel structure, fireproofed to comply with the one-hour standard curve, when it is subjected to traveling fire. The results show that while no collapse occurs during the 12.5%, 50% and 100%, the structure collapses under the 25% fire size at 75 min. This seems to be in contradiction with traditional belief, where it is assumed that taking into consideration a larger-scale fire in a compartment would increase the safety margin. The investigation performed also underlines that the fireproofing of structures does not necessarily provide adequate resistance under traveling fires.

KEYWORDS

Standard fire curves, traveling fire, steel structures, robustness, fireproofing.

INTRODUCTION

What the natural fire curves and the standard fire curves have in common is that they consider a homogenous temperature throughout a compartment. While this assumption can be justified in small and medium compartments, it is not deemed to be precise in large compartments, as it has been revealed in several tests and observations that large compartments do not burn simultaneously throughout the enclosure (Stern-Gottfried and Rein, 2012b). This is the reason why the application of the natural fire curves is confined to compartments with areas up to 500 m^2, heights up to 4 m, and with no opening on the roof. In addition, highly conductive linings cannot be included to develop the fire curves. Although the majority of buildings designed in the last century fall within the scope of the natural fire curves, very few newly constructed buildings would meet the requirements mentioned (Jonsdottir et al., 2010). In addition, observations from real fires have proved that in large open areas the fire travels either vertically between the floors and/or across the floor plates. Therefore, combustible materials inside a compartment are not burnt concurrently and are consumed at a rate governed by the existing ventilation (Stern-Gottfried et al., 2010). This leads to a non-uniform temperature in the compartment.
There are a number of investigations concerning traveling fire, either vertically or horizontally. However, most of the structural studies mentioned above, however, have assumed that the fire moves suddenly from one zone to next. Besides, only a selected number of different temperatures were assumed in the investigations, which in turn is far from the situation in a real fire. In addition, studies considering the global response of structures under traveling fire are rare. Investigating the global robustness of structures subjected to traveling fire is thus of importance, and is the focus of the current study. From a different perspective, as steel structures are highly vulnerable to fire, they are normally fireproofed using insulation materials or are encased in concrete, both of which materials are less conductive and thus slow down the heat penetration. Nevertheless, the installation of the insulation materials is usually implemented based on the traditional fire curves, such as the standard or natural fire curves. Since there is almost no regulation regarding fireproofing procedures for large open-plan steel composite structures, an investigation is planned here to examine whether a fireproofed steel structure, already designed to meet a standard fire curve, ISO 834, can resist a traveling fire.

HORIZONTALLY TRAVELING FIRE

The influence of non-uniform temperatures on structural members was investigated by Gillie and Stratford (Gillie et al., 2012). They showed that the effect of non-uniform temperature on large open areas could not be ignored. There is also an innovative method for considering traveling fire proposed by Gottfried et al. (Gottfried et al., 2010, Stern-Gottfried and Rein, 2012b, Stern-Gottfried and Rein, 2012a). Based on their model, the temperatures arising from the fire can be divided into two relative regions, near field and far field, as illustrated in Figure 1. The near field temperature (T_{nf}) refers to the region where the combustible materials are being burnt, and hence only a portion of the compartment at any time is influenced. On the other hand, the far field temperature (T_{ff}) refers to the regions that are yet to burn. It was shown in the Gottfried et al.'s work that the far field temperature is higher than the ambient temperature (T_∞), as a result of layers of hot gases inside the compartment. The near field size pertains to the available ventilation, and is defined as an input to the model. In addition, the near field temperature depends on the flame temperature, and thus relies on the type of fuel being consumed. Details and assumptions made in this study for modelling of traveling fire are based on what were made in (Stern-Gottfried and Rein, 2012a).

Figure 1 Illustration of traveling fire (Stern-Gottfried and Rein, 2012a, Wang et al., 2012)

CASE STUDY STRUCTURE

The traveling fire methodology is applied here to a generic four-story steel moment-resisting frame designed as a conventional office building. The building consists of four bays of 6 m in each direction with storey height of 3.2 m. An internal frame is selected here to be investigated. Beams and columns are fire-protected for the one-hour standard fire curve, ISO834, after application of the insulation material to the members. The temperature at any one point of the steel sections does not exceed 550 ºC. The one-hour fire resistance was selected in line with the French and British fire code regulations, where it is mentioned that conventional office buildings up to four stories – irrespective of the skeleton properties – shall have 30-60 minutes fire resistance (Holicky M et al., 2005). Table 1 shows the sections used for the studied frame.

Table 1 Section of all members of the generic frame

Story	External Column	Internal Column	Beam
1,2	UC356 × 368 × 153	UC356 × 368 × 202	UB457 × 152 × 67
3,4	UC356 × 254 × 107	UC356 × 368 × 153	UB457 × 152 × 67

The structure is dimensioned for load combinations of 6.5 kPa for dead load and 2.0 kPa for live load. The slab is made of normal-weight concrete with a 100 mm thickness. Grade 43 steel, with yield strength of 275 MPa and Young's modulus of 210 MPa at ambient temperature, is used for the structural analysis. On the other hand, a question can arise whether a three-dimensional model should be considered. To respond, detailed comparisons have shown that there is a close agreement between two-dimensional and three-dimensional models, such as those conducted by Usmani (Usmani, 2005). Here, in the light of these previous studies, a two-dimensional frame is selected for the analysis. Moreover, as the concrete slab has an important role in the fire resistance of a structure, its effective length is also involved in the frame, which is 1000 mm, based on ACI 318-08 (ACI318, 2008).

DEVELOPMENT OF NUMERICAL MODEL

Modelling of Structure

OpenSees (Mazzoni, 2007) is used here to analyse the case study structure subjected to traveling fire. For this, a series of nonlinear dynamic analyses are performed. To model the steel behaviour, a bilinear kinematic stress-strain curve is assigned to the structural elements using Steel02Thermal from the OpenSees materials library. A strain hardening modulus of 1% E is considered to model the inelastic strain range of the material. Young's modulus and yield stress were reduced depending on temperature, in accordance with the reference to Eurocode. In addition, beam-column elements in combination with fiber cross-sections are used to model the cross-sectional areas. Plasticisation of elements over the member length and cross-section is considered as well. Large displacement effects are also taken into consideration through the employment of co-rotational transformation of the geometric stiffness matrix. All connections are assumed to be ideally rigid.

Thermal Analysis

To investigate the robustness of the frame subjected to the traveling fire, the first step is to perform the cross-sectional thermal analysis. For doing this, the SAFIR program, is employed (Franssen, 2005). Since SAFIR is a fiber-based program, the variation of temperature in all of the fibers can be obtained. Results of the temperature history over time are then transferred to OpenSees for performing the structural analysis. In order to reduce the computational time, the time-temperature results of a number of fibers, along with the height of the cross-section, are selected and then cast into OpenSees as shown in Figure 2.
Figure 3 shows the variation of peak flange and web temperatures versus fire sizes of 12.5% to 100%, based on a grid size of 1500 mm. It is understood from the figure that the peak temperature occurs under the application of the 12.5% fire size, while it declines along with increasing fire size. This is because the larger fire size has a higher far field temperature but shorter duration. By contrast, the smaller fire size has a fairly low far field temperature with higher duration.

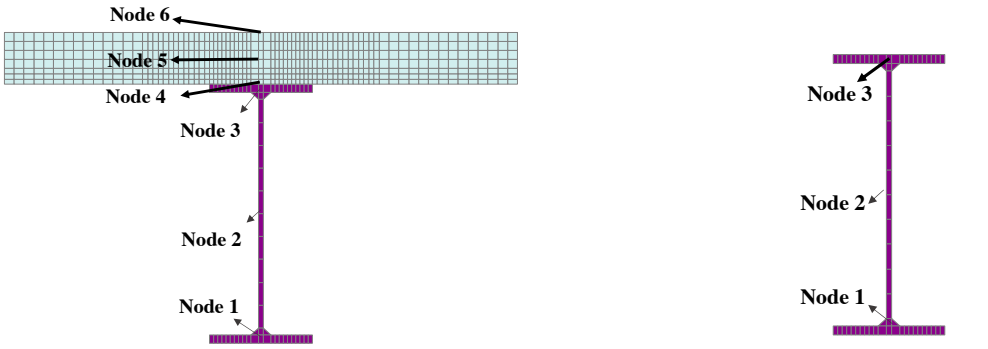
Gravitational Loading

As the traveling fire is defined in the time domain, all loads have to be defined in the time domain as well. The gravitational loads considered for the fire limit state comprise a combination of 100% of dead load and 50% of live load (BSI, 1991). For the case study here, this was a total line load of 45 kN/m. To work within the realm of time domain, the gravity loads were linearly increased during 5 seconds to reach their final values, and then, for the remainder of the analysis, times were kept unchanged.



a) Beams and slab b) Columns

Figure 2 Fibers selected from thermal analysis by using SAFIR

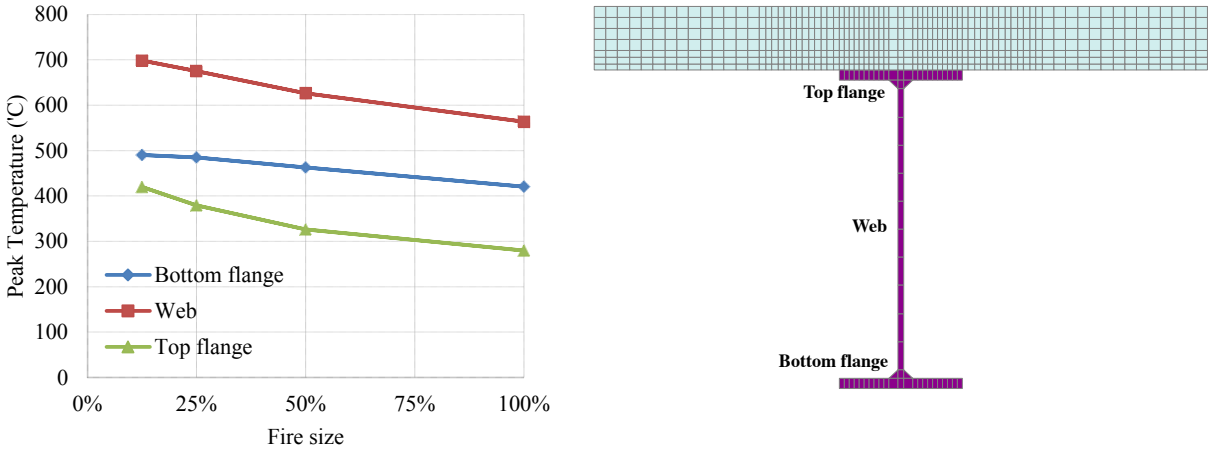


Figure 3 Variation of flange and web peak temperature versus fire size

Application of the Fire

The first story of the frame is subjected to the traveling fire as shown in Figure 4. It is assumed that the fire commences from axis A toward the other axes, while four fire sizes of 12.5%, 25%, 50% and 100% are selected for the analysis. Information for the fire sizes is shown in Table 2, including the heat release rate, the maximum total burning duration, the spread rate, and the near field temperature (which is assumed to be 1200 °C). The grid size (Δx) of 1500 mm is selected; hence each span is divided into four quarters which are supposed to provide adequate resolution for the far field temperature and the total burning time. The exterior sides of the external columns are not exposed to the fire. In addition, the top sides of the beams are not exposed to fire, as it is supposed that the top side is protected by the concrete slab.
The gas phase temperatures for beams and columns are then plotted separately, some of which are shown in Figure 5. These curves clearly show that the temperature variation in longitudinal direction of the case study plan is not constant, and thus, while some nodes are being heated up, some of them are being cooled. This variation in the temperature is important, since it may intensify the collapse risk, because different temperatures can result in different tensile forces in axially restrained beams.

RESPONSE OF THE CASE STUDY STRUCTURE TO THE FIRE SCENARIOS

Robustness Assessment

There are various failure criteria that mostly relate to one structural member, such as the thermal and the strength failure criteria mentioned in ASTM E119 (ASTME119-01, 2001). Most fire engineers would say that a steel member has failed when its temperature goes beyond 550 ºC. While using this failure criterion can provide much simplicity for controlling the stability of a member, its use is arguable for a building structure such as the case study here. Indeed, it is challenging to say that failure of a member – even though it is accepted that for instance at 550 ºC the member has failed – will automatically result in a chain of successive failures in other members. This relates to the definition of progressive collapse, where the robustness of a structure to resist a localized failure is scrutinized. After failure of a structural member, if an alternative load path is found, i.e. the load can be re-distributed to other members, the structural integrity is maintained. Mostly, when two successive columns fail, the load cannot be redistributed, and hence, progressive collapse occurs. In following part, response of the structure to fire sizes of 50% and 100% are not shown since they do not lead to instability of any structural member.

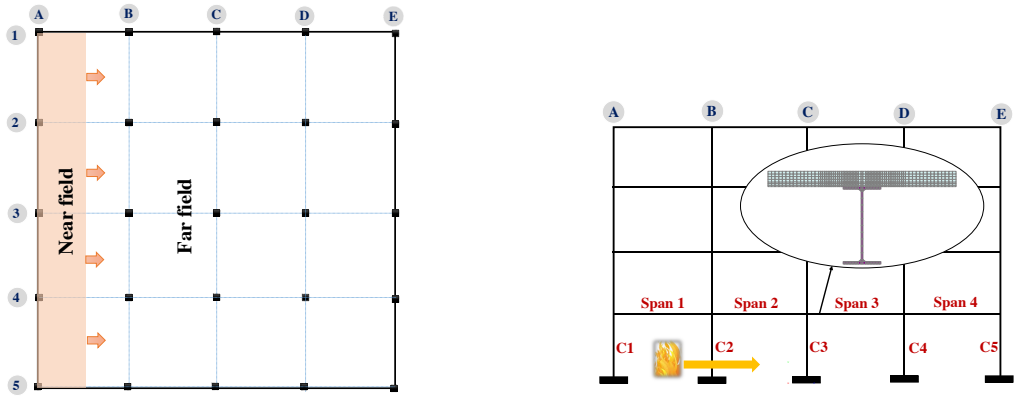

Figure 4 Application of the traveling fire to the case study

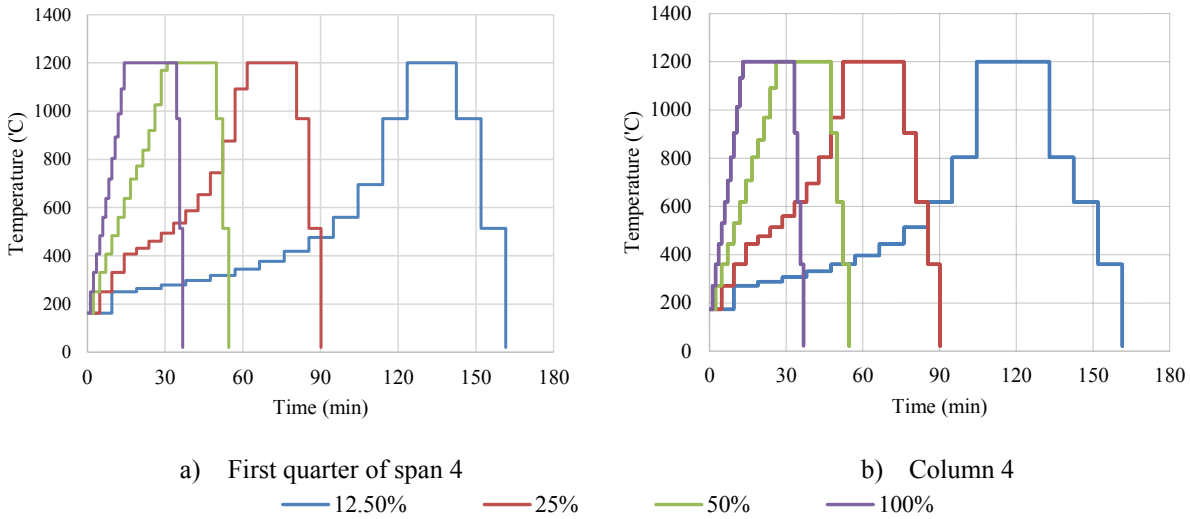
Table 2 The size range of the fire

Fire size (%)	A_f (m^2)	$\dot{Q}$ (MW)	t^*_{total} (min)	s (m/min)	T_{nf} (°C)
12.50	72	36	161.50	0.16	1200
25.00	144	72	90.25	0.32	1200
50.00	288	144	54.62	0.63	1200
100.0	576	288	36.81	1.26	1200

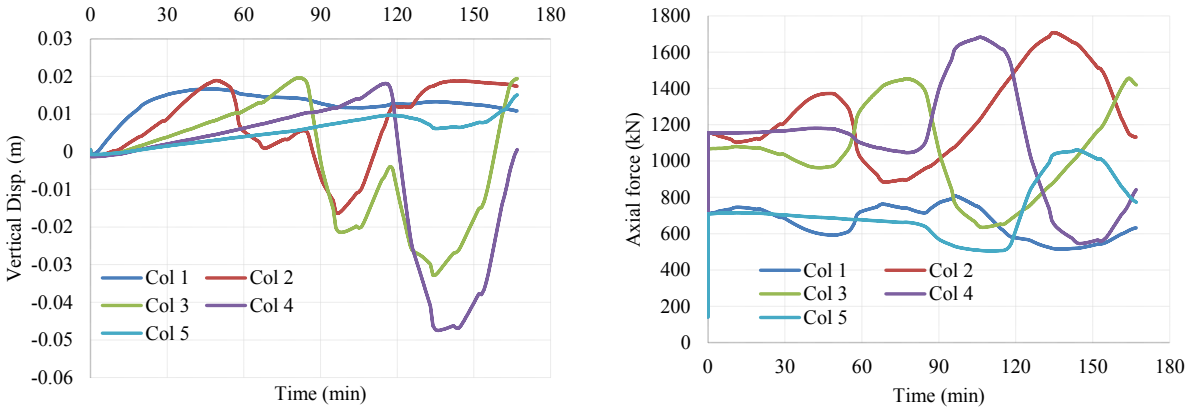
Fire Size of 12.5%

Figure 6 shows the response of the structure under the application of the 12.5% fire size. As is seen in Figure 6a (the vertical displacements at the top side of the columns), no global failure occurs. However, some transient instabilities are experienced during the analysis, mainly due to the buckling of some columns. The global stability of the structure can be justified because of the structure's capacity to redistribute loads from the failed elements to other elements. This can better be understood in Figure 6b, where the axial loads of the columns are shown. As is seen, larger distribution of the loads occurs when the fire travels across the story in such a way that columns 2 and 4 tolerate much more axial loads than the other columns. It is observed that, as the temperature rises, column 1 experiences more compression force, resulting in a decrease in the axial load of column 2. However, as the temperature of column 2 increases, its axial force increases while the axial force of column 1 decreases. This state continues until column 2 buckles at 49.18 min, when the temperature is 601.61 ºC (web temperature) and thus, its load is relocated to column 3. Furthermore, when the near field temperature has passed beyond column 2, which means the temperature decreases, it can again carry more axial load. Then, when at 81.71 min (web temperature of 597.97 ºC) column 3 buckles, its load is transferred to the adjacent columns 2 and 4



a) First quarter of span 4 b) Column 4

Figure 5 Gas phase temperatures

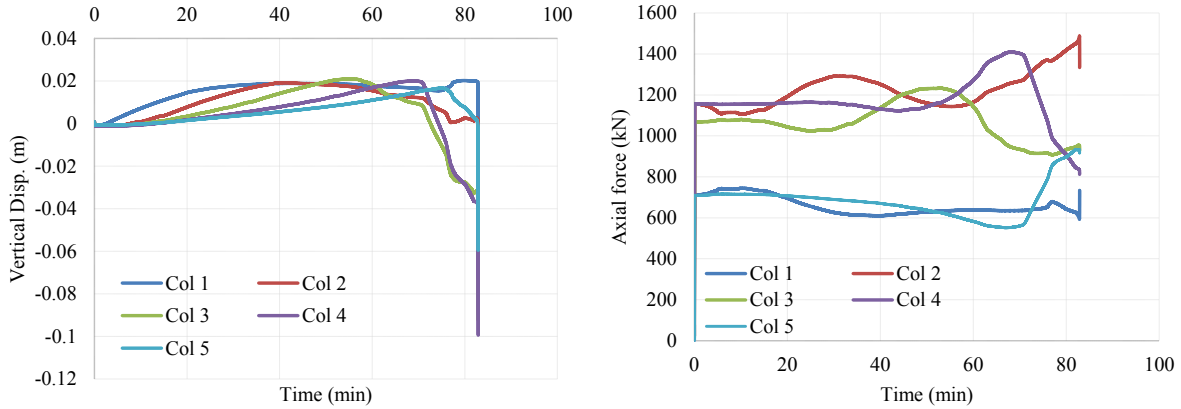


a) Vertical displacement b) Axial `

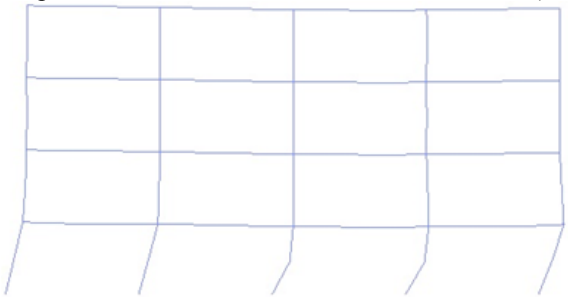
Figure 6. Response of the structure under the traveling fire size of 12.5%

Fire Size of 25%

The response of the structure under the 25% fire size is shown in Figure 7. As seen in Figure 7a, the structure collapses when column 5 buckles at 74.95 min (temperature 458.66 ºC). It can also be seen that the compression force in column 1 increases over the heating phase. However, when column 2 is exposed to higher temperatures, its axial force increases while the axial force of column 1 decreases. This continues until buckling of column 2 occurs at 41.33 min (web temperature of 602.8 ºC). At this moment, column 3 carries the gravitational load that is supposed to be carried by column 2. This continues until the buckling of column 3 at 55.25 (web temperature of 633.11ºC). As with the previous column, the load is transferred to columns 2 and 4. This structural behaviour continues until the bucking of column 5, at which point (based on the temperature of adjacent columns) there is no sufficient alternate path to transfer the loads carried by failed columns. The total collapse occurs at this time, as shown in Figure 7c.



a) Vertical displacement b) Axial force



c) Deformed frame after the application of the fire size of 25% (t= 74.95 min)

Figure 7. Response of the structure under the traveling fire size of 25%

GENERAL CONCLUSION FROM THE RESULTS

As a general conclusion, it is evident that the stability of the frame is largely dependent on the fire size, a point that could not be understood prior to the investigation performed here. The structure remains stable in all of the fire scenarios except for the 25% fire. This conclusion is in contradiction with traditional belief, which deems that the assumption of a larger-scale fire in a compartment is a more-conservative assumption, and one that can thus increase the safety margin. The results of the investigation performed here become more noteworthy when reminded that the structure has already been designed and fireproofed to resist the one-hour standard fire curve, ISO 834. It is also worth noting that while the fire size decreases, the maximum gas temperature increases, as shown in Figure 8. In terms of the structural engineering view, nevertheless, the fire size with the maximum temperature does not necessarily bring about the most critical situation, as was investigated here. In other words, the fire size and the method of application of fire to a large open area can lead to different results, ranging from no damage to total collapse. As there is a low possibility of a uniform fire in a large compartment, it is essential to consider the results of a traveling fire in order to arrive at more accurate results. The results of the investigation performed here are more noteworthy when it is re-stated that the building had already been fireproofed, leading to the presumption that it would remain stable under the possible fires. As there are almost no fire regulations standardized for large compartments, particularly as regards fireproofing, more investigations are thus required to arrive at a better understanding of the application of traveling fire to large compartments.

ABSTRACT

Fire resistance of cold-formed light gauge steel frame (LSF) wall systems is enhanced by lining them with single or multiple layers of wall boards with varying thermal properties. These wall boards are gypsum plasterboards or Magnesium Oxide (MgO) boards produced by different manufacturers. Thermal properties of these boards appear to show considerable variations and this can lead to varying fire resistance levels (FRL) for their wall systems. Currently FRLs of wall systems are determined using full scale fire tests, but they are time consuming and expensive. Recent research studies on the fire performance of LSF wall systems have used finite element studies to overcome this problem, but they were developed based on 1-D and 2-D finite element platform capable of performing either heat transfer or structural analysis separately. Hence in this research a 3-D finite element model was developed first for LSF walls lined with gypsum plasterboard and cavity insulation materials. Accurate thermal properties of these boards are essential for finite element modelling, and thus they were measured at both ambient and elevated temperatures. This experimental study included specific heat, relative density and thermal conductivity of boards. The developed 3-D finite element model was then validated using the available fire tests results of LSF walls lined with gypsum plasterboard, and is being used to investigate the fire performance of different LSF wall configurations. The tested MgO board exhibited significant variations in their thermal properties in comparison to gypsum plasterboards with about 50% loss of its initial mass at about 500 ºC compared to 16% for gypsum plasterboards. Hence the FRL of MgO board lined LSF wall systems is likely to be significantly reduced. This paper presents the details of this research study on the fire performance of LSF wall systems lined with gypsum plasterboard and MgO board including the developed 3-D finite element models, thermal property tests and the results.

INTRODUCTION

Cold-formed LSF wall frame systems are widely adopted in contemporary buildings due to higher strength-to-weight ratio, better durability, enhanced thermal comfort, light-weight, aesthetic appearance, and cost effectiveness compared to hot-rolled steel frame systems. Fire resistance of LSF wall systems is an important factor in preventing the spread of fire and eventually the building collapse due to material degradation of cold-formed steel at elevated temperatures. This can be achieved by having single or multiple layers of wallboards on both sides of the LSF wall to prevent the steel studs from being heated to failure temperatures.

Fire performance of LSF wall systems can be understood by performing full-scale fire tests. Many experimental research studies have been performed on various LSF wall configurations exposed to fire. However, these full-scale fire tests are time consuming and expensive. On the other hand, finite element analysis (FEA) provides a simple way of investigating the fire performance of different LSF wall systems and understanding their thermal-mechanical behaviour. Recent numerical research studies have focused on investigating the fire performances of LSF wall systems by using finite element methods. Most of these methods were developed based on 2-D FE platform capable of performing either heat transfer or structural analysis separately.

Recently, researchers have mainly focused on understanding the fire behaviour of different LSF wall system configurations while incorporating new strategies to improve the fire performance (i.e. increase the FRLs). These strategies were experimentally and numerically evaluated by incorporating different stud sections (Kesawan and Mahendran, 2015), adding more plasterboard layers (Sultan and Kodur, 2000), changing the type of wall boards from conventionally used gypsum plasterboards to MgO boards and calcium silicate boards (Chen et al., 2012), using enhanced plasterboards by additives and fillers (Keerthan and Mahendran, 2013), including external or sandwiched insulation between two plasterboards (Kolarkar 2010), including different insulation materials with varying thickness and materials such as rock, glass, and cellulose fibre insulation

materials (Gunalan, 2011) and evaluating the difference between realistic and standard fire curves (Ariyanayagam, 2013).
Measured data from experimental investigations need to be evaluated with the use of numerical analysis results. Validated numerical models can then be used to perform parametric analysis by changing the configurations of LSF walls with different components. This will enable better understanding of the research problem. Different types of finite element modelling and analysis software are currently available. In recent research studies, SAFIR and Abaqus were extensively used and are the most commonly used FE software to investigate the thermal performances of LSF wall systems. The information related to these studies can be found in Nassif et al. (2014), Keerthan and Mahendran (2012), Shahbazian and Wang (2013) and Feng et al. (2003).

This research is focused on investigating the fire performance of LSF wall systems by using 3-D heat transfer finite element (FE) models of existing LSF wall system configurations. The analysis results were validated by comparisons with available fire test results of five different load bearing LSF wall configurations. The fundamental understanding of the thermal performance of LSF wall systems was improved by using newly validated 3-D finite element models. Accurate thermal properties of LSF wall components, especially those of wall boards are essential for FE modelling, and thus they were measured at both ambient and elevated temperatures in this research study. This experimental study on thermal properties included specific heat, relative density and thermal conductivity of LSF wall boards such as gypsum plasterboard and MgO board.

3-D FE MODEL DEVELOPMENT AND VALIDATION

Overview

Fire performance of LSF wall systems has been widely investigated using full-scale fire tests and then compared with FEA results. Many research studies used a simplified approach to simulate the test results. This simplified approach was mainly based on 1-D and 2-D uncoupled FE models, which were developed with appropriate thermal-mechanical properties for LSF wall components such as wall boards, cavity insulation and studs as well as boundary conditions such as convection and radiation. However, the effects of wall board configurations, cavity shapes, stud shapes, noggings, service holes in studs, partially fire exposed LSF walls and different boundary conditions will develop non-uniform temperature profiles across the LSF wall during a fire event, and thus 1-D or 2-D model are not suitable. Therefore, in this study, a 3-D FE modelling approach was developed and validated with full-scale fire test results. The newly developed FE thermal models can be fully coupled to the structural modelling of the studs, which is an advantage of using the newly developed 3-D FE models. This section presents the details of the FE thermal model development and validation using Kolarkar's (2010) test results for different LSF wall configurations with gypsum plasterboards and with and without cavity insulation. These configurations were simulated using 3-D heat transfer models developed using Abaqus/CAE Version 6.13. The thermal properties used in the 3-D FEA are discussed next.

Thermal Properties of Conventional LSF Wall Components Used in FEA

Gypsum Plasterboard

An important aspect of FE thermal model validation is the appropriate use of thermal properties for the components. Therefore, measured thermal properties of gypsum plasterboard were used in the FE models with linear curve approximation to the actual measured properties. The linear curve approximation was adopted to avoid overloading the analysis with more data points and also to reduce the analysis time. The measured and proposed specific heat, thermal conductivity and density are shown Figures 1 to 3. Figure 1 shows the measured and proposed specific heat variation in gypsum plasterboard. Gypsum plasterboard exhibits two specific heat peaks of 17,500 and 13,500 J/kg/°C at 140 and 170 °C, respectively. This is mainly due to the dehydration of chemically bound water inside the gypsum plasterboard. Therefore, gypsum plasterboard will absorb heat and delay the temperature rise when exposed to fire during these peak temperatures.

Figure 2 shows the measured and proposed thermal conductivity of gypsum plasterboard. The measured thermal conductivity value of gypsum plasterboard at ambient temperature is approximately 0.2 W/m/ºC. This value reduces during the dehydration processes. However, after complete dehydration of water at about 200 ºC, the thermal conductivity was proposed to increase to 0.3 W/m/ºC at 800 ºC. This increase is due the burning of gypsum plasterboard outer layers, which is made of paper. It was further modified after this temperature in order to include the effect of ablation and cracking in gypsum plasterboard after 800 ºC. Figure 3 shows the relative

density of gypsum plasterboard, which shows a mass loss of about 16 % during the dehydration process. After this process, the relative density remains unchanged.

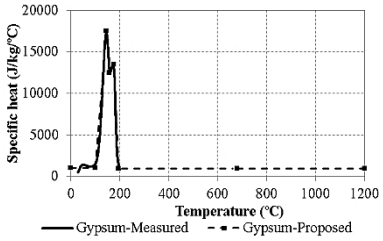

Figure 1 Gypsum plasterboard specific heat

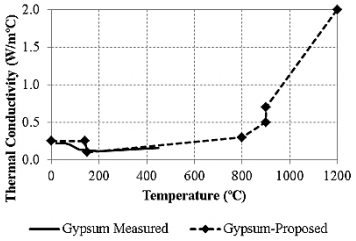

Figure 2 Gypsum plasterboard thermal conductivity

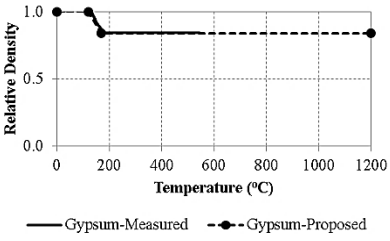

Figure 3 Gypsum plasterboard density

Steel

Thermal properties for steel were obtained from Eurocode 3: Part 1-2 (BS EN 1993-1-2:2005). The specific heat and thermal conductivity profiles are shown in Figures 4 and 5. The density of the steel remains constant at 7,850 kg/m^3 at all temperatures.

Insulation

The measured thermal properties for glass fibre, rock fibre and cellulose fibre insulation materials reported in Keerthan and Mahendran (2012) were used in FEA. They proposed constant specific heat values of 900, 840 and 1250 J/kg/ºC and density values of 15.42, 100 and 125 kg/m^3 for glass fibre, rock fibre and cellulose fibre insulation material, respectively. However, the conductivity values varied with temperature as shown in Figure 6. As the glass fibre melts at about 600–700 ºC, it was assumed to increase from 0.6 to 10 W/m/ºC after 600 ºC.

FEA Model Configurations

This section presents the details of FE model development and validation using Kolarkar's (2010) fire test results for LSF wall systems with five different configurations of 16 mm gypsum plasterboards and lipped channel studs (90×40×15×1.15 mm) spaced at 600 mm as listed in Table 1. The tests were conducted for 2.4 m × 2.1 m LSF walls exposed to standard fire time-temperature curve on one side. These five tests are referred to as Models 1 to 5 in FEA.

Table 1 LSF wall configurations tested by Kolarkar (2010)

Model No.	Configuration	Insulation	Board Configuration	Failure Time
1		None	Single board	54
2		None	Double board	111
3		Glass Fibre	Double board	101
4		Rock Fibre	Double board	107
5		Cellulose Fibre	Double board	110

FEA Modelling Strategies

The 3D FE models of the above LSF wall configurations were developed in Abaqus/CAE Version 6.13 with only two middle studs and gypsum plasterboards as shown in Figure 7. The other studs were replaced with gypsum plasterboards, because only the middle two studs are the critical studs in the tests. Considering the symmetry of the test specimens, the model was rescaled to 0.6 m height to reduce the analysis time. All the LSF components were modelled using 8-node linear heat transfer brick elements (DC3D8). A mesh density of 50 mm on the x-y plane and 2 mm through thickness mesh of the model components was selected based on a sensitivity analysis of Models 1 and 2 and comparison of stud and plasterboard time-temperature profiles.

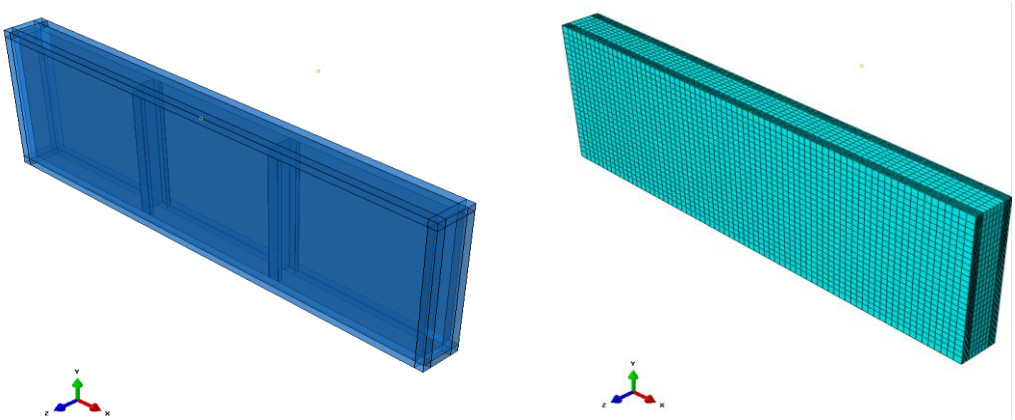

Figure 7 3-D FE model of LSF wall (Model 2: LSF wall lined with double plasterboards)

Boundary Conditions

There are three major heat transfer modes in FEA, named as conduction, convection and radiation. The conduction effect was defined using appropriate conductivity values as discussed earlier. The convection heat transfer was defined by assigning convective film coefficients of 25 and 10 W/m^2/ºC on the fire and ambient sides, respectively. This value was selected based on the values proposed in past research studies (Keerthan and Mahendran, 2012). Finally, the radiation heat transfer was defined by assigning an emissivity value of 0.9 on all the surfaces of LSF walls. The wall's top, bottom and sides were assigned with no boundary conditions, thus no heat transfer occur through them. In addition to these boundary conditions, the LSF wall components modelled using heat transfer solid elements (DC3D8) were connected using tie constraints to ensure solid-solid heat transfer between them.

Standard fire curve was defined as an amplitude curve following a time-temperature profile based on ISO 834, where $\theta = 345\log 10(8t + 1) + 20$ (θ – temperature and t – time). This was assigned to the fire exposed side as boundary condition. The sink temperature for the fire side was assigned to follow the fire curve, whereas a room temperature value of 23 ºC was assigned on the ambient side of the gypsum plasterboards. The Stefan-Boltzmann constant (σ) of 5.67×10^{-08} W/m^2/ºC^4 was also assigned to the FE model. In addition to the above boundary conditions, the models without interior cavity insulation materials were modelled in Abaqus/CAE using closed cavity radiation in enclosures. The cavity surfaces enclosed by the LSF wall components were selected first and then a cavity radiation emissivity of 0.9 was assigned to those surfaces.

FEA Results and Discussion

The 3D FE model were analysed until the LSF wall failure times reported by Kolarkar (2010), which were given in Table 1. Temperature contours obtained from FEA for Model-3 are shown in Figure 8. The experimental average time-temperature profiles (hot flange - HF, web and cold flange - CF) of the middle two studs were plotted with the FEA results in Figures 9 to 13. In addition, the average time-temperature profiles measured on the plasterboard surfaces of the wall (Fire side – Fire, Fire side cavity surface – Fire-In, Ambient side cavity surface – Amb-In, Ambient side – Amb) were also plotted with FEA results in Figures 14 to 18. The results showed a very good agreement between the experimental and FEA results for all five LSF wall configurations. The 3D heat transfer FE models were able to capture the transient temperature profiles with good accuracy and most importantly, the hot flange temperature values were predicted with very good accuracy at the failure time.

The failure times observed during the fire tests of LSF wall configurations 1 to 5 were 54, 111, 101, 107 and 110 minutes, respectively (refer Table 1). Therefore, these validated FE models can be used to accomplish further research on different wall configurations. In addition, the failure times of non-load bearing and load bearing LSF walls can be predicted using these models based on a limiting temperature approach. Finally, these models can be utilized by changing the material properties to investigate other available LSF wall components such as different wall board (MgO board, cement fibre board and perlite board) and cavity insulation materials.

THERMAL PROPERTIES OF MGO BOARD

A commonly used MgO board that is currently available in the Australian market was used in the preliminary experimental studies of this research.

Specific Heat

Specific heat values of five samples taken at different locations of the MgO board were measured as shown in Figure 19. The first peak of specific heat variation occurs at about 120 ºC with a specific heat value of about 10,000 J/kg/ºC. This specific heat value almost remains constant with minor peaks up to 275 ºC. As stated by Chen et al. (2013), this is due to the dehydration reactions within the MgO board ($5Mg(OH)_2.MgCl_2.8H_2O \rightarrow 5Mg(OH)_2.MgCl_2 + 8H_2O$). After this, a sharp peak with a specific heat value of about 35,000 J/kg/ºC occurs at about 375 ºC. This shows that a major chemical reaction occurs during that period, which was illustrated by Chen et al. (2013) as the hydrolysis ($5Mg(OH)_2.MgCl_2 \rightarrow 4Mg(OH)_2 + 2MgO + 2HCl$) and pyrolysis reactions ($Mg(OH)_2 \rightarrow MgO + H_2O$).

Relative Density

The relative density variation of five samples taken from the same MgO board is shown in Figure 20. The ambient density of the MgO board was about 1025 kg/m^3. It appears that MgO board loses over 25% of its initial mass until it reaches a temperature of about 350 ºC. A sudden drop in relative density occurs between 350 and 400 ºC, where the initial mass is further reduced by approximately 20%. This higher mass loss occurred due to hydrolysis reaction as highlighted in the specific heat test results. After that, another 5% reduction can be observed when the temperature reached 530 ºC. The total loss of mass in the MgO board samples is approximately 50% of the initial mass. Such higher loss of mass in MgO board may lead to shrinkage and cracks, which may affect the fire performance of MgO board lined LSF wall systems.

Thermal Conductivity

Figure 21 shows that MgO board has a thermal conductivity of 0.45 W/m/°C at room temperature. At elevated temperatures, the overall thermal conductivity values decreased to 0.12 W/m/°C at an average temperature of about 200 °C due to dehydration reactions. An attempt was made to conduct a thermal conductivity test on the MgO board at 450 °C. However, it could not be completed due to bending of the specimen when heated to the desired temperature as the contact between the hot plate and the specimen was not achieved. Further tests are needed for the MgO board at elevated temperatures to better understand their fire performance.

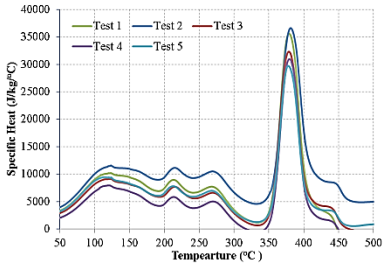

Figure 19 Specific heat

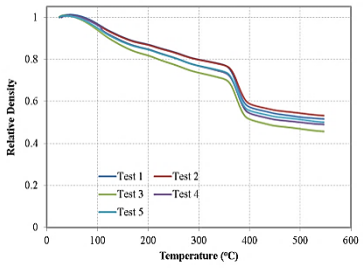

Figure 20 Relative density

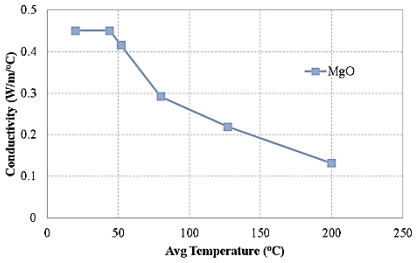

Figure 21 Thermal conductivity

Discussions

Thermal property tests showed that the selected MgO board loses about 50% of its initial mass, which will affect its fire performance. The effect of this higher mass loss will be detrimental to the fire performance of LSF walls lined with MgO boards. Therefore, further research is needed using other available MgO boards to investigate their thermal properties at elevated temperatures. Preliminary FE analyses using the 3-D modelling approach and the measured thermal properties of MgO board indicate inferior fire performance of LSF wall lined with MgO board. Fire tests need to be conducted for LSF walls lined with MgO board to further investigate these findings.

CONCLUSIONS

This research paper has presented detailed 3-D FE model development strategies and validation of FEA results using the measured time-temperature profiles in an experimental study of five different LSF wall configurations lined with gypsum plasterboard. In addition, thermal properties of gypsum plasterboard and MgO board were also measured to investigate its potential to be used in LSF walls. The following conclusions can be made from this research study.

- The 3-D FE model developed using Abaqus/CAE with measured thermal properties of gypsum plasterboard was able to accurately predict the transient time-temperature profiles. These 3-D FE models can be used as a benchmark for further parametric studies with different LSF wall configurations based on different types of boards, cavity insulation materials and different stud sections.
- Thermal property tests showed that MgO board loses about 50% of its initial mass compared to 16% of mass in gypsum plasterboard, which will affect the fire performance of LSF walls lined with this type of MgO board.
- Preliminary analyses using the 3-D modelling approach and the measured thermal properties of MgO board indicate inferior fire performance of LSF wall lined with MgO board. Fire tests need to be conducted for LSF walls lined with MgO board to further investigate these findings.

ABSTRACT

This paper presents the effects of sodium and potassium based activators on compressive strengths and physical changes of class F fly ash geopolymer exposed to elevated temperatures. Samples were heated at 200^0C, 400^0C, 600^0C and 800^0C to evaluate the residual compressive strength after 28 days of curing. The fly ash geopolymer were synthesized with combined sodium silicate and sodium hydroxide solutions and potassium silicate and potassium hydroxide solutions by varying mass ratios of Na_2SiO_3/NaOH and K_2SiO_3/KOH of 2, 2.5 and 3. Results show that in the cases of Na_2SiO_3/NaOH ratios of 2 and 2.5, the compressive strengths of geopolymers are decreased at 400, 600 and 800°C, with exception at 200°C. The reduction is significantly high from 32-61% at 800°C compared to ambient temperature strength. However, significant improvement is noticed in the case of Na_2SiO_3/NaOH ratio of 3, where the residual compressive strengths are increased upto 600°C. Better results on the geopolymer synthesized with potassium based activators are obtained where the residual compressive strength up to 600°C are much higher than their sodium based counterparts. The geopolymer containing K_2SiO_3/KOH ratio of 3 even gained about 5% strength at 800°C. It is also found that the fly ash geopolymer synthesized with potassium based activators is more stable at elevated temperatures than its sodium based counterparts in terms of higher residual compressive strengths, lower mass loss, lower volumetric shrinkage and lower cracking damage.

KEYWORDS

Geopolymer, fly ash, elevated temperatures, sodium silicate, sodium hydroxide, potassium silicate, potassium hydroxide.

INTRODUCTION

Geopolymeris a new construction material which gained its popularity in recent years due to its environment friendliness and excellent mechanical and durability properties in severe environment. Geopolymer is first introduced by Davidovits (1991) and is generally made by reacting aluminate and silicate bearing source materials with alkali activator. Excellent fire resistance of geopolymer is its most significant advantage over cement based binder due to its ceramic like property.

Extensive researches have been conducted to study various mechanical and durability properties of geopolymer. Significant efforts have also been made by many researchers to study the effect of elevated temperatures on mechanical properties of geopolymer. However, most of the studies were on different geopolymers which consisted of various types of source materials and alkali activators, e.g. fly ash activated by sodium based alkali activators (Rickard et al., 2012, Abdulkareem et al., 2014, Ranjbar et al.,2014, Shaikh and Vimonsatit, 2015), fly ash activated by combined sodium and potassium based activators (Kong and Sanjayan, 2008 and 2010, Bakharev, 2006), combined fly ash and slag activated by sodium based activator (Guerrier and Sanjayan, 2010), metakaolin activated by combined sodium and potassium based activators (Kong et al., 2007), etc.. Among all above source materials the class F fly ash is rich in silica and alumina and low in calcium oxide, which enables its higher stability in fire than others. Moreover, it is cheaper, easily and widely available than other source materials.

This paper presents the effects of sodium and potassium based activators on the compressive strength of fly ash geopolymer at various elevated temperatures of 200, 400, 600 and 800°C. The effects of silicate to hydroxide ratios for both sodium and potassium based activators on the compressive strengths and physical changes like the mass loss, volumetric shrinkage, damage cracking at above elevated temperatures are also evaluated.

EXPERIMENTALPROGRAM

The experimental program is consisted of two parts. The first part is geopolymer paste containing sodium based activators combinations, where three different sodium silicate to sodium hydroxide ratios of 2, 2.5 and 3 are considered and for each ratio the geopolymers are heated at 200, 400, 600 and 800ºC temperatures as well as at ambient temperature. Thus fifteen series of pastes are cast and tested at elevated temperatures in the first part. The second part is similar to the first part in every aspect except the alkali activators where potassium silicate and potassium hydroxide are used. For each series, in both parts, six 50 mm cube specimens are cast and tested and the average value is shown in the results. Detail experimental program and mix proportions can be seen in Table 1. In all pastes a constant activators/fly ash ratio of 0.35 is considered.

MATERIALS AND MIXING

Class F fly ash supplied by Gladstone power station of Queensland was used as source material to prepare the geopolymer pastes. Table 2 shows the chemical compositions of the fly ash. The activating alkali liquids consisted of Na_2SiO_3 and NaOH solutions as well as K_2SiO_3 and KOH solutions. The Na-based activator was composed of 8.0 M sodium hydroxide (NaOH) and D Grade sodium silicate (Na_2SiO_3) solutions. NaOH solution was prepared with a concentration of 8.0 M using NaOH beads of 97% purity and tap water. The D Grade Na2SiO3 solution was supplied by PQ Australia with a specific gravity of 1.51 and a modulus ratio (Ms) equal to 2.0 (where Ms = SiO_2/ Na_2O, Na_2O = 14.7% and SiO2 = 29.4%). The NaOH and Na_2SiO_3 solutions were mixed together with Na_2SiO_3/NaOH mass ratio of 2, 2.5 and 3 to prepare the Na-based activators. The K-based activator was composed of 8.0 M potassium hydroxide (KOH) and potassium silicate (K_2SiO_3) solutions. KOH solution was prepared with a concentration of 8.0 M using KOH flakes of 90% purity supplied by Perth Scientific, Australia and tap water. The K_2SiO_3 (KASIL 2236 Grade) solution was supplied by PQ Australia with a specific gravity of 1.32 and a modulus ratio (Ms) equal to 2.23 (where Ms = SiO_2/K_2O, K_2O = 11.2% and SiO_2 = 24.8%). KOH and K_2SiO_3 solutions were mixed together with K_2SiO_3/KOH mass ratio of 2, 2.5 and 3 to prepare the K-based activators.

Table 2 Chemical Composition of Fly Ash (mass %)

Compounds	SiO_2	Al_2O_3	Fe_2O_3	CaO	Na_2O	K_2O	TiO_2	MgO	P_2O_5	SO_3	TiO_2	MnO	LOI
Fly ash	51.11	25.56	12.48	4.3	0.77	0.7	1.57	1.45	0.885	0.24	1.32	0.15	0.57

All pastes were prepared in a Hobart mixer. To prepare the Na- and K-based geopolymer paste the alkaline activators in the form of solution were added to the fly ash and mixed for about 4 min. The fresh geopolymer pastes were cast into standard 50 mm plastic cube moulds and compacted using a vibrating table. The specimens

were subjected to heat curing. In this regard, all moulds were sealed to minimize moisture loss and placed in an oven at 70ºC for 24 h. At the end of heat curing period, the specimens were removed from the oven and kept undisturbed until being cool and then removed from the moulds and left in the laboratory at ambient temperature until the day of testing. Compressive strength of all specimens was measured according to AS 1012.9:2014. For each mix, at least six specimens were tested in order to check the variability of performance under compression. The volume stability or in other words the volumetric shrinkage of pastes was determined by measuring the length of three sides of the cubes before and after heating at respective elevated temperatures. The difference in volume changes indicates the shrinkage and six specimens were used to measure the shrinkage for each series. Similar method was used to determine the mass loss of geopolymer pastes after exposed to respective elevated temperatures.

ELEVATED TEMPERATURE EXPOSURE:

A locally manufactured kiln was used to heat the geopolymer specimens, where the specimens were heated up to 800°C. The specimens were positioned inside the kiln where two thermocouples were touched the specimens, and two more thermocouples were also inserted into the kiln in order to monitor the kiln air temperature. The thermocouples were connected to the data logger and were used to monitor the temperature inside the concrete and the kiln air as shown in Figure 1. A heating rate of 500°C per hour was selected. During heating process the temperatures of four thermocouples were monitored. Once the specimen's surface reached the target temperature, the temperature inside the kiln was hold for one hour. The rate of temperature increase in the kiln and in the specimen is shown in Figure 2.

RESULTS AND DISCUSSIONS

The measured compressive strengths of geopolymer pastes containing different Na_2SiO_3/NaOH ratios of 2, 2.5 and 3 after exposing to 200, 400, 600 and 800°C temperatures are shown in Figure 3. It can be seen that the residual compressive strengths of geopolymer paste containing Na_2SiO_3/NaOH ratio of 2 and 2.5 are increased by about 9-11% at 200°C compared to ambient temperature strength. However, with further heating at 400, 600 and 800°C temperatures the residual compressive strengths of above geopolymer pastes are decreased below the ambient condition (see Figure 4). On the other hand, the same geopolymer paste containing Na_2SiO_3/NaOH ratio of 3 showed significant increase in residual compressive strength by about 25-35% up to 600°C with exception at 800°C, where the residual compressive strength is decreased by more than 30% (See Figure 4).

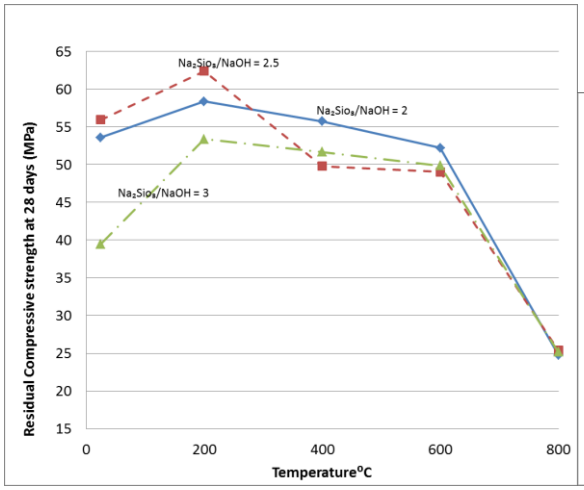

Figure 3 Residual compressive strength of geopolymer pastes containing Na-based activators at various elevated temperatures

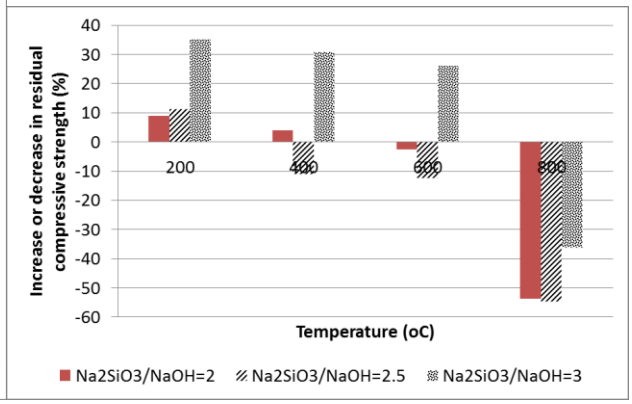

Figure 4 Relative increase or decrease in residual compressive strength of geopolymer pastes containing Na-based activators at various elevated temperatures compared to ambient temperature.

The effect of K-based activators on the compressive strength of geopolymer paste at elevated temperatures is also evaluated in this study and is shown in Figures 5-6. Figure 5 shows the measured compressive strengths of geopolymer pastes containing different K_2SiO_3/KOH ratios of 2, 2.5 and 3 after exposing to 200, 400, 600 and 800°C temperatures. It can be seen in the figure that for all three K_2SiO_3/KOH ratios the residual compressive strengths of geopolymer pastes are much higher than the ambient temperature strength and the residual compressive strengths are increased with increase in elevated temperatures until 600°C. It is also interesting to see that at 400 and 600°C the geopolymer paste containing K_2SiO_3/KOH ratios of 2 and 2.5 show about 40-55% increase in compressive strength compared to ambient condition. Although the increase in compressive strength of paste containing K_2SiO_3/KOH ratios of 3 is slightly lower (about 22-26%) at those temperatures, the

compressive strength is increased by about 5% at 800°C temperature, which is not observed in the case of K_2SiO_3/KOH ratios of 2 and 2.5 (see Figure 6).

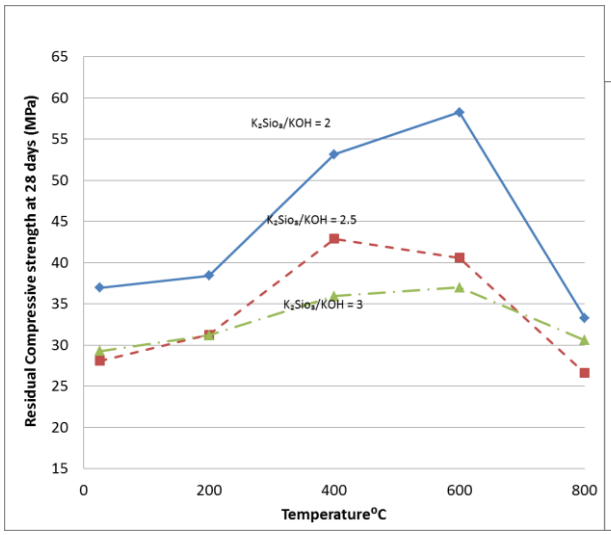

Figure 5 Residual compressive strength of geopolymer pastes containing K-based activators at various elevated temperatures

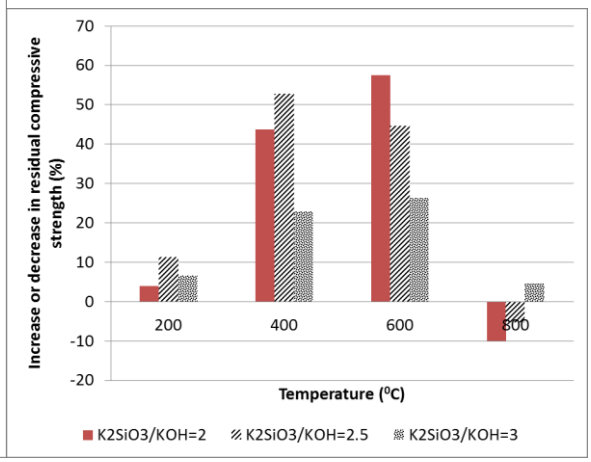

Figure 6 Relative increase or decrease in residual compressive strength of geopolymer pastes containing K-based activators at various elevated temperatures compared to ambient temperature.

By comparing both Na and K based geopolymer series in Figure 7 it can be clearly seen that the K-based activators show higher compressive strength retention capacity for geopolymer pastes than its counterpart Na-based series compared to ambient temperature strength. It can also be seen that in both geopolymer the ambient strength decreases with increase in silicate/hydroxide ratios for both Na- and K-based activators. This is attributed to the low water evaporation and less geopolymer structure formation due to excessive sodium silicate and potassium silicate (Chew, 1993). Interestingly the geopolymer with K_2SiO_3/KOH=3 exhibited higher compressive strength at all elevated temperatures than ambient temperature, which is also true for Na-based counterpart, however up to 600°C. The increase in compressive strength in the former can be attributed to the lower diffusion coefficient of K^+ at elevated temperatures, which results in higher melting temperature (Bakharev, 2006).

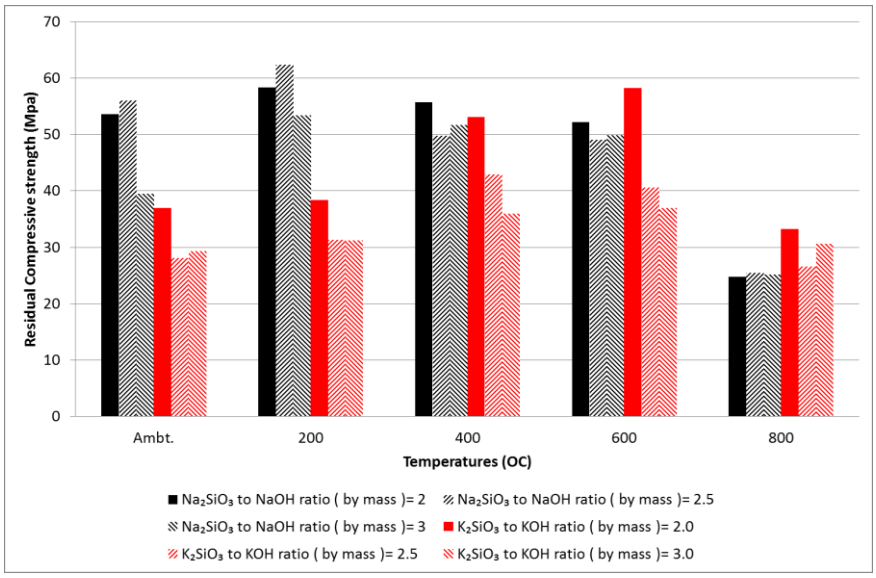

Figure 7 Comparison of compressive strengths of Na- and K-based geopolymer pastes.

The effects of elevated temperatures on physical changes of both Na- and K-based activator synthetized geopolymers are shown in Figures 8-10. Figure 8 shows the formation of cracks on specimens' surface for both geopolymers. It can be seen that up to 400°C no cracks are formed in both geopolymers. However, Na-based geopolymer showed signs of cracks at 600°C and it becomes worst at 800°C, where many wide cracks on the surface are formed. The geopolymer containing K-based activator, however, survived from surface cracking up to 600°C, but fine cracks are formed at 800°C. Figure 9 shows the reduction of mass of both geopolymers at various elevated temperatures. It can be seen that the mass loss of Na-based geopolymer is slightly higher than that of K-based counterpart. An interesting observation is also noted that by increasing the Na_2SiO_3/NaOH ratios the mass loss is slightly increased, which an opposite phenomenon is in K-based system. It can also be seen that up to 400°C significant reduction in mass loss of about 8-10% is observed in both geopolymers and the mass loss becomes stable afterword. In the case of volumetric shrinkage of both geopolymers at elevated temperatures similar results to those of mass loss are also observed, where the K-based geopolymer showed lower shrinkage than its Na-based counterpart at all elevated temperatures.

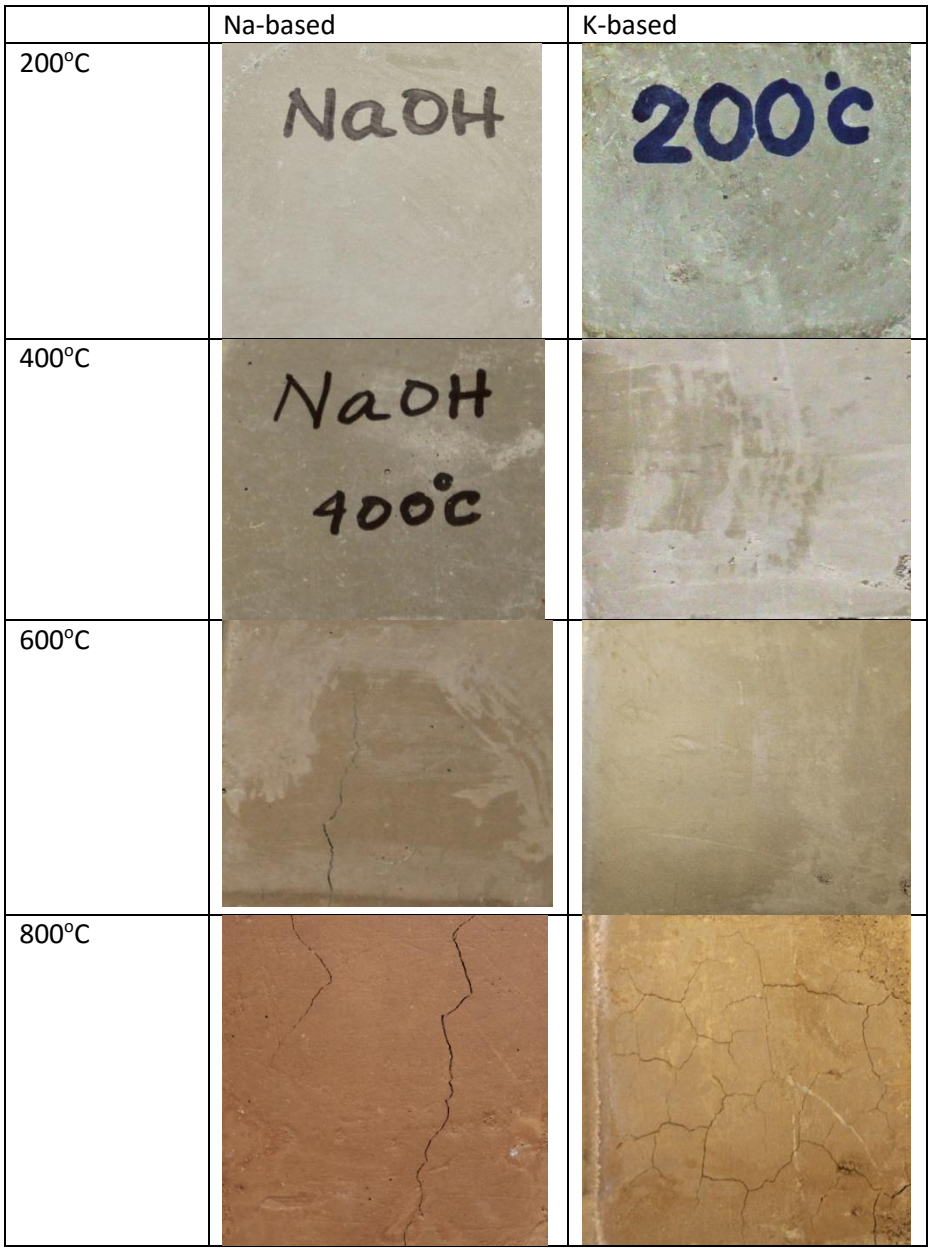

Figure 8 Cracking behaviour of fly ash geopolymers containing Na- and K-based activators at elevated temperatures.

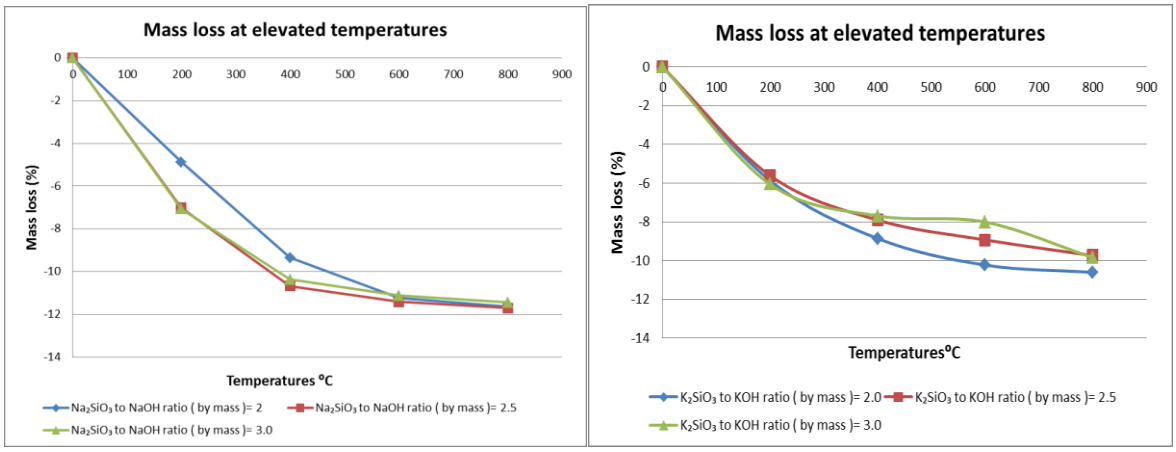

Figure 9 Comparison of mass loss of Na- and K-based geopolymer pastes at elevated temperatures.

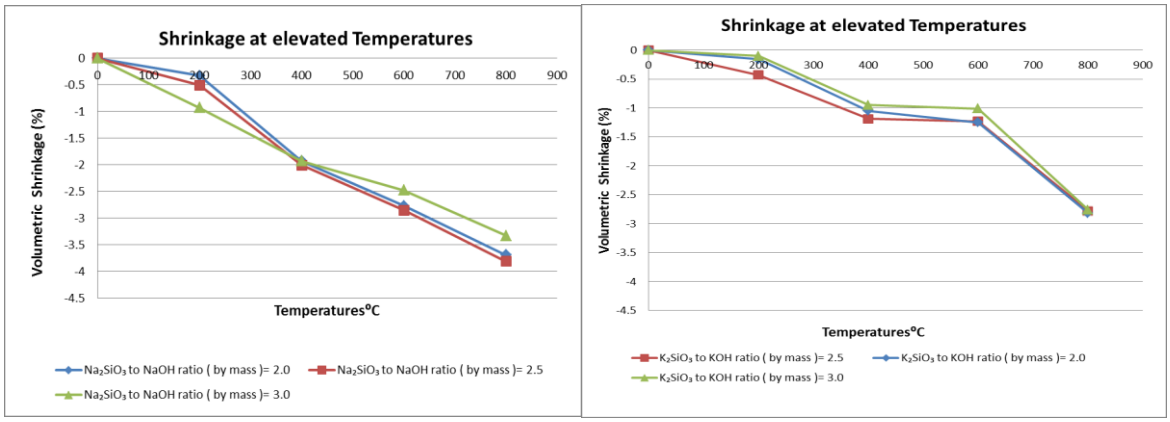

Figure 10 Comparison of volumetric shrinkage of Na- and K-based geopolymer pastes at elevated temperatures.

CONCLUSIONS

Based on limited experimental variables in terms of Na and K-based activators, the ratios of silicate to hydroxide of above activators, elevated temperatures on the residual compressive strengths, volume stability and mass loss of geopolymer pastes the following conclusions can be drawn:

1. The geopolymer pastes containing Na-based activator exhibited higher compressive strength at ambient temperature and higher compressive strength at elevated temperatures up to 400ºC than its K-based counterpart.
2. At 600ºC the compressive strength of geopolymer containing K-based activator is slightly higher than its Na-based counterpart.
3. The geopolymer paste containing K-based activator exhibited higher residual compressive strengths at all elevated temperatures compared to ambient temperature than its Na-based counterpart.
4. The geopolymer paste containing K-based activator with K_2SiO_3/KOH ratio of 3 exhibited the highest residual compressive strengths at all elevated temperatures compared to ambient temperature than its Na-based counterpart.
5. The volume stability and mass loss of geopolymer paste containing K-based activator is higher and lower, respectively than its Na-based system.
6. The geopolymer pastes containing K-based activator exhibited fewer surface cracks than that of Na-based activator.

ACKNOWLEDGMENTS

Grateful acknowledgements are due to Cement Australia for donating class F fly ash from Gladstone power station of Queensland and IMCD Australia Limited for donating potassium silicate in this study.

Life-cycle Performance of Structures

PLANNING FOR DURABILITY AND LIFE CYCLE MAINTENANCE OF BUILDINGS DURING DESIGN

Paul Sandeford [1,*],

ABSTRACT

Many buildings experience durability issues, including water leakage, corrosion, etc. well within their assumed 50 year life. Components may also require routine replacement which is not communicated to the owners or properly planned for. Decisions made at design stage have a profound impact on these in-service performance, maintenance and whole of life cycle issues. Whilst adherence to codes may be sufficient it is not a guarantee that all components will last the distance. It is thus critical that durability is considered as a key input during design. This was recognised for transport infrastructure when Department of Transport and Main Roads, Queensland produced a guideline for durability design of all its infrastructure. This now forms an industry accepted part of DTMR's project brief. In Australia there is a requirement for structural certification of buildings before occupation. Buildings could also benefit from requiring a durability report as part of certification. This would include assessment of critical durability components and the likely life cycle maintenance and component replacement requirements, certified by an appropriately qualified Engineer, or other qualified professional. It would benefit owners of building portfolios and reduce risk to buyers of units in high rise buildings with complex maintenance requirements that they do not have the background to understand. It would also improve sustainability by ensuring the intended design life is reached. This paper presents some of the typical durability issues that arise on buildings and proposes an outline of how a planned durability approach can be built in to the procurement process.

KEYWORDS

Durability, sustainable design, time dependent performance, leakage, corrosion.

INTRODUCTION

In recent years there has been a significant shift to a greater proportion of high rise units in the new building approvals. This was summarised by Kusher, (2015) based on data produced by the Australian Bureau of Statistics (ABS) in March 2015 as follows:

- 9,767 units approved for construction compared to 9,651 houses,
- This is only the 3rd time units have exceeded houses,
- 45.4% of all building approvals were units in the previous year
- Of those 60.5% were in blocks greater than 4 storeys high.

This is the continuation of a long term trend as illustrated in Figures 1 and 2.

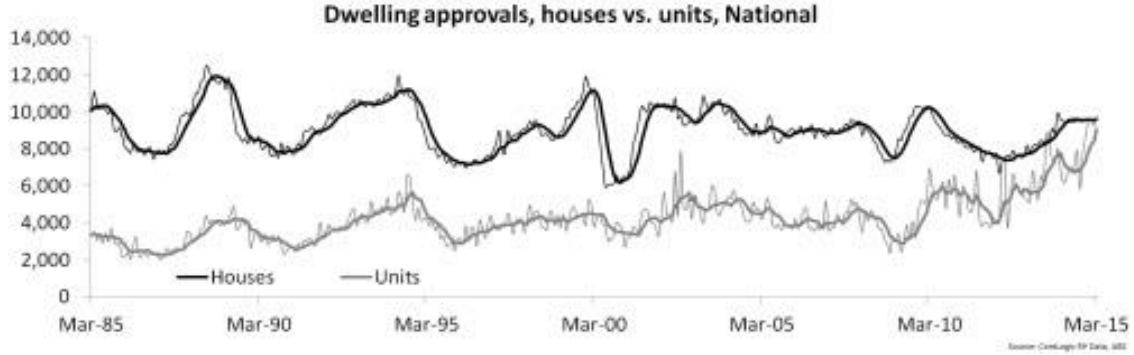

Figure 1 Dwelling Approvals, Houses vs units, Australia (Kusher, 2015)

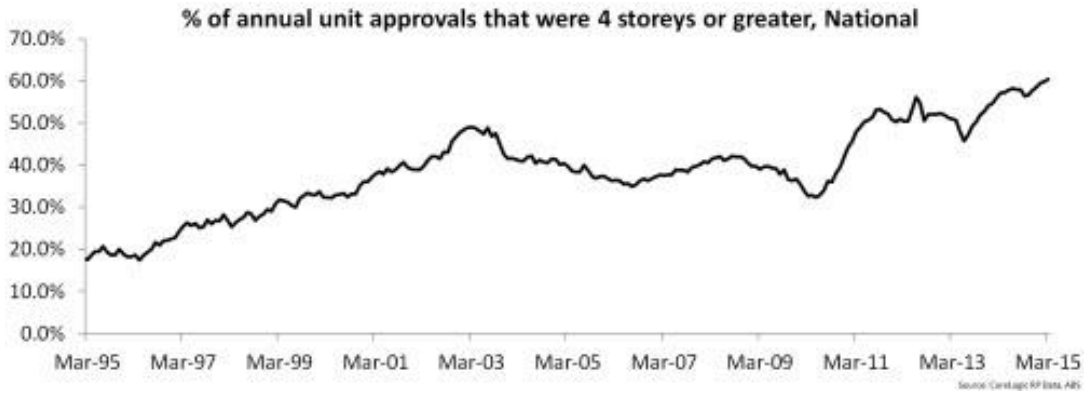

Figure 2 Percentage of Units Approved 4 Storeys or Greater, Australia (Kusher, 2015)

This can be observed empirically in the inner suburbs of any Australian city through the presence of tower cranes.

The author's experience as an Engineer specialising in the investigation and remediation of buildings and other infrastructure with defects is that many of these unit complexes experience significant defects far earlier in their life than would be expected. These defects typically relate to water ingress and corrosion, usually due to a combination of poor detailing, poor material selection and poor workmanship. This is acknowledged in the industry. In a recent article, Williams (2015) states:

"The national survey on strata-titled property conducted by Queensland's Griffith University, and shown exclusively to Domain, revealed that the unit owners questioned by the author, Professor Christopher Guilding, named building defects as their No. 1 challenge. It was also identified as the most important issue for strata lawyers, and in the top five by resident building managers."

Population in Australia is projected to grow, employment opportunities will continue to be in the cities, which already experience issues of urban sprawl and lack of public transport. As a result the trend to high rise inner suburb infill development will continue. Ordinary people will buy into developments without the knowledge of the risks that they may be taking on and surveys carried out on prospective unit purchases by surveyors qualified for domestic housing will not pick up issues that will require costly remediation. The industry needs to address this situation if it is not to lead to widespread discontent.

EXAMPLES OF TYPICAL EARLY DEFECTS

In the author's experience, these generally relate to water ingress and its consequences, notably corrosion..

CURRENT INDUSTRY DOCUMENTS ADDRESSING DURABILITY

National Construction Code

The National Construction Code (2015) gives performance based guidelines as to durability. As an example it requires that

> "*A building must resist:*
> *• rain water, coming through the roof or walls, due to poor waterproofing or flashing;*
> *• surface water, coming through openings which are too low; and*
> *• ground water, which could rise up through porous floors or walls."*

The means by which this is achieved is left very much to the designers and builders, but clearly in many instances the outcome is not as it should be.

Australian Building Codes Board – Durability in Buildings

This gives an excellent guide as the issues to be considered in designing a durable building including performance criteria, factors affecting durability design and designing for durability. It is, however, necessarily high level and a guide only.

Building Certification System

The building certifier has overall responsibility for confirming that the building has been constructed in accordance with the relevant regulations. This is a significant responsibility for one person and typically the certifier calls on specialists to undertake some of those works for them. This is notably the case for the structural elements where the certifier usually requires completion of Forms 15 and 16, referring to design compliance and inspection to confirm construction in accordance with the design respectively by a registered professional structural engineer.

It has been acknowledged that the building certification system in Queensland is in need of upgrading. Barrister at Law, Andrew Wallace (2014) was commissioned by the QBCC to carry out a review of the system and his report is currently being considered for changes to the requirements. It includes, amongst other recommendations, improved accountability of certifiers and all stakeholders in the building industry for the outcomes of the projects in which they are involved. This also includes improved inspection and applicator qualifications, which if acted upon, will go some way to addressing the problems.

INFRASTRUCTURE INDUSTRY APPROACH

A similar situation pertained in the infrastructure sector until recently, with bridges and culverts in particular requiring major repairs and maintenance well within their stipulated design life. This was recognised by Department of Transport and Main Roads (DTMR) who commissioned their Guideline for The Preparation of Road Structure Durability Plans (2009). This provides a framework for design for durability. Details of the guideline and the thinking behind them were presented by the author at the fib conference in Stockholm, Sandeford (2012). This approach is described here. Whilst not completely applicable to buildings, it provides a framework that could be adapted.

DTMR Approach

DTMR's aim was to provide a standardised guide requiring designers to consider durability as part of the design process in a consistent manner. The guide set out the preferred approach for the development and implementation of road structure durability plans for new construction and the format of summary tables to enable the standardised collation of information. By requiring designers to consider the materials, design detailing, construction methods and operational aspects of structures**,** the objective of longer lasting, low maintenance structures can be achieved.

The guideline sets out the requirements for the content of durability plan reports to be prepared by the designer and provides the format of summary tables in a series of linked spread sheets to enable the standardised collation of information. These tables complement the durability plan report, and provide a summary of the durability plan requirements which include:

- the identification of deterioration mechanisms and hence durability intent;
- materials selection;
- the development of mitigation measures to ensure that the design intent is met;
- provisions for inspection, maintenance and replacement of components;
- the identification of durability critical construction activities; the verification of constructed components to confirm compliance and;
- construction departures from the specification and remedial measures;

Reports at Various Stages

The durability plan forms a series of reports, namely:

- **Concept Design**: Considers the concept design, environmental information and highlights potential durability issues that will require consideration during the detailed design process. For major components, it defines failure criteria, details those that cannot be maintained or replaced, identifies outline maintenance/replacement methodologies. Includes the development of durability requirements that will significantly affect cost and further investigation of the environment that may be needed for the detailed design.
- **Engineering Design**: Considers durability issues of the Engineering design. It includes comments on compliance of design and supply specifications with requirements for durability. Highlights durability issues that will require Contractor's consideration and assessment during engineering design process. The report incorporates comments on design, specifications, construction method statements and process review procedures.
- **Construction Records:** Verifies the Quality and Inspection Records and finished product in relation to compliance with the Durability Plan.

The report process should be repeated and the tables added to as repair and maintenance is undertaken. These items and their relation to the asset's life are illustrated in Figure 10.

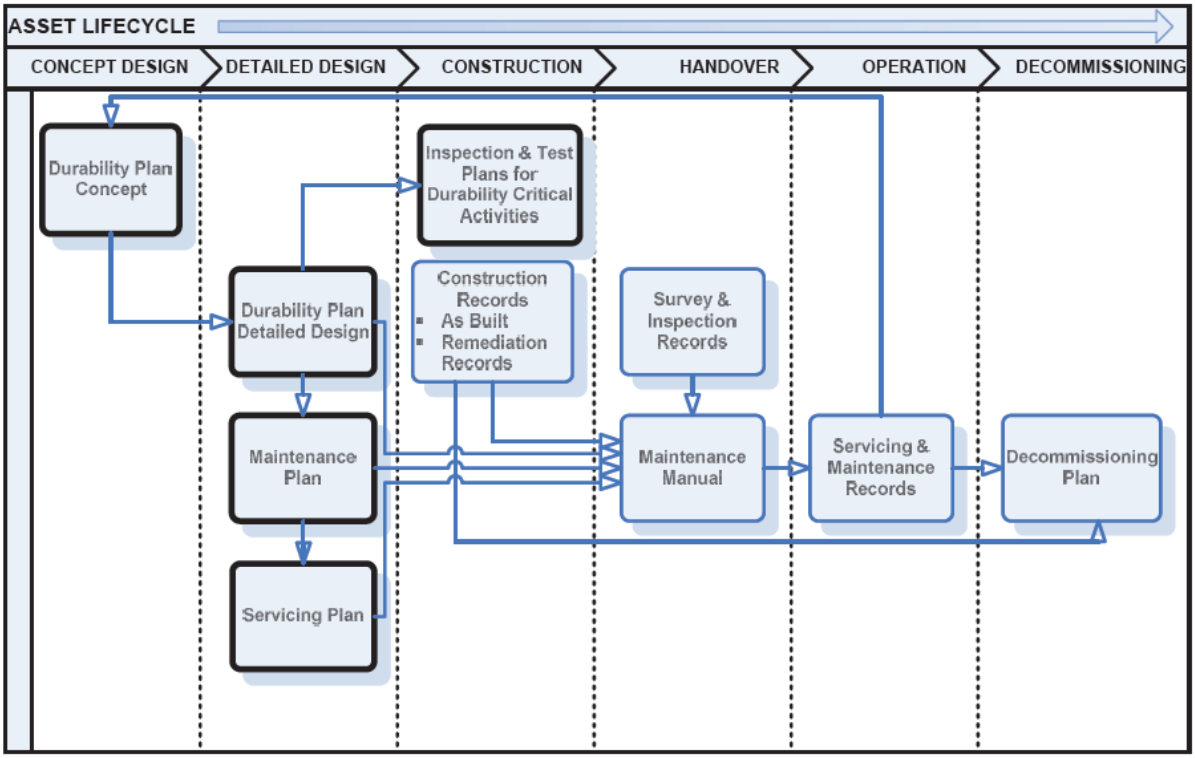

Figure 10 Durability Plan Documents and flow of information through the asset lifecycle DTMR, 2009)

Areas to be addressed in the durability plan and the sequence are defined as follows and in Figure 11. At each stage, information generated is added to the summary spreadsheet tables.

Service Life Criteria

The overarching requirement for the project design life, typically 100 years for DTMR, will require further component by component definition. Differing components will have differing design lives and failure criteria. DTMR publish an inspection guidance document which sets out a methodology for subdivision of bridge structures into components; this is referred to as a guide with the caveat that further subdivision may be required. Within the subdivision process, consideration must be given to the "replaceability" or "maintainability" of the component, e.g. foundations vs. hand rails.

Durability limit state for each component will need to be defined. Code definitions of this tend to be very broad. Definition of the condition at which the component is considered to have reached the end of its life is critical, e.g. for reinforced concrete this could be damage significantly reducing the structural strength, first corrosion cracking or corrosion initiation.
Linked to this is the intermediate intervention level for maintenance or component replacement.

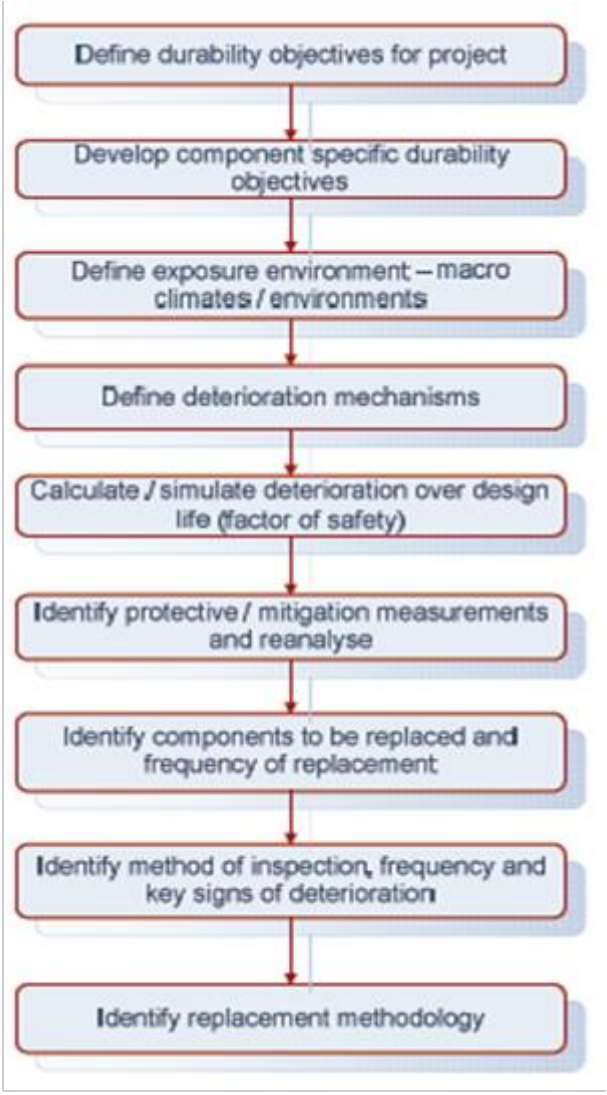

Figure 11 Durability Report Process Flow Chart (DTMR, 2009)

Exposure Conditions

Codes give broad guidance on exposure. In AS 3600 and AS 4312 for concrete and steel respectively this is based on proximity to the coast. This does not take into account variations within the structure nor variation in attack/failure mechanism. The structure's location will need to be broken down into exposure categories, e.g. below ground submerged, below ground above water table, permanently submerged,, splash, spray, atmospheric (exposed), atmospheric (sheltered).

Combining the list of components and their design lives with the exposure assessment will highlight a series of potential deterioration mechanisms. All should be listed but typically one mechanism is likely to be governing load case and this will dictate the durability design requirements. A detailed assessment is unlikely to be required for all components, particularly in a benign environment. Conversely, for a critical component or a significant structure, detailed modelling may be required to provide confidence that the durability measures adopted will achieve the design life, e.g for concrete components**,** chloride or carbonation modelling, ground water attack, AAR, DEF, early thermal crack modelling, all in relation to the proposed mixes.

Assessment of Design Solutions

Where code provisions are assessed as insufficient, additional protective measures must be provided. The full range of solutions should be considered; examples for concrete include: corrosion inhibitors, controlled permeability formwork, cathodic prevention, supplementary cementitious materials, stainless steel reinforcement, fibre reinforcement, surface sealers, or enhanced maintenance regimes. In most cases, it is not envisaged that detailed durability modelling will be required. The level of detail required will depend on a number of factors including: the complexity of the structure, the classification of road carried, and its location. The designer must give careful consideration to:

- Necessary activities to facilitate safe component replacement. Replacement activities should minimise disruption to the use of the structure.
- Buildabililty; the risk of design intent not being achieved is increased where construction is difficult. Examples include closely packed reinforcing or poor workability concrete.
- Planned inspection, and maintenance activities in terms of safe access with minimised disruption to occupants, defined trigger levels, planned and recorded activities. It may be prudent to include additional protective measures to ensure the durability of components that cannot be readily inspected.
- Additional compliance measures for durability critical activities in the construction phase specification, notably curing and check measurements on cover after casting.

Verification Report

The provision of relevant information to the owner and operator of any structure is an important part of asset management. This information can be referred to as the “birth certificate” of the structure and documents design issues, construction and condition of the structure at hand over. On completion of construction, the designer and contractor must compile the durability plan verification report as part of the as built records. This would include an update of the durability plan incorporating any changes necessitated during construction, records of materials used, construction departures and mitigation measures adopted. The updated durability plan summary tables must also be similarly completed to serve as a concise summary of the durability intent, how this was achieved and verified, and the required maintenance and inspection activities. These documents will be then be transferred to the DTMR Bridge Information System.

DISCUSSION

Adaptation of Infrastructure Approach

The infrastructure industry approach could be used to address key concerns regarding the durability of residential and commercial buildings with modification:

- The level of detail would be reduced. The building envelope (roof and façade) is the element that will require consideration.
- The life of the structure will be reduced; most road infrastructure is designed for a life of 100 years, buildings are likely to be 50 years, unless of a monumental nature.
- Exposure conditions are likely to be less severe, road infrastructure may be in tidal zones, buildings will at most experience exposure to sea spray if built on the beach.
- More flexibility would be required, typically the number of components on a bridge are limited compared with the huge variety of design options and available materials for a building.

The process could utilise similar spreadsheets to this in the DTMR methodology to document the process. At DA stage an outline only would be submitted, consisting of the exposure conditions, key construction materials and how they will reach the required life, especially the need to replace them during that time, e.g. sealants and gaskets around windows, roof waterproof membranes. Necessarily, the approving authority would require much more detailed submission around vulnerable installations such as planter boxes or box gutters. During detailed

design, this would be developed, including clear detailing of specific areas of concern, e.g. window fixing, joints between differing materials in the façade, flat roof waterproofing and drainage details.
On completion, any modifications would be added to the design, and the spreadsheets in a similar manner tot the DTMR requirement. This would be a key step in the process. Unlike institutional asset owners, owners of residential developments usually have very poor records of the "as constructed" situation of their buildings. It should be a requirement that the spreadsheets and as built drawings are lodged with a central authority so that they can be accessed in future years by the building owners and the professionals they engage to conduct work for them.

A key factor in this would also be the requirement for the spreadsheets to include the maintenance intervals and activities for the various components, together with current costings. This would then form the basis of the asset management plan and inform the buyers and the building managers of the obligations they have to maintain the building in order that deterioration does not become significant and onerous to deal with. It will clarify the expectation that the building will last for 50 years without significant maintenance.

Examples of Improvements

Some examples of how this might lead to an improved outcome include:

- Seafront residential buildings are subject to salt spray and older buildings are experiencing chloride induced corrosion of reinforcement within the 40-60 year life indicated in AS3600. A considered approach to cover, concrete mix design and coating or waterproofing would address this situation.
- External walls are often single skin concrete block placed directly onto concrete floor slabs, then rendered on the exterior and painted. Movement at this interface leads to cracking and tracking of water back into the building. Simply installing a low step behind the blockwork wall combined with drainage points would prevent moisture ingress to the building.
- Planter boxes against residential walls present a significantly increased risk of water ingress. Waterproofing of these areas can be affected by root growth. This detail should be eliminated or a gap allowed between the building wall and the planter box so that leakage can drain.

CONCLUSIONS

As Australia's cities have grown, there has been a shift to high rise residential development. This will continue as the population grows and pressure builds for conveniently located accommodation for employment opportunities.

Defects in these strata titled developments are recognised as a significant problem by the industry. If left unaddressed, these defects will lead to a lack of confidence in this type of development, placing further pressure on traditional housing stock. The means by which these high rise developments are approved and certified have also been recognised as requiring improvement.

A parallel exists with the infrastructure industry which in recent years has introduced a requirement for all road infrastructure to have a durability report as part of the design deliverables. In this the designers detail how the asset will reach its required design life and the maintenance and replacement of components needed within that life in order to keep the asset functioning at an acceptable level. This requirement has also been adopted for much water and marine infrastructure.

An opportunity exists to improve the outcomes for buildings by requiring a simplified, but similar approach to building envelopes, such that the designer is required to document the means by which the building will meet its performance requirements over its life and the maintenance and replacement required from the owners.

ABSTRACT

The life-cycle structural robustness is generally investigated with respect to the initial time of construction, when the structure is intact. However, in the evaluation of life-cycle robustness of existing structures it may be of interest to evaluate the impact of deterioration on the structural performance with reference to the actual damage state and performance level existing at the time of inspection and/or assessment. In this paper, a robustness criterion presented in previous works is extended to consider the influence of the damage level on the time-variant robustness of existing concrete structures over the remaining structural lifetime. In addition, the role of the importance of the structure in the assessment of the life-cycle robustness is considered. The effectiveness of the proposed approach is shown through the application to the deterministic and probabilistic assessment of the life-cycle robustness of a reinforced concrete pier of an existing bridge.

KEYWORDS

Structural robustness, Life-cycle performance, Concrete structures, Bridges, Corrosion.

INTRODUCTION

As a consequence of several dramatic structural failures, due to extreme hazards such as blast or aircraft impact, the importance of reliable design procedures leading to conceive robust structures is nowadays widely recognized (Ellingwood and Dusenberry 2005, Ellingwood 2006, Ghosn and Frangopol 2007). This is not limited to buildings, but it is a major concern also for bridges (Starossek 2008). Therefore, new design concepts and methods are needed to ensure safety, redundancy and robustness of buildings and bridges against the occurrence of exceptional damaging events (Ghosn *et al*. 2010, Okasha and Frangopol 2010a, Zhu and Frangopol 2012, 2013, 2014, 2015, Frangopol and Saydam 2014). In addition, damage involving disproportionate effects could also arise continuously in time, due to aging and deterioration processes (Frangopol and Curley 1987, Biondini and Restelli 2008, Biondini *et al*. 2008, Biondini 2009, Okasha and Frangopol 2010b, Decò *et al*. 2011, Biondini and Frangopol 2014a, 2014b). These effects are particularly relevant for bridge structures due to their environmental exposure. Notable events of bridge collapses due to the environmental aggressiveness and related phenomena, such as corrosion and fatigue, include the Silver Bridge in 1967, and the Mianus River Bridge in 1983. Structural robustness should therefore be considered as key factor for a rational approach to life-cycle design of deteriorating structures (Biondini and Frangopol 2014a). In this context, it is of great interest to investigate the evolution in time of robustness under a progressive deterioration of the structural performance.

Recently, the time factor has been explicitly included in a lifetime scale for a time-variant measure of structural robustness both in deterministic and probabilistic terms (Biondini 2009, Biondini and Frangopol 2014a). A robustness criterion has been introduced by comparing the loss of performance due to a certain damage scenario with an acceptable robustness target. Moreover, the life-cycle structural robustness has been investigated with respect to the initial time of construction, when the structure is intact. However, in the evaluation of life-cycle robustness of existing structures it may be of interest to evaluate the impact of deterioration on the structural performance with reference to the actual damage state and performance level existing at the time of inspection and/or assessment. In this paper, the proposed robustness criterion is hence extended to consider the influence of the damage level on the time-variant robustness of existing structures over the remaining structural lifetime, with emphasis on concrete structures exposed to corrosion. In addition, the importance of the structure in the assessment of the life-cycle robustness is considered.

To this purpose, criteria and methods for the definition of time-variant performance indicators and quantitative evaluation of life-cycle robustness of concrete structures are presented. The effects of the damage process on the structural performance are evaluated by using a methodology for life-cycle assessment of concrete structures in aggressive environment under uncertainty (Biondini *et al*. 2004, 2006). The proposed approach is applied to the deterministic and probabilistic assessment of the life-cycle robustness of a reinforced concrete (RC) bridge pier with box cross-section by taking into account the actual damage state and performance level at different time instants over the structural lifetime. The results highlight the essential role of the environmental exposure and show the influence of the importance of the structure in the assessment of the life-cycle structural robustness.

TIME-VARIANT MEASURE OF STRUCTURAL PERFORMANCE AND DAMAGE

Performance Index

A failure of a system is generally associated with the violation of one or more limit states. Focusing on concrete structures, limit states of interest are the occurrence at the material level of local failures associated to cracking of concrete and yielding of steel reinforcement, which represent warnings for initiation of damage propagation, as well as reaching of global failures associated with the ultimate capacity of critical cross-sections of structural members and/or system collapse. Since the structural performance of concrete structures deteriorates over time, the limit states need to be evaluated by means of time-variant structural analyses taking into account the effects of the damage process (Biondini *et al*. 2004, 2006).

By denoting $\lambda=\lambda(t) \geq 0$ a time-variant performance indicator associated to the occurrence of a prescribed limit state, its ratio to the performance indicator $\lambda_0=\lambda(t_0) \geq \lambda(t)$ referred to a time instant $t_0 \leq t$ provides an effective time-variant measure of structural performance within the range [0, 1] over the time interval $[t_0, t]$:

$$\rho(t,t_0)=\frac{\lambda(t)}{\lambda(t_0)} \tag{1}$$

In general, the reference time is associated with the initial time of construction, $t_0=0$, when the structure is intact. However, in the evaluation of life-cycle robustness of existing structures it may be of interest to evaluate the expected impact of deterioration on the structural performance at time t with reference to the actual damage state and performance level existing at time $t_0>0$.

Damage Index

In concrete structures damage is generally induced by diffusion of aggressive agents, such as sulphates and chlorides, which may lead to deterioration of concrete and corrosion of reinforcement (CEB 1992). The diffusion process can be effectively described by using the Fick's diffusion equation (Glicksman 2000):

$$D\nabla^2 C=\frac{\partial C}{\partial t} \tag{2}$$

where D is the diffusivity coefficient of the medium, $C=C(\mathbf{x}, t)$ is the concentration of the chemical component at point $\mathbf{x}$ and time t, $\nabla C = \mathbf{grad}\, C(\mathbf{x}, t)$ and $\nabla^2=\nabla\cdot\nabla$. In this study, such equation is solved numerically by using cellular automata (Biondini *et al*. 2004).

Structural damage induced by diffusion is modelled by a degradation law of the effective resistant area for both concrete and reinforcing steel bars by means of dimensionless damage indices $\delta_c=\delta_c(t)$ and $\delta_s=\delta_s(t)$, respectively, which provide a direct measure of the damage level within the range [0, 1]. In particular, damage rates depend on the concentration of the aggressive agent (Bertolini 2008). Despite the complexity of such relationship at the microscopic level, simple coupling models can often be successfully adopted at the macroscopic level in order to reliably predict the time evolution of structural performance (Biondini *et al*. 2004, 2006). In this study, the damage indices $\delta_c=\delta_c(\mathbf{x}, t)$ and $\delta_s=\delta_s(\mathbf{x}, t)$ at point $\mathbf{x}$ and time t are correlated to the diffusion process as follows:

$$\frac{\partial \delta_c(\mathbf{x},t)}{\partial t}=\frac{C(\mathbf{x},t)}{C_c \Delta t_c} \tag{3}$$

$$\frac{\partial \delta_s(\mathbf{x},t)}{\partial t}=\frac{C(\mathbf{x},t)}{C_s \Delta t_s} \tag{4}$$

where C_c and C_s represent the values of constant concentration $C(\mathbf{x},t)$ which lead to a complete damage of the materials after the time periods Δt_c and Δt_s, respectively. The damage rate coefficients $q_c=(C_c\Delta t_c)^{-1}$ and $q_s=(C_s\Delta t_s)^{-1}$ depend on both the type of corrosion mechanism and corrosion penetration rate. Moreover, the initial conditions $\delta_c(\mathbf{x},t_{cr})=\delta_s(\mathbf{x},t_{cr})=0$ with $t_{cr}=\min\{t \mid C(\mathbf{x},t)\geq C_{cr}\}$ are assumed, where t_{cr} is the corrosion initiation time and C_{cr} is a critical threshold of concentration (Biondini *et al*. 2004). These relationships can be calibrated based on available data for corrosion rate under sulphate and chloride attacks (Pastore and Pedeferri 1994, Bertolini *et al*. 2004).

The damage indices δ_c and δ_s provide a comprehensive description of the damage evolution over the structure. However, due to their *local* nature, they do not seem handy for global evaluations of system robustness. A more synthetic *global* measure of damage is necessary. A global damage index Δ^* within the range [0, 1] may be derived from δ_c and δ_s by a weighted average over the volume of the materials (Biondini 2009). By denoting $\Delta_c=\Delta_c(t)$ and $\Delta_s=\Delta_s(t)$ the contribution of concrete and steel, respectively, for a concrete member the time-variant global damage index $\Delta^*=\Delta^*(t)$ can be defined at the cross-sectional level as follows:

$$\Delta^*(t)=[1-\omega(t)]\Delta_c(t)+\omega(t)\Delta_s(t) \tag{5}$$

$$\Delta_c(t)=\frac{\int_{A_c} w_c(\mathbf{x},t)\delta_c(\mathbf{x},t)d\mathbf{x}}{\int_{A_c} w_c(\mathbf{x},t)d\mathbf{x}} \tag{6}$$

$$\Delta_s(t)=\frac{\sum_m w_{sm}(t)\delta_{sm}(t)A_{sm}}{\sum_m w_{sm}(t)A_{sm}} \tag{7}$$

where $\omega=\omega(t)$, $w_c=w_c(\mathbf{x},t)$, and $w_{sm}=w_{sm}(\mathbf{x}_m,t)$ are suitable weight functions, A_c is the area of the concrete matrix, and A_{sm} is the area of the m^{th} steel bar located at $\mathbf{x}_m=(y_m, z_m)$. It is worth noting that this cross-sectional formulation can be extended at the structural level by an average integration over all members of the system. In case any portion of material volume is expected to play a specific role in the damage process, suggested values for the weights are $w_c=w_{sm}=1$ and $\omega=(f_s A_s)/(f_c A_c)$, where ω is the mechanical ratio of reinforcement, f_c is the concrete strength in compression, f_s is the steel strength, and $A_s=\sum_m A_{sm}$.

For existing structures it would be of interest to evaluate the damage $\Delta^*=\Delta^*(t)$ expected at time t with respect to the actual damage state $\Delta^*=\Delta^*(t_0)$ existing at current time $t_0>0$. To this purpose, the following damage index provides a time-variant measure of damage within the range [0, 1] over the time interval $[t_0, t]$:

$$\Delta(t,t_0)=\frac{\Delta^*(t)-\Delta^*(t_0)}{1-\Delta^*(t_0)} \tag{8}$$

where $\Delta^*(t_0)=0$ and $\Delta(t,t_0)=\Delta^*(t)$ for a reference time $t_0=0$ associated with the initial construction.

TIME-VARIANT STRUCTURAL ROBUSTNESS

Robustness Criterion

The knowledge of the time-variant performance index $\rho=\rho(t,t_0)$ is in general not sufficient to formulate a measure of structural robustness. In fact, structural robustness can be viewed as the ability of the system to suffer an amount of damage not disproportionate with respect to the causes of the damage itself (Ellingwood and Dusenberry 2005). According to this definition, a measure of robustness should arise by comparing the system performance in the original state, in which the structure is fully intact, and in a perturbed state, in which a prescribed damage scenario is applied (Frangopol and Curley 1987, Biondini and Restelli 2008). To this aim, a robustness criterion is formulated as a function of both the performance index $\rho=\rho(t,t_0)$ and the related damage index $\Delta=\Delta(t,t_0)$ as follows:

$$R(t,t_0)=\rho(t,t_0)^{\alpha}+\Delta(t,t_0)^{\alpha} \tag{9}$$

where $R=R(\rho,\Delta)=R(t,t_0)$ is a robustness factor, and α is a shape parameter of the boundary $R=1$. The structural system is robust when the criterion is satisfied ($R\geq 1$), and not robust otherwise ($R<1$). This criterion has been proposed in Biondini (2009) for a measure of time-variant robustness with respect to the initial undamaged state of the structure ($t_0=0$) and is here extended to the case of damaged structures ($t_0>0$).

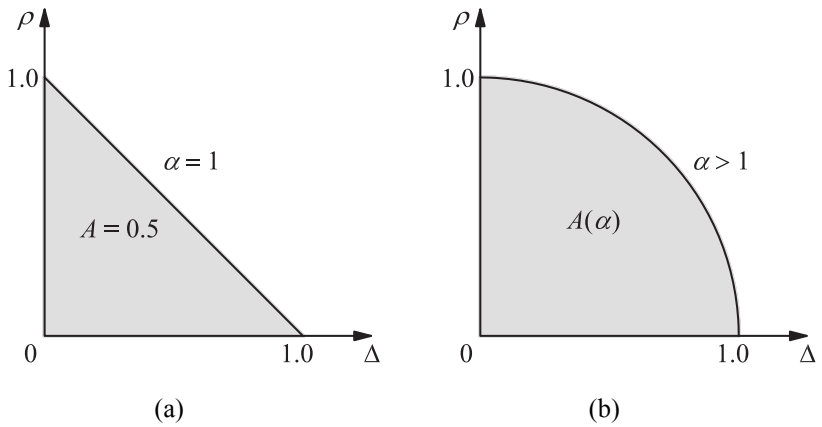
Importance Factor

The value of the parameter α should be selected according to the acceptable level of damage susceptibility for the structure under investigation. A value $\alpha=1$, which indicates a proportionality between acceptable loss of performance and damage, should be appropriate in most cases. Values $\alpha>1$ could be required for structures of strategic importance, and values $\alpha<1$ should be avoided, since they allow for disproportionate damage effects, or used for temporary structures. The importance factor α emphasizes that the robustness measure depends not only on system properties and damage mechanisms, but also on the importance of the system.

A proper value of the importance factor α can be chosen with reference to the area $A=A(\alpha)\in[0,1]$ of the region lying below the boundary curve $R=1$ (Di Silvestri *et al*. 2014):

$$A(\alpha)=\left\{ \int_0^1 \rho(\alpha,\Delta)d\Delta \;\middle|\; R=1 \right\}=\int_0^1 (1-\Delta^{\alpha})^{\frac{1}{\alpha}}d\Delta \tag{10}$$

which leads to $A=0$ for $\alpha=0$, $A=0.5$ for $\alpha=1$, and $A=1$ for $\alpha=\infty$. This concept is illustrated in Figure 1 for (a) $\alpha=1$ and (b) $\alpha>1$. Possible values of the importance factor α and the corresponding area $A(\alpha)$ for temporary structures, ordinary structures, and structures of strategic importance, are listed in Table 1.



(a) (b)

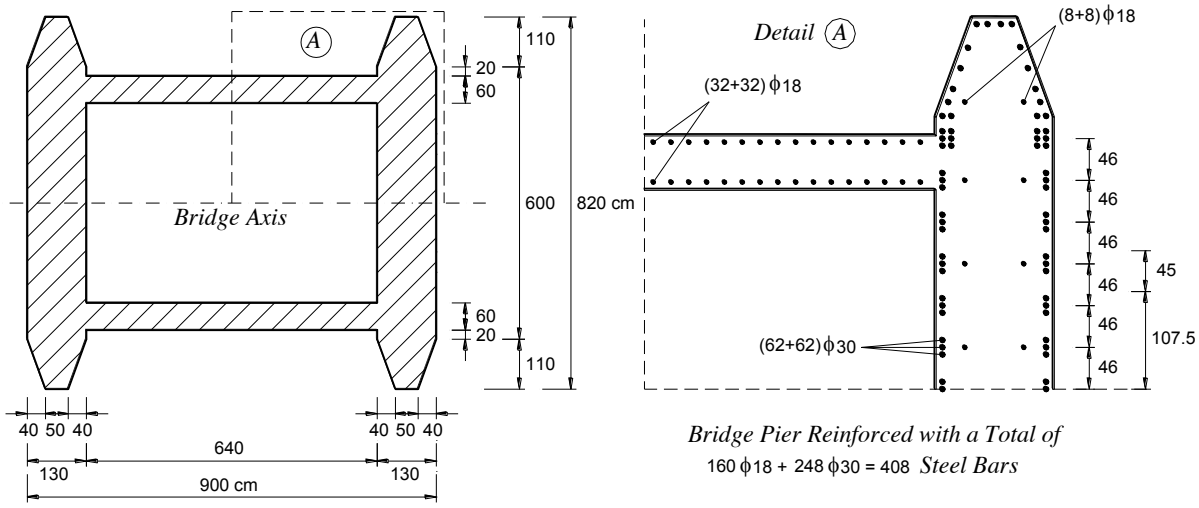
Type of Structure	Area $A(\alpha)$	α
Temporary	0.25	0.6
Ordinary	0.50	1.0
Strategic	0.75	1.8

APPLICATION TO A RC BRIDGE PIER

The life-cycle reliability and maintenance planning of the RC piers of an existing bridge have been investigated in a previous work (Biondini *et al*. 2006). The life-cycle structural robustness of the piers has been also evaluated with reference to the undamaged state at the initial time $t_0=0$ (Biondini and Frangopol 2012). In this study, the robustness analysis is extended to consider the impact of deterioration on the structural performance with reference to the actual damage state and performance level existing at current time $t_0>0$. In addition, the role of the importance of the structure in the assessment of the life-cycle robustness is considered.

The box-cross section of the bridge pier is shown in Figure 2.a. The cross-section has main geometrical dimensions d_y=8.20 m and d_z=9.00 m, and it is reinforced with 160+248=498 steel bars having diameter ∅=18 mm and ∅=30 mm, respectively, as shown in Figure 2.b. The material strengths are f_c=30 MPa for concrete in compression, and f_{sy}=500 MPa for reinforcing steel. Additional information on the constitutive properties of the materials and the methodology adopted for the cross-sectional non-linear structural analysis can be found in Biondini *et al*. (2006) and Biondini and Frangopol (2012).



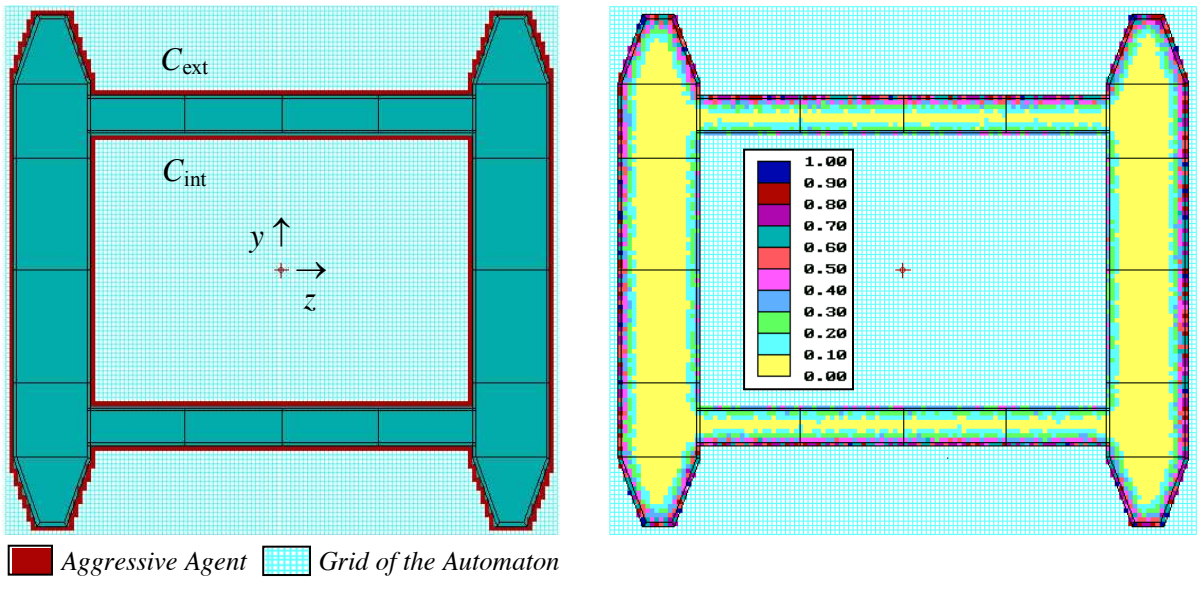
(a) (b)

Figure 2. Box cross-section of a bridge pier. (a) Geometrical dimensions. (b) Detail with reinforcement layout.

A diffusivity coefficient $D = 10^{-11}$ m^2/sec is assumed. Damage rates are defined by assuming C_{cr}=0, C_c=C_s=C_0, Δt_c=5 years and Δt_s=7.5 years. Figure 3.a shows the grid of the cellular automaton adopted for the simulation of the diffusion process and the location of the aggressive agent, with concentration $C(t)$=C_{ext} along the external surface of the pier and $C(t)$=C_{int} along the internal one. As an example, Figure 3.b shows the map of concentration $C(\mathbf{x},t)/C_0$ of the aggressive agent for the case C_{ext}=2C_{int}=C_0 after 50 years from the initial time of diffusion penetration.

Table 1. Concentration of the agent for the exposure scenarios.

	Case (I)	Case (II)	Case (III)
C_{ext}	C_0	C_0	0
C_{int}	C_0	0	C_0

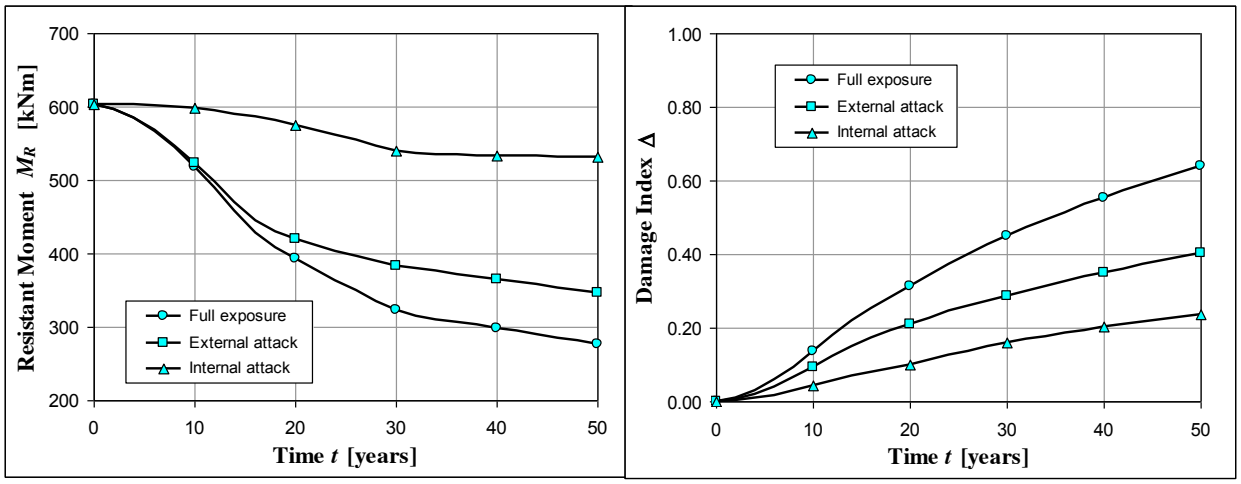


(a) (b)

Figure 3. Box cross-section of a bridge pier. (a) Structural model, grid of the cellular automaton and location of the aggressive agent. (b) Map of the concentration $C(\mathbf{x},t)/C_0$ of the aggressive agent for C_{ext}=2C_{int}= C_0 after 50 years from the initial time of diffusion penetration.

The effects of damage induced by diffusion over a 50-year lifetime is shown in Figure 4.a in terms of time-evolution of the resistant value M_R=$M_R(t)$ of the bending moment M_z under the axial force N =–100 MN for the

three exposure scenarios listed in Table 1. The corresponding time evolution of the damage index $\Delta=\Delta(t,t_0)$ is shown in Figure 4.b for $t_0=0$, that is $\Delta(t,0)=\Delta^*(t)$. The comparison of the results illustrated in Figures 4.a and 4.b shows that, as expected, case (I) with full exposure of the cross-section is the worst scenario in terms of global damage and strength deterioration. Moreover, case (II) with external exposure only is more critical than case (III) with internal exposure only, since the area exposed to the aggressive environment in case (II) is larger than in case (III). However, the separate knowledge of the time quantities M_R and Δ does not allow to measure structural robustness.



(a) (b)

Figure 4. Time evolution of (a) resistant bending moment $M_R=M_R(t)$, and (b) damage index $\Delta=\Delta(t,t_0)$ for $t_0=0$ ($\Delta=\Delta^*$) under the three exposure damage scenarios listed in Table 1.

A time-variant measure of structural robustness is achieved by assuming the resistant bending moment as performance indicator, or $\lambda(t)=M_R(t)$, and by relating the corresponding performance index $\rho=\rho(t,t_0)$ to the damage index $\Delta=\Delta(t,t_0)$. The time evolution of the robustness factor $R=R(t,t_0)$ for the three investigated exposure scenarios is shown in Figure 5 with respect to three reference time instants $t_0=0$, 10, and 20 years, and for two values of the importance factor $\alpha=1.0$ (Figure 5.a) and $\alpha=1.8$ (Figure 5.b).

The diagrams shown in Figure 6.a are associated with an importance factor $\alpha=1.0$, that is appropriate for ordinary bridge structures. First of all it is noted that the robustness of the bridge pier may increase over time, despite the structural performance significantly decreases, with a reduction of the resistant bending moment of over 50% after 50 years of lifetime for the case of full exposure (Figure 5.a). In particular, for $t_0=0$ and $t_0=10$ years the bridge pier is robust for case (III) and not robust for case (II) over the whole lifetime. For case (I) the pier is not robust only in the early stage of the lifetime, since after about 20 years the susceptibility of the structure to damage tends to decrease, reaching $R\approx1$ after about 40 years. However, this recover of robustness is achieved after extensive damage which may involve an unacceptable decay of bending strength. It is also worth noting that in case (I) the lifetime robustness is always higher than in case (II), and for $t_0=20$ years it is also higher than in case (III), despite that a reversed tendency is observed in terms of resistant moment $M_R=M_R(t)$. This clearly indicates that strength and robustness are different performance indicators that may exhibit opposite trends over time.

Depending on location and traffic demand, the functionality of bridges could represent a key issue to ensure the resilience of infrastructure road and highway networks. Therefore, for bridges of strategic importance, values $\alpha>1$ should be adopted in the assessment of the life-cycle structural robustness. The diagrams shown in Figure 6.b are associated with an importance factor $\alpha=1.8$, that corresponds to $A(\alpha)=0.75$ (see Table 1). For this level of importance, the bridge pier is not robust over the 50-year lifetime for all cases studied. In some cases, the robustness of the pier initially decreases, and is partially recovered at the end of the lifetime, when the decay of bending strength and the consequent loss of structural safety may become unacceptable. However, with respect to the importance level $\alpha=1.0$, the attainment of the minimum robustness and subsequent recovery is delayed from 20 to about 30 years. Moreover, a reversed trend is found for the larger values of the reference time t_0. In fact, for $t_0=0$ the minimum robustness is achieved again for case (II). However, if robustness is computed for increasing values of the reference time t_0, the susceptibility to damage decreases for case (II) and increases for case (I), and the latter becomes the worst scenario for $t_0=20$ years. These results demonstrate that bridges of

different importance should be designed by taking into account different target values of structural robustness. This can be achieved by means of the proposed importance factor.

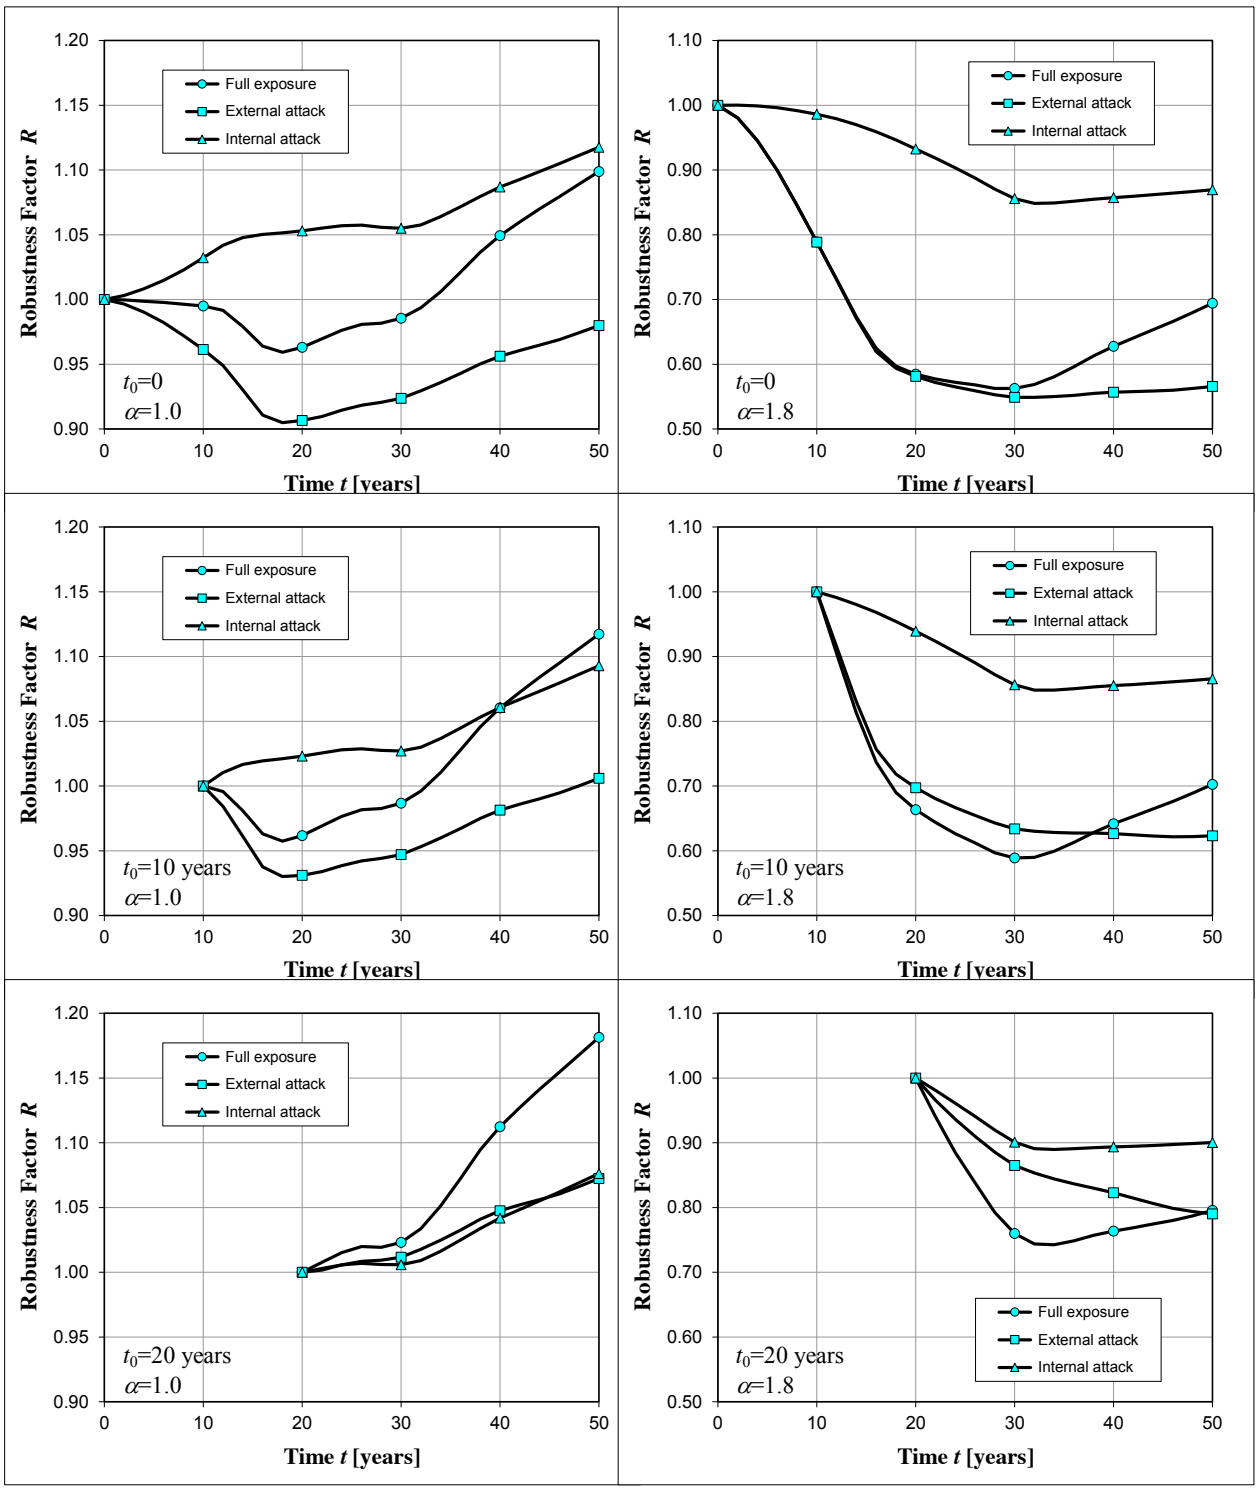


Figure 5. Time evolution of the time-variant robustness factor $R=R(t,t_0)$ associated with the three exposure scenarios for three reference time instants t_0=0, 10, and 20 years, and two values of the importance factor: (a) α=1.0; (b) α=1.8.

Finally, the effects of uncertainty on the lifetime structural robustness of the bridge pier is investigated for case (I) of full exposure with respect to the initial time t_0=0 by taking into account the importance of the bridge. The probabilistic model assumes as random variables the material strengths f_c and f_{sy}, the coordinates (y_p, z_p) of the nodal points p=1,2,… which define the two-dimensional geometry of the RC cross-section, the coordinates

(y_m, z_m) and the diameter $\varnothing_m$ of the steel bars m=1,2,…, the diffusivity coefficient D and the damage rates $q_c=(C_c\Delta t_c)^{-1}$ and $q_s=(C_s\Delta t_s)^{-1}$. These variables are assumed to be uncorrelated with the probabilistic distribution and statistical parameters listed in Table 2. Based on this model, a probabilistic analysis is performed by Monte Carlo simulation. A posteriori estimation on the goodness of the sample size is based on a monitoring of the mean and standard deviation of the robustness factor $R=R(t)$ for each time step over the lifetime.

Figure 6 shows the time evolution of the statistical parameters of the robustness factor $R=R(t)$ based on a sample of 3000 Monte Carlo realizations for α=1.0 (Figure 6.a) and α=1.8 (Figure 6.b). These results confirm the trend found from the deterministic analysis and show that the effects of uncertainty tend to increase over time periods when the susceptibility to damage increases and robustness decreases.

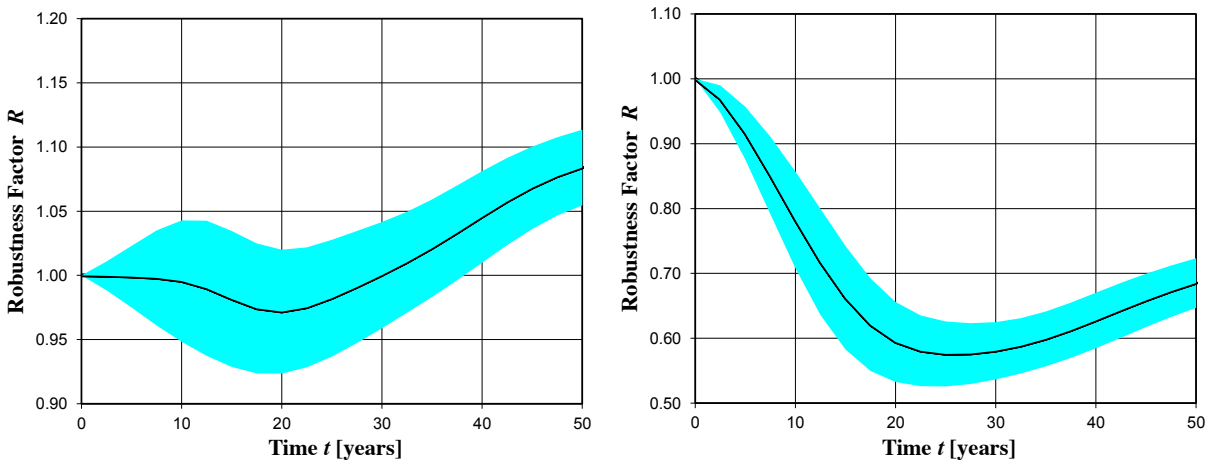
Concrete damage rate, $q_c=(C_c\Delta t_c)^{-1}$	Normal (*)	$q_{c,nom}$	$0.30\ q_{c,nom}$
Steel damage rate, $q_s=(C_s\Delta t_s)^{-1}$	Normal (*)	$q_{s,nom}$	$0.30\ q_{s,nom}$

(*) Truncated distributions with non negative outcomes are adopted in the simulation process.



(a) (b)

Figure 6. Time evolution of the statistical parameters of the time-variant robustness factor $R=R(t)$ computed with respect to the initial time t_0=0 for case (I) of full exposure, and for two values of the importance factor: (a) α=1.0; (b) α=1.8. The shaded region is bounded by the mean plus one standard deviation (upper bound) and the mean minus one standard deviation (lower bound).

CONCLUSIONS

The life-cycle robustness of deteriorating concrete structures has been investigated in deterministic and probabilistic terms. A robustness criterion proposed in previous works has been extended to consider the influence of the damage level on the time-variant robustness of existing concrete structures over the remaining structural lifetime. The proposed criterion allows to consider the relevance of the structure by means of an importance factor. Possible values of the importance factor have been provided for temporary structures, ordinary structures, and structures of strategic importance.

The proposed approach has been applied to the life-cycle robustness assessment of a RC bridge pier with box cross-section exposed to corrosion. Three exposure scenarios have been investigated: case (I) with full exposure of the cross-section, case (II) with external exposure only, and case (III) with internal exposure only. In terms of damage and strength deterioration the results showed that, as expected, case (I) is the worst scenario and case (II) is more critical than case (III). However, when the strength values are computed for the same amount of damage, different trends may arise. For bridges of ordinary importance robustness is maximum for case (III) with internal exposure, intermediate for case (I) with full exposure, and minimum for case (II) with external exposure. Moreover, if the assessment is made by considering the structure already damaged, robustness tends to be maximum in case (I). However, this tendency is reduced as the importance of the structure increases, and case (I) becomes the worst scenario also in terms of robustness for bridges of strategic importance.

These results are not intuitive and can be fully explained only through a proper time-variant measure of structural robustness able to account for the effects of damage under uncertainty. In fact, the probabilistic analysis confirmed the deterministic results and showed that the effects of uncertainty tend to increase over time periods when the susceptibility to damage increases and robustness decreases. This makes the robustness predictions less reliable when the system is not robust.

ABSTRACT

A Public-private partnership (PPP) is contract framework designed to carry out public works in the hope that the more advanced knowledge and financial support of private agents may be advantageous to develop better infrastructure projects that serve public needs. This relationship, which is embodied by a principal (e.g., government) and an agent (e.g., independent contractor), is inherently conflictive. Three main factors give rise to such conflict: the interests of the public and private party do not generally coincide, there is information asymmetry between them and their interaction unfolds in environments under uncertainty. Traditionally, the regulations put forth to mitigate the cost overruns caused by moral hazard, low performance levels and litigations are determined by methods which neither take into account a formal mathematical description of the interaction among participants nor the deterioration of physical components and their susceptibility to natural hazards. In this paper we propose an alternative approach that addresses these issues. We describe an agent-based model which represents the infrastructure system as an entity that is affected by the operations of three players: principal, agent and nature. They perform operations on the infrastructure, based on their own strategies and perceived payoffs, but are bound by a contract that constraint their actions. The purpose of the model is to simulate the interaction history among players and compute the resulting outcome in the form of the utility that each player receives. The model can be used within an optimization routine to determine which contractual rules maximize the utility for both players simultaneously.

INTRODUCTION

The development of infrastructure systems often come about when the principal (i.e., the entity who owns the project, usually a government agency) delegates to an agent (i.e., a private firm) the design, construction and operation of the infrastructure. One of the most widely used category of this kind of delegation is the Public-Private Partnership or PPP (Yescombe 2007). The history of an infrastructure project results from the interplay between: (1) the economic game that is set up between the principal and the agent, (2) the regulatory framework that imposes additional constraints on them, and (3) the behavior of the physical systems. The very act of delegation creates a moral hazard (Dutta and Radner 1994), which the principal must control. The design of the regulatory framework is the primary leverage point that the principal has at her disposal to control the moral hazard problem.

The study of contracts for infrastructure projects often come in two variants. The first approach is fundamentally inductive, managerial and mostly qualitative; it deals with the many subtleties in the interface of finance, regulation and institutions (Meunier and Quinet 2010; Yescombe 2007). The second is based on game theory and economics; it is deductive and quantitative, and deals with economic agents, information, utility functions and optimization problems(Auriol and Picard 2013; Medda 2007). The former, while being empirical and close to concrete examples often lack the ability to produce a rigorous prescription of contract design, and is often sustained by experience, the extrapolation from past events and guided by subjective opinion. The latter, on the other hand, is only able to produce precise quantitative specifications at the cost of reducing the real problem by imposing overly simplified assumptions that allows the problem to be mathematically tractable. Neither the first nor the second approach typically model the problem as a dynamic and path dependent interaction; they both overlook the fact that the physical system deteriorates over time, which in turn elicits reactive actions from

players. Thus, an ideal solution should focus on designing contracts based on reliable, reproducible quantitative models that acknowledged the intricate details of real socio-economic interactions and the inevitable deterioration of physical systems.

Such approach to this problem is challenging, since it encompasses several disciplines. The usual way in which economists analyze economic games is by using formal mathematical models. However, this approach is only feasible for simple problems; when features of non-linearity, discontinuity or heterogeneity are included, the model quickly becomes intractable. The alternative to analytical methods are the computational models. The advent of powerful computers has made it possible to approach questions and problems of a complex nature in almost all fields of knowledge, from formal and natural sciences to social sciences(Epstein 1999). The most prominent example in the social sciences, the agent-based computational models (ABM), have provided a framework to better understand complex interactions among individuals (i.e, agents) and to simulate the evolution of their interactions (Helbing and Balietti 2011; Johansson and Helbing 2010).Due to its generality, agent-based models have begun to transcend the boundary of social sciences to be applied to engineered systems. The remarkable advantage of ABMs is that besides simulating socio-economic interactions, they could simultaneously emulate a realistic description of physical interactions between agents. The addition of the latter feature is not yet widely used, and we have found only in K. L. Sanford Bernhardt and McNeil (2008)an instance with the mentioned feature being specifically targeted at modeling the life-cycle of civil infrastructure systems.

In this paper we present an agent-based model that includes the three aspects that influence the history of an infrastructure project: the interaction among stakeholders, the regulatory framework, and the physical performance of the system. This model defines the existence of players that interact with each other to accomplish their goals, while being restricted by a natural environment. The proposed approach represents a substantial contribution to the development of large infrastructure systems since it integrates technical, economic and contractual aspects that are essential for the success of a project. In essence, this model goes beyond the use of traditional life-cycle cost modeling –which is only focused on the relationship between costs and the physical performance of the system– by including in the analysis actors and strategies that actually define in practice the system behavior.

METHODOLOGY

Principal-Agent Problem

The principal-agent problem in the economics literature describes the conflict that arises when an uninformed entity (the principal) delegates a task to a better informed entity (the agent) in exchange of a wage (Bolton and Dewatripont 2005; Laffont and Martimort 2009). The principal's problem is described by the following bi-level (Colson et al. 2007) optimization problem

$$\max_{w(\cdot)} \quad E[u_P(q,w)] \tag{1}$$

subject to:

$$\tilde{e} = \arg\max_{e} \quad E[u_A(e,w)] \tag{2}$$

$$\bar{u} \leq E[u_A(\tilde{e},w)]$$

where $q(e,\theta)$ is the output (the result of the agent's activity as a measurable quantity) that depends on the effort $e$exerted by the agent, and a random variable θ that introduces uncertainty in the value of output;$w(q)$ is the wage function;u_P is the principal's utility which increases with output ($\partial u_P/\partial q > 0$) and decreases with wage transferred($\partial u_P/\partial w < 0$); and u_A is the agent's utility which decreases with effort($\partial u_A/\partial e < 0$) and increases with wage received($\partial u_A/\partial w > 0$). The first constraint (incentive compatibility constraint) is used to model the fact that the agent will try to maximize his own utility for any choice of $w(\cdot)$; in other words it models the rationality of the agent. The second constraint (participation constraint) makes sure that the wage offered will be greater than some reservation utility $\bar{u}$ that the agent would receive if he hadn't accepted the contract. This makes sure that the contract offer is in fact voluntarily accepted by the agent.

The basic principal-agent has two limitations. First, it is a static model that does not consider the intrinsic dynamic nature of actions and thus is unable to model the behavior of agents and physical systems throughout

time. Second, it assumes that the principal has perfect knowledge of the output, which is clearly contrary to the reality of infrastructure projects.

Agent-Based Model

These two limitations are solved by the agent-based model proposed in this paper. The relationship between principal and agent is a continuous-time dynamic game where they both can perform proactive actions at any time. Also, the infrastructure system is an object with specific physical characteristics (e.g., material properties, topology, etc.) and whose behavior is defined by physical laws. Finally, nature is a third player, which does not have preferences, but can exert discrete or continuous demands on the infrastructure affecting its performance, for example, favoring degradation (Sanchez-Silva et al. 2011). The model is path dependent and it is constructed by the sequential actions of the three players (principal, agent and nature). Figure 1 shows two possible history paths of a game: the upper figure is the history of the infrastructure's performance while the lower tree represents the two possible branching histories built by the sequential action of players.

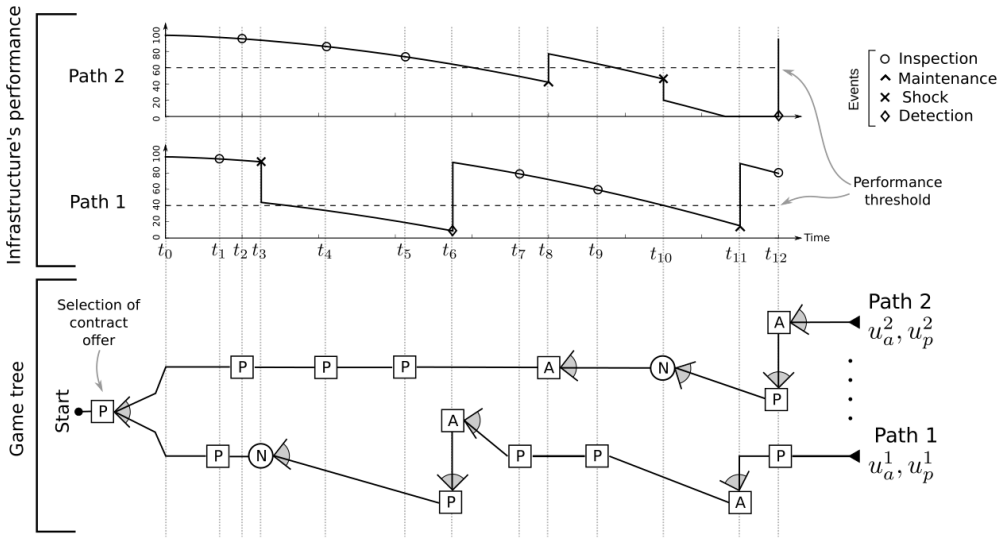

Figure 1. Two sample paths of a game. Top: Performance history of infrastructure. Bottom: Two branches of a game tree. P: Principal, A: Agent, N: Nature (adapted from Paez-Perez and Sanchez-Silva 2015).

In a sample path of this complex interaction, the principal offers a contract to the agent at the beginning of the game. If the agent accepts, a time continuous interaction will begin until the end of the contract. The principal can perform inspections to the system: if the performance measured is below some threshold –specified by the contract– she will impose a penalty fee to the agent. The main objective of the principal is to maximize the time that the system is operating above certain specific threshold; i.e., guarantee an acceptable availability. On the other hand, the agent has to operate the system so that he can maximize his profit. This means that he has to define the design criteria and a voluntary maintenance program that complies with the principal requirements; if detected under the threshold, he will be forced to pay some penalty and repair the system to some performance level greater than the threshold. The decision variables of the actions of each one of the three players are listed in Table 1.

The central part of the model is the definition of the interaction among all three players. Then, the model assumes that this interaction is built by the successive actions of players. At any given time, the game is in one of four stages, as shown in Figure 2. Stage 0 represents the beginning of the game, where the contract is offered. If accepted, the game switches to Stage 1, where the three players can perform proactive actions. If a violation is detected, the game is on Stage 2, where only the principal is allowed to act by selecting the penalty fee. Once it has been charged to the agent, the game transitions to Stage 3 where the agent must perform a mandatory maintenance action, the completion of which leads the game to return to Stage 1. The game will transition between these stages until the end of the contract is reached.

Table 1. Decision variables of player's actions

Player	Action	Decision variables
Agent	Voluntary maintenance	Time Performance goal
	Mandatory maintenance	Performance goal
Principal	Contract offer	Contract duration Performance threshold Payment schedule Revenue rate function Fare
	Inspection	Time
	Selection penalty fee	Monetary value
Nature	Shock	Time Magnitude of environmental demand

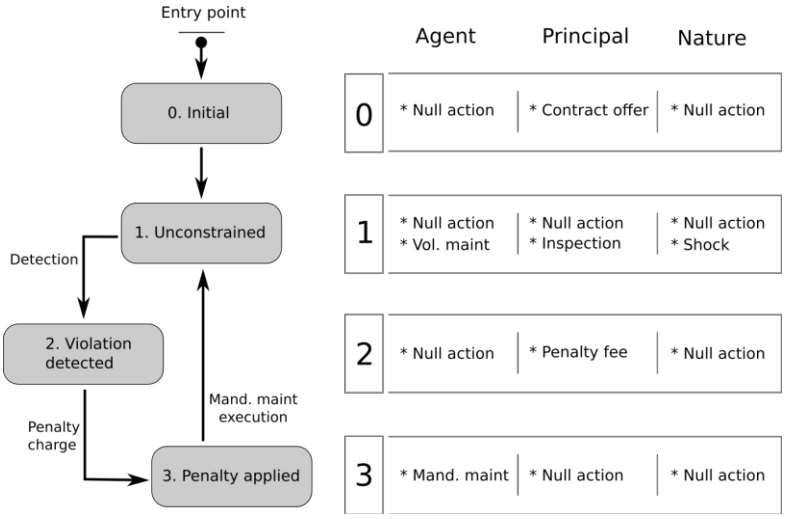

Figure 2. State chart of the game.

Players' actions are discrete and instantaneous. However, during the time that elapses between two successive actions, the game is governed by a different process. While the actions of players are realized by instantaneous changes in the state variables of the game, the continuous processes –such as progressive deterioration or the permanent flow of revenue received the agent– evolve gradually. This evolution is governed by a set of differential equations. The relationship between the state variables of the game is presented in *Figure 3*with a stock-flow diagram, widely used in problems of system dynamics. The alternation of agent-based behavior with system dynamics makes our model a hybrid simulation (Swinerd and McNaught 2012).

A stock represents the accumulation of a substance and a flow represents the rate of its movements between stocks. Arrows represent relationships of influence between different components (stocks and flows). The stocks in this model are: (1) the performance of the infrastructure, (2) the principal's monetary balance and (3) the agent's monetary balance. These are the basic state variables of the game. These variables are increased or decreased by flows, whose rates are controlled by various other elements. This creates the network of dependencies depicted in Figure *3*. For further details, see Paez-Perez and Sanchez-Silva (2015).

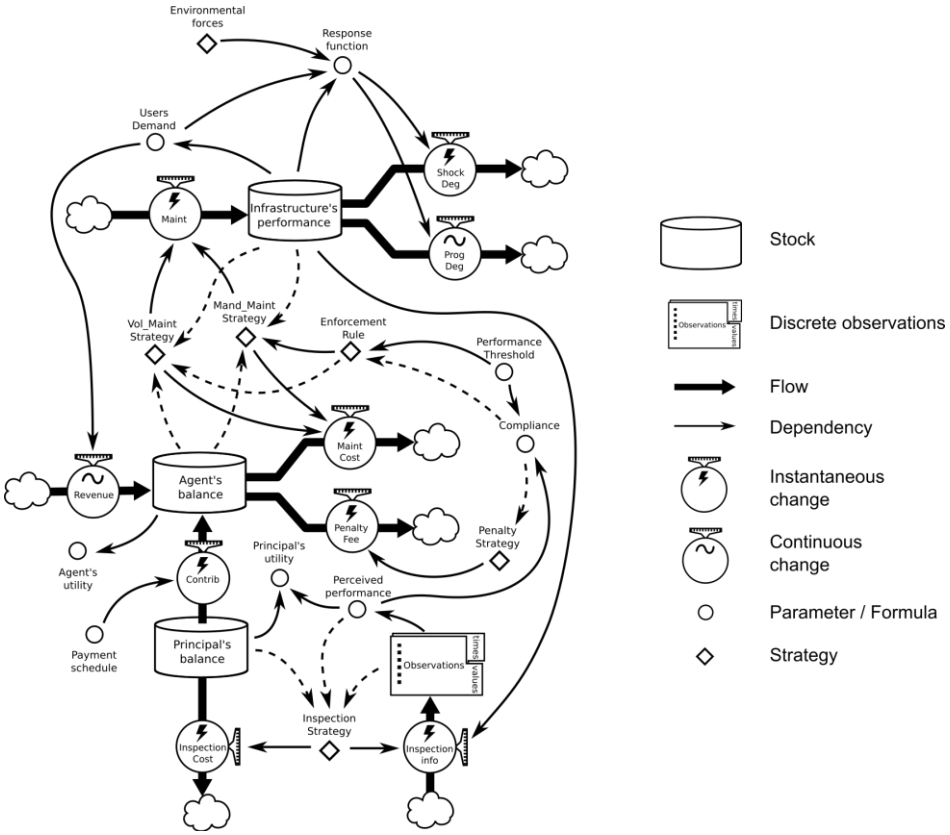

Figure 3. Stock and flow diagram of dynamic interaction (adapted from Paez-Perez and Sanchez-Silva 2015).

Strategies

The series of actions performed by a player during the interaction are dictated by a strategy. A strategy is an algorithm that tells a player which action to perform (by computing the appropriate decision variables. See Table 1) contingent upon the perceived current state of the world and recalled information. A player's strategy therefore determines his behavior throughout the entire game. The game simulated by the agent-based model is the transformation:

$$(u_A, u_P) = G(s_A, s_P, \phi) \tag{3}$$

where s_A and $s_P$are the strategies of agent and principal, respectively, and ϕ is a vector of problem parameters. Therefore, the principal's optimization problem for our agent-based model can be re-written as

$$\max_{s_P} \quad E[{u_P}^*] \tag{4}$$

subject to

$$\widetilde{s_A} = \underset{s_A}{arg\ max} \quad E[u_A] \tag{5}$$

$$\bar{u} \leq E[{u_A}^*]$$

where the utilities $({u_A}^*, {u_P}^*) = G(\widetilde{s_A}, s_P, \phi)$ are the result of some principal's strategy s_P and the agent's optimum response $\widetilde{s_A}$ to s_P. The expected values of utility are obtained from the iterated execution of G with the appropriate input.

The agent-based model that describes the transformation G was implemented as an object-oriented program in MATLAB, whose class diagram is presented in Figure 4.Principal, Agent and Nature are classes. Each player class computes their next action by using their strategy objects. The particular strategy objects for each player

are assigned at the beginning of the game. The players also have attributes (not shown in the class diagram) which serve as a memory database storing past observed events. Strategies are able (but not required) to use this memory to compute the values for the decision variables of the action they produce. Infrastructure class contains a shock and continuous response function (see Figure 3) and a record of the performance history. Nature contains the infrastructure object, so that all actions on infrastructure must be performed through the nature class.The contract class has a penalty fee strategy object and contains other information about the game (mostly problem parameters), considered as *common knowledge*. A realization object builds one interaction history of the game. The game evaluation class contains many realization objects of a single game specification. A realization object is therefore the concrete implementation of the transformation G. The public repository of the implemented model can be found at https://github.com/davpaez/contract-design.

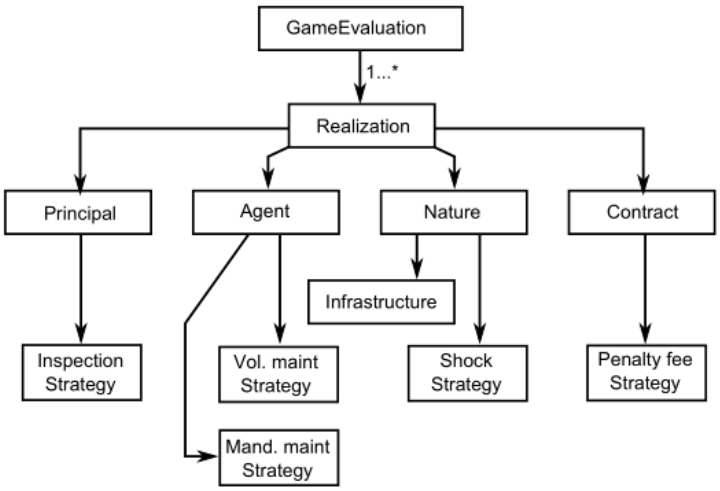

Figure 4. Simplified UML class diagram (adapted from Paez-Perez and Sanchez-Silva 2015).

RESULTS AND DISCUSSIONS

In this section, we present an example problem in order to illustrate some of the specifications needed to run a realization of a game (i.e., the transformation G) and the produced outcome. Consider a PPP for the construction of some interurban highway. For the purpose of this example, assume that the infrastructure performance is measured in a scale from 0 to 100 (in appropriate units). The environmental conditions cause the system to degrade as a result of progressive deterioration (e.g., oxidation of asphalt binder on hot mixed asphalt concrete) or shocks as a result of extreme natural events (e.g., earthquakes or floods).The contract specifies (according to the principal needs) that the highway must operate above a performance threshold of 70 and that the contract duration is 25 years. The initial construction investment is \$875M and the agent receives a total revenue of \$1800M which is evenly spread throughout the duration of the contract. Each inspection costs \$0.875M and a \$400M government contribution is transferred to the agent at the beginning of the game. The principal has established a strategy of inspections whose interval is exponentially distributed with rate $\lambda = 0.5$. The agent's voluntary maintenance strategy is adaptive and it tries to predict, based on previous observations, when the next inspection will occur and will perform a maintenance intervention just before.

At the top of Figure *5*, a realization of the system performance (measured with respect to some physical quantity within the range [0,100]) is shown. The x marks indicate the points at which shocks occur, circles the state of the system at the time of inspections, crosses the points where the agent carries out an intervention and diamonds, the points where a detection occurred and a mandatory intervention by the agent is required. It is important to note that the principal's knowledge of performance is only approximate as seen in Figure 5, it is merely a belief she holds based on the discrete inspections. Note also that because inspections are carried out at random, in certain periods the system is operating below the required threshold without being detected by the principal. In some other cases, this unacceptable condition is detected and the agent is punished with a penalty and forced to update the system. For simplicity it is assumed that all maintenance interventions take the infrastructure system to the maximum performance.

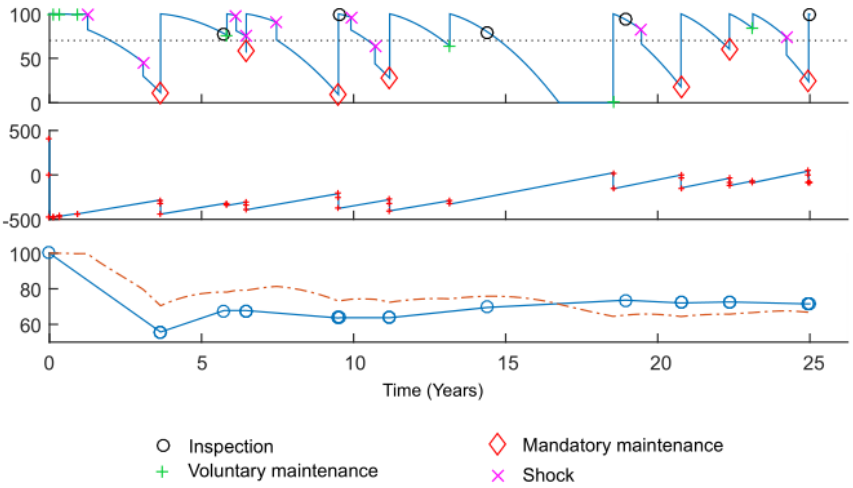

Figure 5. Single realization of a game. Top: Performance history of infrastructure system. Center: Agent's monetary balance. Bottom: mean value of performance as approximated by the principal using a linear interpolation between inspections (continuous line) and exact mean value of performance (dotted line).

Incentives are not only sensitive to contractual conditions but also to some problem parameters. For instance, if the maintenance cost function (the function that relates a change in performance to the cost of such intervention) were non-linear and a unitary improvement in performance was much cheaper when the infrastructure is performing well than when it is not, then the agent may be naturally inclined to keep the system at high performance levels. As it is rather usual in economic games, the goodness of a strategy is contingent on what other players' strategies are; in other words, there may not be a dominant strategy. Thus, the goodness of this maintenance strategy would also depend on the inspection strategy and the penalty policy imposed.

If this game is executed several times (using Monte Carlo simulation), we can plot the variables of interest, i.e., the player's utilities, as shown in Figure 6. The agent's utility is assumed to be equal to his monetary balance at the end of the game, while the principal's utility is equal to the approximate mean value of performance at the end of the game. Also, we can plot histograms to inspect their distribution and compute the probability that the game yields utilities above some desired values. This means the model can effectively calculate the reliability of a particular contract for the game specified. Thus, the model can be used to assess the effects of different strategies and/or parameters by comparing the outcome of each variation. Further expansion of this model includes the implementation of an optimization routine for finding the best contract for a specific problem instance.

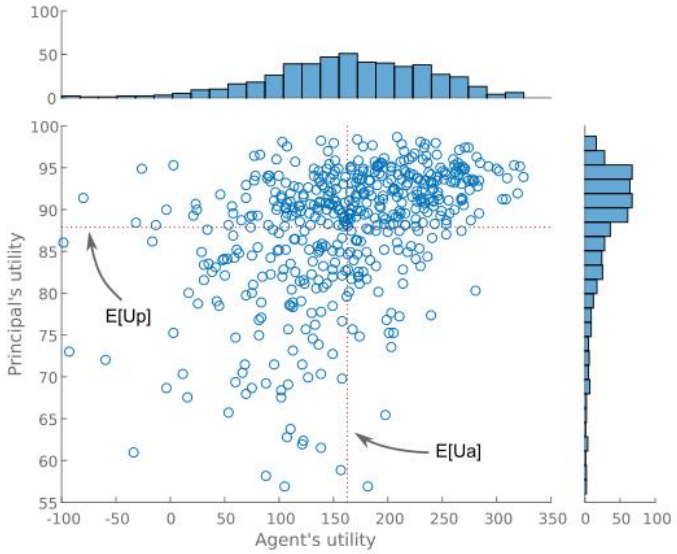

Figure 6. Utility scatter of 500 realizations of a game and a histogram for each utility.

CONCLUSIONS

Based on the principal-agent problem, the paper presents a dynamic continuous-time game where the principal, the agent and nature interact and affect one another and the infrastructure system under consideration. By characterizing the possible primitive interactions, we constructed an agent-based model whose execution allows us to model the various history paths that could have unfolded and derive from those a distribution for the variables of interest and reliability measures of the contract. This model may be used in a variety of circumstances where economic actions between self-interested agents are intertwined with physical systems that are subject to natural pressures and whose behavior is uncertain.

The development of an infrastructure project is at its core a social endeavor, for no single individual could by himself design, build and maintain a large physical system. Given its social nature, economic mechanisms must be designed so that they lead to a prescriptive account of concrete desired output. However, the means to achieve *what should be* (economic mechanisms) are blind if they are not guided by the descriptive knowledge of *what is* (the natural sciences and its application in engineering).Computational models give us the tools to embrace complexity and design mechanisms in a more holistic manner.

ABSTRACT

Various methods have been used by researchers to evaluate the time-dependent reliability of structures. Among them, the stochastic-process-based method is theoretically the most rigorous but also computationally the most expensive. To enable the wide application of the stochastic-process-based method in the time-dependent reliability analysis of complex problems, an efficient importance sampling method is presented. This new method, extended from an existing method for time-independent reliability analysis, offers an efficient solution for time-dependent problems of structural systems with multiple important regions. Furthermore, to enhance the efficiency and robustness of the proposed method, a number of numerical measures are proposed. The capability and efficiency of the proposed method are demonstrated through two numerical examples.

INTRODUCTION

Structures experience deterioration and varying load effects during their service life, so the reliability of a structure during its lifetime is a time-independent problem. For this reason, time-dependent reliability analysis has been used by many researchers to evaluate the structural safety of structural systems throughout their service life. Different researchers have adopted different methods in their analysis, and these methods can, in some cases, lead to dramatically different results(Yang et al., 2015). The theoretically rigorous method(i.e. the stochastic-process-based method) for time-dependent reliability analysis usually involves tedious computations, which hinders their application to complex reliability problems with multiple important regions (e.g. time-dependent reliability of structural systems). The objective of this paper is to propose a new and efficient sampling method to facilitate the wide application of the stochastic-process-based method in complex time-dependent reliability problems.

During the service life of a structure, its resistance is likely to deteriorate due to factors such as material degradations (e.g. steel corrosion) and damage from overloading or natural disasters. In addition, the load that a structure has to resist may change over time. Therefore, the performance function of a structure is time-dependent:

$$g(t) = R(t) - S(t) \tag{1}$$

where $R(t)$ and $S(t)$ are the time-dependent resistance and load effect, respectively. In order to assess structural safety during the entire service life, various methods have been proposed by researchers(Melchers, 1999), e.g. the point-in-time reliability method, the time-integrated method, and the stochastic-process-based method. Among these methods ,the stochastic-process-based method is the most accurate and assumes that the arrival of live load events follows a discrete stochastic process(Yang et al., 2015). Using this method, the time-dependent failure probability can be computed using the conditional probability theory as follows:

$$P_f\left(t \mid \mathbf{x}_c\right)=\sum_{k=1}^{\infty}\Pr\left[g\left(\tau;\mathbf{x}_v\left(\tau\right),\mathbf{x}_c\right)<0,\tau<t \mid \mathbf{x}_c,k\right]\Pr\left[N\left(t\right)=k\right]$$
$$P_f\left(t\right)=\int_{\Omega}P_f\left(t \mid \mathbf{x}_c\right)f_{\mathbf{X}_c}\left(\mathbf{x}_c\right)d\mathbf{x}_c \tag{2}$$

where $N(t)=k$ represents the situation that k load events have occurred prior to time t; $\mathbf{x}_v$ and $\mathbf{x}_c$ are the time-dependent and the time-independent variables respectively; $f_{\mathbf{X}c}$ is the probability density function (PDF) of $\mathbf{x}_c$; and τ is any time prior to the time of interest, t. This method was first proposed by Mori and Ellingwood(1993) and has thereafter been extensively used in the time-dependent reliability analysis of deteriorating infrastructure (Enright and Frangopol, 1999; Lounis and Amleh, 2003; Ellingwood, 2005; Akiyama et al., 2010; Okasha and Frangopol, 2010).

Eq. 2means that the performance function should not be very complex. For time-dependent reliability analysis, the performance function can usually be simplified to either Eq. 1 or the following equation:

$$g\left(t\right)=R\left(t\right)-S_D-S_L\left(t\right) \tag{3}$$

where the time-independent dead load effect S_D is isolated from the time-dependent load effect. The integration in Eq. 2usually needs to be carried out with an efficient simulation method such as the adaptive importance sampling method(Mori and Ellingwood, 1993). Although the conventional adaptive importance sampling method(Mori and Ellingwood, 1993; Enright and Frangopol, 1999) can effectively reduce the computational burdenfor simple problems, the stochastic-process-based method still faces computational difficulties, especially for those problems involving multiple random variables and multiple important regions, e.g. in system reliability problems. This is mainly because the method(Mori and Ellingwood, 1993) employs a unimodal sampling function that cannot generate samples efficiently when the actual regions of importance are multimodal. To facilitate the application of the stochastic-process-based method in complex problems, a cross-entropy-based adaptive sampling method using Gaussian mixture is proposed in this paper. The method is an extension of Kurtz and Song's (2013) method for time-independent reliability problems to time-dependent domains. The proposed method also includes a number of improvements formulated to enhance the efficiency and robustness of the original method developed by Kurtz and Song(2013). Two numerical examples are given to illustrate the efficiency of the new method.

CROSS-ENTROPY-BASED ADAPTIVE IMPORTANCE SAMPLING USING GAUSSIAN MIXTURE

Generally, the probability of failure is extremely low in structural reliability problems, resulting in the low efficiency of crude Monte Carlo simulation. In order to improve efficiency, importance sampling has often been used by switching the sampling effort to the more important region(s)with $h_V(\mathbf{x};\mathbf{v})$, the PDF of a new sampling function with parameters $\mathbf{v}$:

$$I=\int_{\Omega}\frac{H\left(\mathbf{x}_c\right)f_{\mathbf{X}}\left(\mathbf{x}_c;\mathbf{u}\right)}{h_V\left(\mathbf{x}_c;\mathbf{v}\right)}h_V\left(\mathbf{x}_c;\mathbf{v}\right)d\mathbf{x}_c \tag{4}$$

where $H(\mathbf{x}_c)=P_f(t|\mathbf{x}_c)$for time-dependent reliability problems. The estimated failure probability and its variance are as follows:

$$\hat{P}_f=\frac{1}{n}\sum_{k=1}^{n}\frac{H\left(\mathbf{x}_k\right)f_{\mathbf{X}}\left(\mathbf{x}_k\right)}{h_V\left(\mathbf{x}_k\right)} \tag{5}$$

$$S_{\hat{P}_f}^2=\frac{1}{n\left(n-1\right)}\sum_{k=1}^{n}\left[\frac{H\left(\mathbf{x}_k\right)f_{\mathbf{X}}\left(\mathbf{x}_k\right)}{h_V\left(\mathbf{x}_k\right)}-\hat{P}_f\right]^2 \tag{6}$$

The number of samples, n, can be several orders smaller than that in crude Monte Carlo simulation if $h_V(\mathbf{x};\mathbf{v})$is reasonably selected. Importance sampling methods have been widely used in complex time-independent reliability problems(Harbitz, 1986; Schuëller and Stix, 1987; Melchers, 1989; Kurtz and Song, 2013). However, these existing importance sampling methods for time-independent reliability problems are inappropriate for time-dependent reliability analysis because the shape or the location of the important region(s) cannot be easily anticipated for time-dependent reliability analysis.

Imposing $S_{\hat{P}_f}^2=0$ in Eq. 6leads to the following expression for the optimal sampling function $h_{Vopt}(\mathbf{x})$:

$$h_{Vopt}\left(\mathbf{x}\right)=\frac{H\left(\mathbf{x}\right)f_{\mathbf{X}}\left(\mathbf{x}\right)}{P_f} \tag{7}$$

which indicates that only one single sample is needed to estimate the probability of failure. Though the direct use of Eq.7 is impossible due to the unknown P_f, a close approximation of the optimal sampling function can significantly enhance sampling efficiency. To achieve this objective, an iterative process can be used to update a

sampling kernel progressively to approach a near-optimal sampling function. This category of importance sampling techniques is referred to as adaptive importance sampling. For time-dependent reliability analysis, Mori and Ellingwood (1993) utilized this type of methods to look for the location (i.e. the mean vector $\boldsymbol{\mu}_{Vopt}$)of the optimal sampling function iteratively. Bucher (1988) updated adaptively both the best location and the best shape (i.e. the covariance matrix $\boldsymbol{\Sigma}_{Vopt}$) of the optimal sampling function.

Because of the existence of an optimal sampling function, one can restate the problem as an optimization problem. In this case, the Kullback-Leibler cross-entropy, an indication of the difference between two probability densities defined as follows

$$D\left(h_{V_1}(\mathbf{X}),h_{V_2}(\mathbf{X})\right)=E_1\left(\ln\frac{h_{V_1}(\mathbf{X})}{h_{V_2}(\mathbf{X})}\right)=\int_\Omega \ln h_{V_1}(\mathbf{x})h_{V_1}(\mathbf{x})d\mathbf{x}-\int_\Omega \ln h_{V_1}(\mathbf{x})h_{V_2}(\mathbf{x})d\mathbf{x} \tag{8}$$

can be used to formulate the following optimization problem that represents the adaptation process of adaptive importance sampling:

$$\mathbf{v}=\arg\min_{\mathbf{w}} D\left(h_{Vopt}(\mathbf{X}),h_V(\mathbf{X};\mathbf{w})\right) \tag{9}$$

In Eqs 8 and 9, D(h_{V1}(X),h_{V2}(X)) is the Kullback-Leibler cross-entropy between the PDF $h_{V1}(\mathbf{X})$ and PDF $h_{V2}(\mathbf{X})$; E_1[ln($h_{V1}(\mathbf{X})$/$h_{V2}(\mathbf{X})$)]is the expected value of ln($h_{V1}(\mathbf{X})$/$h_{V2}(\mathbf{X})$) with $\mathbf{X}$ being drawn following the PDF $h_{V1}(\mathbf{X})$; and $\mathbf{w}$ is the group of parameters of sampling function $h_V(\mathbf{X};\mathbf{w})$.

The optimization problem has analytical solutions for distributions in the exponential family(Rubinstein and Kroese, 2004; Kurtz and Song, 2013).Kurtz and Song (2013)applied Eq. 9 to time-independent reliability problems with multiple important regions by using Gaussian mixture given below as the importance sampling kernel:

$$h_V(\mathbf{x};\mathbf{w})=\sum_{j=1}^{n_w}\pi_j N\left(\mathbf{x};\boldsymbol{\mu}_j,\boldsymbol{\Sigma}_j\right) \tag{10}$$

where n_w is the total number of Gaussian components; $N(\mathbf{x};\boldsymbol{\mu}_j;\boldsymbol{\Sigma}_j)$is the PDF of the j-th multivariate Gaussian distribution with a mean vector $\boldsymbol{\mu}_j$ and a covariance matrix $\boldsymbol{\Sigma}_j;\pi_j$, with $\sum_{j=1}^{n_w}\pi_j=1$and $0\le\pi_j\le1$, are weighting factors of the Gaussian components; the parameters $\mathbf{w}$, therefore, have($3\times n_w$)components, i.e. $\mathbf{w}=\{\pi_1,\ldots,\pi_{nw},\ldots,\boldsymbol{\mu}_j,\ldots,\boldsymbol{\mu}_{nw},\boldsymbol{\Sigma}_j,\ldots,\boldsymbol{\Sigma}_{nw}\}$. Since a multivariate Gaussian distribution is in the family of exponential distributions, the analytical solution for the optimization problem given by Eq. 9 can be deduced following the same procedures given in the existing studies(Rubinstein and Kroese, 2004; Kurtz and Song, 2013). Eqs 11to 13 show the updating rules for $\boldsymbol{\mu}_j$, $\boldsymbol{\Sigma}_j$ and π_j, j=1,…,n_w(Kurtz and Song, 2013):

$$\boldsymbol{\mu}_j=\frac{\sum_{i=1}^{n_{sub}}H(\mathbf{x}_i)W(\mathbf{x}_i;\mathbf{u},\mathbf{w})\gamma_{i,j}\mathbf{x}_i}{\sum_{i=1}^{n_{sub}}H(\mathbf{x}_i)W(\mathbf{x}_i;\mathbf{u},\mathbf{w})\gamma_{i,j}} \tag{11}$$

$$\boldsymbol{\Sigma}_j=\frac{\sum_{i=1}^{n_{sub}}H(\mathbf{x}_i)W(\mathbf{x}_i;\mathbf{u},\mathbf{w})\gamma_{i,j}\left(\mathbf{x}_i-\boldsymbol{\mu}_j\right)\left(\mathbf{x}_i-\boldsymbol{\mu}_j\right)^T}{\sum_{i=1}^{n_{sub}}H(\mathbf{x}_i)W(\mathbf{x}_i;\mathbf{u},\mathbf{w})\gamma_{i,j}} \tag{12}$$

$$\pi_j=\frac{\sum_{i=1}^{n_{sub}}H(\mathbf{x}_i)W(\mathbf{x}_i;\mathbf{u},\mathbf{w})\gamma_{i,j}}{\sum_{i=1}^{n_{sub}}H(\mathbf{x}_i)W(\mathbf{x}_i;\mathbf{u},\mathbf{w})} \tag{13}$$

where n_{sub} is the number of simulations in each adaptation step;$W(\mathbf{x};\mathbf{u},\mathbf{w})$is referred to as the likelihood ratio between $f_{\mathbf{X}}$ and h_V, i.e.

$$W(\mathbf{x};\mathbf{u},\mathbf{w})=\frac{f_{\mathbf{X}}(\mathbf{x};\mathbf{u})}{h_V(\mathbf{x};\mathbf{w})} \tag{14}$$

and $\gamma_{i,j}$is referred to as the "responsibility" of the component distribution $N(\mathbf{x};\boldsymbol{\mu}_j,\boldsymbol{\Sigma}_j)$with respect to the observation $\mathbf{x}_i$, as defined in the following equation:

$$\gamma_{i,j}=\Pr\left[\mathbf{X}\square\, N\left(\mathbf{X};\boldsymbol{\mu}_j,\boldsymbol{\Sigma}_j\right)\mid\mathbf{X}=\mathbf{x}_i\right]=\frac{\pi_j N\left(\mathbf{x}_i;\boldsymbol{\mu}_j,\boldsymbol{\Sigma}_j\right)}{\sum_{k=1}^{n_w}\pi_k N\left(\mathbf{x}_i;\boldsymbol{\mu}_k,\boldsymbol{\Sigma}_k\right)} \tag{15}$$

The detailed deduction of Eqs 11 to 15 can be found in the aforementioned studies(Rubinstein and Kroese, 2004; Kurtz and Song, 2013).Eqs11 to 15 provide a clear and explicit adaptation procedure to approach the near-optimal sampling function. Following Eqs11 to 15, parameters **w** will adapt to the optimal parameters **v** in Eq. 9, leading to an efficient sampling function that can dramatically reduce the computational cost. In particular, in each adaptation step (i.e. step i), $\mathrm{w}^{(i)} = \{\pi_1^{(i)}, \ldots, \pi_{nw}^{(i)}, \boldsymbol{\mu}_1^{(i)}, \ldots, \boldsymbol{\mu}_{nw}^{(i)}, \boldsymbol{\Sigma}_1^{(i)}, \ldots, \boldsymbol{\Sigma}_{nw}^{(i)}\}$can be determined using Eqs11 to 15 with$\mathrm{w} = w^{(i-1)}$.Usually, the adaptation process converges to the optimal values after only a few steps.

Additionally, it should be noted that the selection of the initial **w** plays an important role in the adaptation process, and possible singularity issues in Eqs11 to 15 can create some difficulties in the numerical implementation. Such computational difficulties have also been noticed by Kurtz and Song(2013), but they did not provide a plausible solution. The numerical robustness issue is further discussed and tackled later in the paper. Finally, it should be mentioned that if a unimodal sampling function is used, i.e.$\gamma_{i,j}$=1andn_w=1,thecross-entropy-based method (i.e. Eqs 11 to 15) reduces to Mori and Ellingwood's(1993)or Bucher's (1988)method, depending on whether only Eq. 11or both Eq. 11 and Eq. 12 are used in the adaptation process. As can be seen later in the numerical examples, the present method is more advantageous than Mori and Ellingwood'sor Bucher's method because it is able to accommodate multiple important regions efficiently in system reliability problems.

TIME-DEPENDENT RELIABILITY ANALYSIS WITH CROSS-ENTROPY-BASED SAMPLING METHOD

Time-Dependent Reliability of Structures and Structural Systems

As stated earlier, the live load should be considered as a stochastic process. In this paper, the time-dependent reliability of bridges is considered as bridges may experience severe deteriorations over their service life. The live load process of a bridge can be regarded as a Poisson process with arrival rate λ. The structural resistance is likely to decrease due to environmental attacks. If structural deterioration is represented by a deterioration function $g_R(t)$, the performance function of a time-dependent reliability problem can be re-written as

$$g(t) = R_0 g_R(t) - S_D - S_L(t) \tag{16}$$

whereR_0 is the initial resistance (time-independent); $g_R(t)$ is the deterministic deterioration function; S_D is the dead load effect (time-independent); and $S_L(t)$is the live load effect (time-dependent).The conditional time-dependent failure probability of RC bridge girders can be expressed as (Mori and Ellingwood, 1993; Enright and Frangopol, 1999):

$$P_f(t \mid r, s_D) = 1 - \exp\left\{-\lambda t\left[1 - \frac{1}{t}\int_0^t F_{S_L}\left(r g_R(\tau) - s_D\right) d\tau\right]\right\} \tag{17}$$

where r and s_D are observations of R_0 and S_D; and F_{SL} is the cumulative distribution function (CDF) at each live load arrival. Eq. 17 can be further simplified forseries systems. According to Mori and Ellingwood (1993), the conditional failure probability of a series structural system can be calculated as

$$P_f(t \mid \mathbf{r}, \mathbf{s}_D) \approx P_f(t \mid \mathbf{r}) = 1 - \exp\left\{-\lambda t\left[1 - \frac{1}{t}\int_0^t F_S\left(\min_{i=1}^{m} \frac{r_i g_{R_i}(\tau)}{c_i}\right) d\tau\right]\right\} \tag{18}$$

where $c_i$arethe distribution factors of live load [e.g. girder distribution factors (GDFs) in bridge superstructures];and m is the number of elements in the series system. It should be noted thatthe uncertainty of dead load has little influence on the time-dependent reliability of bridge superstructures (Mori and Ellingwood, 1993; Enright and Frangopol, 1999). Therefore, the CDFs of $S_L$havebeen substituted by those of the total load effect S in Eq. 18.In the time-dependent reliability analysis, Eqs17 and18 are evaluated by numerical integration, while the total probability of failure is computed with a simulation method. For system reliability problems, multiple important regionsmay occur(Mori and Ellingwood, 1993), which will compromise the efficiency of existingmethods. The above cross-entropy-based sampling method using Gaussian mixture provides anefficientalternative in such situations.

Numerical Robustness of Cross-Entropy-Based Adaptive Importance Sampling Using Gaussian Mixture

Initial Parameters of Gaussian Mixture

The initial parameters of Gaussian mixture, **w**, play an important role in the efficiency and robustness of the new method. A good guess of important regions can dramatically increase the speed of convergence and decrease the required number of samples while a poor guess can either increase the computational cost or cause convergence to only some of the important regions instead of all of them. Kurtz and Song's(2013) method has two major deficiencies in the selection of the initial **w** (Yang et al., 2015).To correct these deficiencies, it is recommended

herein that the Latin hypercube sampling method be used to generate $\boldsymbol{\mu}_j$ in Eq. 10. As an efficient stratified sampling method, Latin hypercube sampling is capable of generating representative values of the whole sample space. Correlation between random variables is controlled with simulated annealing (Vořechovský, 2004). The target correlation matrix can be defined according to the configuration of the considered structural system. For a series system, a negative-correlation matrix can be used as the target correlation matrix. Higham's(2002) algorithm is employed to find the nearest correlation matrix if the proposed correlation matrix is not positive definitive. This algorithm is also able to deal with systems with elements of different degrees of importance.

Covariance Updating and Control

During the adaptation process, the covariance of samples may shrink or expand to mimic the optimal sampling function. This process does give a good approximation of the optimal sampling function. However, as indicated by Melchers(1990) and shown in numerical example 1 given later, the estimated failure probability may oscillate around the real value when the covariance of the sampling function becomes too small. It is also inefficient to use a larger standard deviation (STD) to overcome the problem as this increases the chance of obtaining sample points of low importance. Moreover, for Gaussian mixture adaptations, a larger STD of sampling function may result in the clustering of Gaussian mixture components.

In the new method proposed in this paper, n_k samples will be generated after the adaptation process in order to determine k_{opt} which is defined as follows:

$$k_{opt} = k_{opt,ij} = \sqrt{\frac{\Sigma_{kij}}{\Sigma_{pre,kij}}} \quad \text{where } i, j = 1,...,n_{RV} \tag{19}$$

where Σ_{kij}areelements of the covariance matrix of the k-th Gaussian component, and $\Sigma_{pre,kij}$ are the elements of the covariance matrix of the k-th Gaussian component right after the preliminary sampling (i.e. the sampling to arrive at the near-optimal sampling function).Based on the results of a trial-and-error process, it is recommended herein that k_{opt} be reduced from 2.00 to 1.00at an interval of 0.05 as long as the simulated failure probability from n_k samples does not drop dramatically(Yang et al., 2015).This control process can mitigate the observed oscillation while preserving the computational efficiency.

Besides the preceding covariance control, the covariance matrix should also be expanded during the first few steps of adaptation in the preliminary sampling so that there are enough points falling into the important region(s). For unimodal sampling functions, Mori and Ellingwood (1993) recommended that $\sigma_{V,i}^{(s)} = k_s \sigma_{Xi}$, where $\mathrm{i} = 1, \ldots, \mathrm{n}_{RV}$ with

$$k_s = \begin{cases} 3.0 & \text{where } s = 1 \text{ for the first adaptation step} \\ 2.2 & \text{where } s = 2,3 \text{ for the second and third adaptation steps} \\ 1.6 & \text{where } s \geq 4 \text{ for the other adaptation steps until convergence} \end{cases} \tag{20}$$

According to Yang et al.(2015), if Gaussian mixture is used, it is proposed that$\Sigma_{kij}^{(s)} = k_s^2 \, \Sigma_{pre,kij}$, where $\mathrm{i} = 1, \ldots, \mathrm{n}_{RV}$with

$$k_s = \begin{cases} 3.0 & \text{where } s = 1 \text{ for the first adaptation step} \\ 1.5 & \text{where } s = 2,3 \text{ for the second and third adaptation steps} \\ 1.2 & \text{where } s = 4,5 \text{ for the fourth and fifth adaptation steps} \\ 1.0 & \text{where } s \geq 6 \text{ for the other adaptation steps until convergence} \end{cases} \tag{21}$$

According to the preceding discussion, the cross-entropy-based adaptive importance sampling method needs two cycles of sampling: preliminary sampling and main sampling. During the preliminary sampling cycle, adaptation is conducted to obtain the near-optimal sampling function. During the main sampling cycle, only a relatively small number of samples are needed to predict failure probability. The results from both cycles of sampling are then combined to obtain an unbiased estimation of failure probability as follows(Mori and Ellingwood, 1993):

$$\hat{w} = \frac{S^2_{\hat{P}_f,main}}{S^2_{\hat{P}_f,pre} + S^2_{\hat{P}_f,main}} \tag{22}$$

$$\hat{P}_f = \left(1 - \hat{w}\right) \hat{P}_{f,main} + \hat{w} \hat{P}_{f,pre} \tag{23}$$

$$S^2_{\hat{P}_f} = \left(1 - \hat{w}\right)^2 S^2_{\hat{P}_f,main} + \hat{w}^2 S^2_{\hat{P}_f,pre} \tag{24}$$

where $\hat{P}_{f,pre}$ and $S^2_{\hat{P}_{f,pre}}$ as well as $\hat{P}_{f,main}$ and $S^2_{\hat{P}_{f,main}}$ are the estimated probabilities of failure and their corresponding variances from the preliminary and the main sampling cycles, respectively.

NUMERICAL EXAMPLES

Example 1: Importance of Covariance Adaptation and Control

Mori and Ellingwood's (1993)method has been widely used in time-dependent reliability analysis. However, this method only updates the location of the sampling function during each adaptation step. This can jeopardize the efficiency of the method when the optimal importance sampling function is highly skewed. In addition, as stated earlier, covariance control is important when covariance adaptation is implemented. Through this example, the importance of covariance adaptation and control is demonstrated. The example is a deteriorating RC bridge girder. The initial resistance R_0 follows a lognormal distribution with a mean equal to 1573 kNm and a COV of 0.17; the dead load S_D follows a normal distribution with a mean of 233.6 kNm and a COV of 0.10; and the live load S_L at each arrival is a normal random variable with a mean of 293.3 kNm and a COV of 0.40. The arrival rate of the live load is 1000 times/year, i.e.λ=1000. Three sampling algorithms were implemented, i.e. Mori and Ellingwood's method, Bucher's method (i.e. covariance adaptation without control), and the new method (covariance adaptation with control). Reliability at the end of the first year was evaluated using all three methods. Herein, only one year is considered so that a skewed import region can be obtained for comparison purpose. In practice, the proposed method can be used for time-dependent reliability analysis of much longer time. During the first year, structural deterioration does not occur, so $g_R(t)$=1. With each method, 12 runs of analysis were undertaken in order to provide a more reliable assessment of the methods. All the results are listed in Table 1.

Table 1Comparison of different methods for problems with skewed important regions

COV(%)	7.35	-	8.53	-	1.36	-

Though the optimal sampling function cannot be determined a priori, its shape can be illustrated by function $H(\mathbf{x})f_{\mathbf{X}}(\mathbf{x})$, as shown in Figure 1(a). As can be seen, the optimal sampling function is indeed skewed. Adaptation of the sampling function with the new method is presented in Figure 1(b) for one specific run in Table 2. For comparison, the sampling PDFs after adaptation are shown as well for Mori and Ellingwood's and Bucher's methods. From Table 1 and Figures1and2, it can be concluded that covariance adaptation can improve the robustness and efficiency of the sampling method.

Example 2: Sampling Using Gaussian Mixture and Time-Dependent Reliability of Series Structural Systems

Gaussian mixture is capable of accommodating multiple peaks of the optimal sampling function and is thus more efficient in system reliability problems. In this example, the time-dependent reliability analysis of a series structural system was conducted to demonstrate the high efficiency of the new method. The system is the superstructure of an RC girder bridge that consists of five girders (Enright and Frangopol, 1999). The system is modelled as a series system, i.e. the failure of any girder indicates the failure of the whole superstructure. Eq. 18 is used in this example. The initial resistance R_0 follows a lognormal distribution with a mean equal to 1790 kNm and a COV of 0.16; the dead load is a deterministic variable equal to 231.2 kNm; and the live load S_L at each arrival is a normal random variable with a mean of 301.4 kNm and a COV of 0.40. The arrival rate of live load is 1000 times/year. In the analysis, it was assumed that all the bridge girders have identical flexural resistance.

The time-dependent reliability of four series structural systems was analyzed using Mori and Ellingwood's(1993)method, the cross-entropy-based method with a unimodal sampling function, and the cross-entropy-based method with Gaussian mixture. These series systems are composed of 2 to 5 elements, and c_i in Eq. 18 is assumed to be 0.51 for all elements in the series systems. Reliability at the end of the first year was evaluated. Similar to the first example, the one year period used in this example is to ensure that the important regions are positioned separately from each other. Since deterioration is not likely to occur in the first year, $g_R(t)=1$forall four systems. The efficiency that can be achieved using Gaussian mixture was examined. Table 2 gives the analysis results. It can be observed that cross-entropy-based importance sampling using Gaussian mixture can significantly increase the sampling efficiency.

Table 2Comparison of computation efficiency for series systems

Element	Method[1]	Sampling parameters[2]					Main sampling		Final results	
		n_w	n_{sub}	n_{adp}	n_{main}	n_{total}	$P_{f,main}$	$\delta_{pf,main}$	P_f	δ_{pf}

Figure 3 Near-optimal sampling functions after adaptation (2 elements)

CONCLUSIONS

A cross-entropy-based adaptive importance sampling method has been proposed for the efficient computation of time-dependent reliability of structural systems. The method uses Gaussian mixture to accommodate multiple important regions that may occur in structural systems. From the results and discussions presented in the paper, the following conclusions can be drawn:

1. The proposed sampling method is more efficient than the existing methods, especially for series systems with multiple important regions.
2. With Gaussian mixture as the sampling kernel, a multimodal near-optimal sampling function can be obtained after only a few steps of adaptation.
3. A number of numerical measures were proposed and shown to improve the efficiency and robustness of the proposed sampling method; these include the use of Latin hypercube sampling, simulated annealing, appropriate design of the target correlation matrix, and updating of this matrix using Higham's algorithm.
4. It is important to control correlation adaptation during preliminary sampling in order to eliminate possible oscillations of the estimated failure probability.

ABSTRACT

The evaluation of the structural strength of an offshore pipeline after 25 years of service is an important issue for extending its lifespan. This is an important environmental and economic issue, especially when the pipeline is related to the oil and gas industry. Remaining strength after corrosion effects are included in the performance equation and can be determined by using maximum operating pressure and capacity equations. The results are then compared from burst test results. In this study, Bayesian updating of probability of failure is used to evaluate the updated probability of failure. The performance equations from the two main codes on corrosion used in this study are B31G and DNV-RP-F101 and they are used validate the results. The sensitivity analysis of the variables such as defect depth and thickness is considered in the analysis. This method could be adopted for evaluating the service life extension and evaluation of pipelines working under extreme environments. FORM and Monte Carlo simulations will be used to determine the updated probability of failure. The method could be used for many engineering structures where either practical approaches are not feasible to determine the remaining life of the structure or the uncertainty of the expected results is too high. The evidence concluded in this study could be used by industry to enhance our understanding of the mechanisms for pipeline failure and processes necessary for its preservation.

INTRODUCTION

Pipeline is a popular and significant mode of transporting liquids for the onshore and offshore oil and gas industry. This is due to many reasons such as economics, easy to lay, and long design life of approximately 20-30 years, which are necessary criteria for offshore pipelines due to undersea work environments. Oil pipelines require continuous assessment for their structural integrity. Pipelines commonly deteriorate due to external or internal corrosion. Though cathodic protection and corrosion resistant paints are used at the time of installation, due to decay, with time their effect decreases significantly to withhold corrosion. This is due to sea environment in which these pipelines are placed and the oil and gas these pipelines transport. This paper refers a pipeline that has already completed its design life and is under constant investigation given that it is severely affected by internal corrosion. The rate of corrosion in sea water is 0.3 to 1 mm / year. External corrosion is protected by cathodic protection and a coat of concrete. Malaysia is an offshore oil producing country. There are approximately three hundred Jacket platforms in operation for more than 30 years. Many of its pipelines networks have already completed their design life, and offshore Jacket platforms continue to produce and temporarily store oil and gas to be transported onshore or to another platform.

Offshore oil and gas pipelines are a complex infrastructure system with a significant impact on the economy, environment, and society. The world is moving towards adopting more proactive and optimised approaches to manage underground pipeline systems for their short and long term renewal planning in a more sustainable way (Tee, Khan et al. 2014). The main causes of their damage are stress corrosion cracking, wall thickness reduction, and the presence of stress concentrators (Amirat, Mohamed-Chateauneuf et al. 2006). Pipelines, like other structures in nature, deteriorate over time. The deterioration of pipelines in the form of corrosion is found to be a major problem for pipeline operators that worsen as pipelines age. The annual direct cost of corrosion, in the U.S. oil industry exceeds $5.1 billion per year (Nuhi, Abu Seer et al. 2011). Corrosion was a major cause of 18% of significant incidents from 1988-2008 (Fessler 2008). Structural engineers and naval architects are becoming increasingly interested in rate of loss of strength of steel and thus in loss of material for offshore and onshore

pipe systems (Teixeira, Guedes Soares et al. 2008). Due to the nature of transported material, it is extremely important to determine the structural reliability of a corroded pipe. The importance of this type of study is due to health, safety, and economic reasons and to prevent hazards and accidents by properly defining the random variables of the governing limit state equation. It is necessary from a green technology point of view to assess and evaluate the strength of offshore pipelines damaged due to corrosion. Offshore pipelines are regularly investigated for internal and external defects by inline inspection tools (ILI). The tolerance limits and uncertainty either underestimate or overestimate defect depth size and thus their reliability needs to be ascertained. Due to the cost involved in replacement, it is essential to determine the exact extent of the damage. Underestimation could cause an environmental catastrophe such as the "Deep-water Horizon oil spill" in 2010 or if overestimated, this will have a huge impact on project costs. This requires that structural reliability shall be evaluated of these pipes. To date, pipelines are perhaps the most economic and efficient means of large scale fluid transportation for crude oil and natural gas compared to rail, truck, and tanker transportation in terms of flexibility of routes and large quantities to be moved (Ilman and Kusmono 2014). Lifetime management of pipelines is necessary for safe hydrocarbon transmission and distribution systems. Reliability analysis is recognised as a powerful decision-making tool for risk-based design and maintenance (Amirat, Mohamed-Chateauneuf et al. 2006).

In this paper, the remaining life of corroded pipelines is determined by using design codes DNV 2010, ASME 1991 and 2009. This paper investigates remaining pipeline strength. Many researchers have worked on corrosion reliability (Melchers 2005; Melchers and Jeffrey 2008; Ahammed 1998; Zhou, Hong et al. 2012; Bai and Bai 2014). The major causes of accidents in liquid and natural gas pipelines are internal and external corrosion defects. As pipelines age, corrosion causes metal loss that reduces the thickness of pipes thereby decreasing the strength of the pipelines (Lee, Kim et al. 2005). These design codes are continuously developed and updated and are used throughout the industry to evaluate the remaining strength of corroded pipelines. Besides that, these codes usually provide prediction of the failure pressure for the corroded pipelines at a fairly high tolerance (Xu and Cheng 2012).

METHODOLOGY

Failure analysis of X52 pipeline and its background

The sampled pipeline is located in peninsular Malaysia with a diameter of 273.05 mm, nominal wall thickness of 11.1 mm, and total length of 6.9 km. It transports wet and semi processed crude oil between two Jacket platforms with a flow rate of 168 m^3/day. The design code is ASME B31G and material grade is API 5L X52. The design pressure was 10.35 MPa at the time of design and maximum allowable operating pressure (MAOP) was set to 9.3 MPa which was subsequently decreased to 4.0 MPa and at the time of last inspection the average operating pressure was 2.8 MPa. It was put into operation in 1982 for a design life of 20 years. The defect assessment was performed using ultra sonic non-destructive scan tests named as the intelligent pigging method of Magnetic Flux Leakage tool to evaluate its internal and external corrosion with confidence level of 80%. This process started in 1984 and subsequently repeated in 1993, 1997, 1998, 1999, 2002, 2003, 2005 and 2006. The main corrosion enhancing elements in hydrocarbon carrying pipeline are acid gases like CO_2 and H_2S both of which dissolve in water and separate to cause carbonate acid corrosion and hydrogen sulphide cracking respectively. The presence of water is a prerequisite for corrosion. Other elements of corrosion include salts, carbonates, bicarbonates, and organic acids such as Ferric chloride, ferrous sulfide, ferric chloride, sand, coating failure, and anode depletion. The operating temperature is 55℃ and it is located below mean sea level of 67.2 m. There were 6000 defects between 10-50% of material loss with the maximum corroded depth recorded as 5.11 mm out of a total depth of 11.1 mm. The most significant defect recorded in 1991 was 2.33 mm and the inspection carried in 2003 reported 5mm. Total number of defects identified in inspection reports of 1993, 1997, 2003 and 2006 are 944, 2186 and 10896 respectively. Out of these, 60% of defects reported were pit defects. The majority of these defects were in one segment of a 250 meters section of the pipeline. In 2008, it was recommended that a segment of 1000 meters should be replaced with a new one due to corrosion between log distances of 93-850 m because single and interacting defects gave (corroded pressure) p_{corr} =0 bar containing the highest density of defects of 88%. Table 1 shows some significant corroded defect lengths and depths of the pipeline section. The data is taken from a section of the pipeline. The absolute distance shown in the first column is based on a 500 meter section of pipe sampled in this study. The distance is mentioned here to show the nearness of corrosion pits. The length and width shows defected length and width of a pit. Depth of pit is shown in terms of percentage of original wall thickness which is 11.1mm. Some of these defects are in close proximity and there is likelihood that they will grow and become one significant defect.

Table 1: Corrosion defect resistance and load variables.

Absolute distance (m)	Length (mm)	Width (m)	Depth (%)	ERF
113.54	247	10	33	1.219
122.73	265	35	40	1.361
134.92	400	80	24	1.075
147.88	374	45	33	1.219
184.71	370	130	26	1.104
197.00	290	130	25	1.089
200.33	310	180	38	1.318
215.11	303	120	39	1.339
230.05	493	37	31	1.184
486.83	250	40	41	1.385

Estimated repair factor (ERF) is used to rank the abnormalities in the pipeline based on their severity. ERF is shown in terms of maximum allowable operating pressure $MAOP$ and safe pressure (P_{safe}) by Eq. (1),

$$ERF = \frac{MAOP}{P_{safe}} \tag{1}$$

Pipeline Burst test analysis

Two meters of pipeline was cut and used for burst pressure test analysis. The water was inserted until a burst in the pipe occurred with water capacity of 100 MPa. The burst pressure is shown in Table 2 with average value of 33.5 MPa. Maximum hoop stress predicted by equation (2) is 36.5 MPa. This burst test which showed confidence in the remaining strength of pipeline was considered necessary to recheck the reliability of the pipeline. The burst test provided a reserve strength which is incorporated into the limit state equation to get the new updated reliability.

Table 2: Pipeline Burst test results

Average measured wall thickness (mm)	Defect Dimensions (mm)			Burst Pressure (MPa)
	Defect depth (d)	Defect length (L)	Defect width (w)	
10.87	4.0	200	100	32.65
10.58	Not available	Not available	Not available	38.50
12.11	6.0	200	100	29.49
Average				33.50

$$P_{max} = \frac{2t\ F_t}{(D - t)} \tag{2}$$

Limit state function

The remaining strength limit state equations are taken from DNV RP-F101 and B31G. When a structure completes its design life, it might have changed in many ways such as with additions or alterations inside the structure, deterioration of its components i.e. change in geometrical dimensions as well as a decrease in the strength due to environment or passage of time. This makes the re-evaluation of strength compulsory if we want to extend its lifespan. Equations (3-4) are the limit state function used in this study for the determination of reliability. The B31G code provides limit state function as shown in Equation (3). P_a is the allowable pressure which is a variable in this study.

$$P = F\frac{(SMYS + 69\ MPa)\ 2t}{D}\left[\frac{1 - 0.85\ \frac{d}{t}}{1 - 0.85\ \frac{d}{t}\frac{1}{M_3}}\right] - P_a \tag{3}$$

Where, $Z = \frac{L^2}{D\,t}$

If $Z \leq 50$, $M_3 = \sqrt{1 + 0.6275\,Z - 0.003375\,Z^2}$

If $Z > 50$, $M_3 = 3.3 + 0.032\,Z$

For DNV code the limit state function is shown by Equation (4), which shows the capacity of the pipe pressure.

$$P_{cap} = 1.05\frac{2t\sigma_t}{(D-t)}\frac{(1-(d/t))}{(1-\frac{(d/t)}{Q})} - P_a \quad (4)$$

Where

$$Q = \sqrt{1 + 0.31\left(\frac{L}{\sqrt{Dt}}\right)^2}$$

Model uncertainties of basic random variables:

Uncertainties in capacity or member strength occur due to material or geometric variability named generally as epistemic uncertainty i.e. uncertainty based on imperfection of information about the variable. Material uncertainties are used to measure statistical spread, evaluated by using the data from fabrication yard and mill test reports. Structural reliability depends on probabilistic nature of material and load uncertainties. Once this data is determined we need to update the structural reliability. For uncertainty analysis, nominal bias values were taken from Zimmerman and Cosham et al. (1998), as shown in Table 3. These nominal bias values were then used to get the actual mean and standard deviation based on the data shown in Table 1.

Table 3: Uncertainty variables.

Random variable	Type of distribution	Bias mean	Bias COV%
Diameter	Normal	1.0	0.06
Wall thickness	Normal	1.01	1.0
Yield strength	Normal	1.1	1.0
Tensile strength	Normal	1.1	1.0
Damaged depth	Normal	1.0	60.0
Damaged length	Normal	1.0	50.0
Model uncertainty (DNV)	Normal	1.05	9.5
Pressure	Normal	1.07	3.0

Pipeline reliability: FORM and MC

Analytical and simulation methods of reliability analysis are used to determine the reliability index. Analytical methods include moment based methods such as First Order Reliability Method (FORM) and Second Order Reliability Methods (SORM). The FORM method is based on the first-order Taylor series approximation of a limit state function. The limit state function must be defined to formulate the FORM and estimate the reliability. The curvature of the limit state around the minimum distance point determines the accuracy of the first-order approximation in the FORM (Lee, Kim et al. 2005). A major simulation method is the Monte Carlo simulation. It is easy to use, robust, and accurate by using a large number of samples, though it requires considerable analysis to achieve a good quality approximation of low probability of failure. The problem with this simulation technique is that it produces noisy approximation of probability. Monte Carlos simulation method involves sampling and estimation to determine structure reliability. Reliability based structures are designed so that their reliability is always higher than the target reliability specified by the codes of design. The main methods for evaluating the remaining strength are based on codes DNV-RP-F101, B31G by ASME based on NG 18 Equation, RSTRENG by Shell. The safety margin between load and resistance is indicated by the limit state function (g) in Equations (5),

$$g = R_i - Q_i \leq 0 \tag{5}$$

Probability of failure is given by Equation (6),

$$P_f = P(g < Q) \tag{6}$$

The reliability index can be found by Equation (7),

$$\beta = \Phi^{-1}(P_f) \tag{7}$$

The probability of failure can be evaluated by Monte Carlo simulation as shown in Equation (8),

$$P_f = \frac{N_f}{N} \tag{8}$$

Target reliability

The reliability based structures are designed so that their reliability is always higher than the target reliability i.e. minimum specified by the well-established standards. Target reliability is required for calibration in order to make sure that certain safety levels are maintained. There is an agreement among researchers that if annual probability of failure due to some cause is less than 1 in 10,000, then it is small in relation to major risks (Efthymiou and Graham 1990). DNV reports acceptable annual target reliability for redundant Jackets as 3.09 or probability of failure of 10^{-4} (Pradnyana, Surahman et al. 2000). In this paper, target reliability of 3.0 is used.

Failure / reliability assessment frame work or life extension scenarios

In this study, two types of analysis are used to find the updated reliability or probability of failure. The first is by using FORM analysis and the second by using Monte Carlo simulation.

i) Updating of Probability of Failure using FORM analysis

For FORM, the updated reliability of the strength of the pipe based on the Burst test was included in the limit state equation for the respective code. The new reliability is calculated and shows its reserve strength. In this study, MATLAB code is formed to solve the limit state equations from each code separately. FERUM open source compiler is used to perform the FORM analysis. The results are shown in Figures (1-8).

ii) Bayesian Updating of Probability of Failure using Monte Carlo Simulation

Epistemic uncertainty is due to shortage of confidence for evaluated probability. This type of uncertainty can systematically updated when more information and data for that random variables becomes available. This method is used to get the updated probability of failure using Monte Carlo simulation (Ang and Tang 2007). The probability of failure is determined using Eq. (8). Probability of survival can be evaluated using number of survival to total number of simulations. The reassessment of the pipeline and its survival probability of (P_s) is incorporated in the reliability analysis, as shown in Equation (9),

$$P_s = \frac{\text{Number of Survival}}{\text{Total Number of Simulations}} \tag{9}$$

Equation (9) provides us the probability of survival depending upon the limit state equation and its variables. When P_f is evaluated given that Ps is also known, then we can find the updated probability of failure (P_{uf}). Failure probability has already been found using Equation (8). The new updated probability of failure is shown by Equation (10),

$$P_{uf} = P(g < 0 | S > 0) \tag{10}$$

Equation (10) provides information of probability of occurrence of an event. Thus when given limit state equation is having failure what is the survival chance at that particular probability level.

$P(g < 0)$ = Probability of failure of limit state function,

$P(S > 0) =$ Probability of survival of limit state function

Now using Equations (9-10) updated probability of failure (P_{uf}) can be determined as shown by Equations (11-12). Equation (11) provides us a tool to calculate the probability of survival in the presence of probability of failures.

$$P_{uf} = \frac{P[g(x)<0 \cap S>0]}{P[S>0]} \tag{11}$$

$$P_{Uf} = P(g|S)P(S) \tag{12}$$

In this study, MATLAB code is formed to solve the limit state equations from each code separately. The results are shown in Figures (9-16).

Burst Test

From the Burst test, the reserve strength of the pipe was determined to be 33.5 MPa. This deterministic value is incorporated in the limit state equations. Thus, an updated reliability can be evaluated based on information provided by the Burst test.

RESULTS AND DISCUSSIONS

The overall results for FORM and Monte Carlo simulation for codes DNV and B31G respectively are discussed below.

FORM analysis

This paper uses FERUM as an open source MATLAB code to generate FORM analysis. Figure 1 shows when the DNV code is used and defect length is fixed up to 200 mm and FORM analysis is made. Figure 1 shows that at defect depth of 4 mm, the reliability index reaches 2.8 for MAOP of 9.3 and 3.2 for MAOP of 4.0 and 2.8. Thus, we can say that the limit for safe running of the pipeline is reached when the defect depth is 4 mm. If the Burst test results are incorporated in resistance of the limit state equation with fixed defect length of 200 mm and using DNV code, Figure 2 shows that it is 4.2 mm where the target reliability is reached and the pipe becomes unsafe. However, in this case, all MAOP values have the same reliability due to the significant increase in resistance.

Figure 3 shows the reliability index values for the DNV code using a constant damaged depth of 4 mm with different Maximum allowable operating pressure (MAOP) values. The reliability decreases up to damage length of 500 mm and remains almost constant for respective MAOP. The reliability indices are 3.0 for MAOP of 4.0 and 2.8, but against a load of MAOP of 9.3, the reliability index decreases to 2.5 which is lower than the target reliability. The pipeline cannot withstand that pressure. Using the DNV code and fixed damaged depth of 4 mm, and if the results from the Burst test is included in the resistance for the limit state equation, then the reliability indices increases significantly. In Figure 4, all the reliability indices show significant increase and the minimum value is 3.47, which is higher than the target reliability.

If the FORM analysis is made with B31G and fixed defect length of 200 mm, then Figure 5 shows that with a design load of MAOP of 9.3, a reliability index of 3.0 is achieved with defect depth of 4.0 mm, and for MAOP of 4.0 and 2.8, the defect depth could reach 5.0 mm. If the Burst test results are also incorporated in the resistance of limit state equation and using B31G with defect length fixed at 200 mm, the FORM results are shown in Figure 6, which shows that all three loads are on the same line and minimum target reliability is reached at defect depth 5 mm. Figures 7 and 8 shows reliability indices for B31G using FORM analysis with fixed defect depth of 4 mm. The Figures show little influence of length on reliability but with load of MAOP of 9.3, target reliability becomes less than 3.0 below defect length of 500 mm. If the resistance also incorporates Burst test results, then reliability indices remain higher than 4.0 even for a load of 9.3 MPa.

Monte Carlo Simulation:

When the Monte Carlo simulation is used to determine the reliability index using DNV code and with fixed defect length of 200 mm, Figure 9 shows that target reliability decreases below defect depth of 4 mm but for other loads, it reaches defect depth of 4.4mm. Figure 10, which uses Bayesian updating, shows that target reliability, is still safe for defect depth of 5 mm. All loads have no difference for reliability index.
Figure 11 shows the reliability index for DNV using Monte Carlo simulation for fixed depth of 4 mm. The load of 9.3 MPa has reliability of 3.0 and less throughout the length, thus it is not safe. Figure 12 shows that with Bayesian updating, the reliability index for all loads is above the target reliability. The variability is due to nuisance in Monte Carlo simulation. Figure 13 shows reliability index for B31G using Monte Carlo simulation for fixed defect length of 200 mm. The reliability index is higher than the target for MAOP of 4 and 2.8 for defect depth of 4.0 but for load 9.3 MPa, it is very near but it reduces for all cases beyond 4 mm. Figure 14 shows the updated reliability using Bayesian updating and that reliability is higher than the target with defect depth of 5 mm for all loads. Figure 15 shows the reliability index for B31G using Monte Carlo simulation for constant defect depth of 4 mm. The Figure shows that a load of 9.3 MPa has reliability higher than the target at defect length of 300 mm but it decreases below that after 300 mm. All other loads are safe for all defect depths. Using Bayesian updating, all loads' reliability index is well above the target reliability.

Sensitivity analysis

Table 4 shows sensitivity analysis results from FORM analysis for B31G and DNV. The Table shows that damaged depth is more sensitive than other variables. It has the same sensitivity in both codes. As compared to B31G, Model uncertainty, wall thickness, and damaged length are also sensitive in DNV.

Table 4: FORM Sensitivity analysis of the Random values.

Random variable	Sensitivity analysis index DNV	Sensitivity analysis index B31G
Wall thickness	0.13	0.2
Diameter	1.9e-4	1.5e-5
Yield strength	-	7.8e-4
Damaged depth	0.99	0.99
Damaged length	0.06	3.1e-4
Pressure	0.008	4.7e-4
Tensile strength	0.008	-
Model uncertainty	0.02	-

CONCLUSIONS

This research used data from an actively corroded pipeline to determine pipeline reliability. The results showed that with pressure of 9.3 MPa and the defect size of 5 mm, it is not possible to extend the life of a pipe if target reliably is set as 3.0. By using Burst test results and Bayesian updating techniques, the reliability index increases compared to reliability index based on design values. Thus, if we include probability of survival and reserve strength, then the pipeline can withstand pressure as high as 9.3 MPa. The DNV code showed more reserve strength compared to B31G. This may be due to the inclusion of model uncertainty in the limit state equation of DNV whereas not model uncertainty is included in B31G. The sensitivity analysis shows that defect depth is a significant factor for the reliability analysis for DNV and B31G codes. Besides that, DNV shows that original wall thickness is sensitive to the reliability index. This method provides good judgement on assessing the pipeline for its life extension. This method could be applied to major structures such as nuclear power plants, dams, and bridges.

Framework to Explore the Design Space for Design of Tall Buildings

Yogesh Unde[1] and Subramaniam Rajan[2]
[1]Graduate Student, [2]Professor
School of Sustainable Engineering & the Built Environment, Arizona State University, Tempe, AZ 85287

ABSTRACT

Design of tall buildings is undergoing a resurgence that is driven by a variety of factors – economical growth, scarcity of land in urban areas, high land costs, increased population density, technological advancements and man's desire to build taller structures. Considerable research work has been done in the last two decades to meet this demand. Computer-based tools that help design engineers explore design alternatives are indispensable in tackling this complex problem. In addition, a framework that finds the near optimal design, adds value to this exploratory work. In this paper, we develop a general framework for the design optimization of buildings using sizing, shape, and topology design variables. Sizing optimization can be carried out using discrete design variables (from a database of available sections) or continuous design variables (cross-sectional dimensions of custom wide flange sections). Similarly, shape optimization can be carried out using either discrete or continuous design variables. And finally, topology optimization can be carried out using boolean design variables. Allowable stress design guidelines are used as constraints along with displacement, inter-story drift, total structural weight, and frequency constraints. The finite element model is made of three-dimensional beam elements. A typical function evaluation involves a linear, static analysis with multiple load cases, a linear, modal analysis to extract the lowest few eigenpairs, and a linear, buckling analysis to find the buckling capacity. An optimization toolbox that contains gradient-based and population-based optimizers, is a part of the framework. Numerical results how that the framework is capable of producing efficient designs effectively.

INTRODUCTION

The demand for tall buildings continues to grow fueled by economic growth, scarcity of land in urban areas, high land cost, technological advances in materials, construction techniques and design principles, growing population in megacities, and above all, the ego to build the tallest building. From 2000 to 2013, the total number of 200-meter-plus buildings completions in existence increased from 261 to 830 – an astounding 318 percent (Safarik and Wood, 2014). The challenges in building higher and taller at a more economical level with due considerations to usability, safety and sustainability have kept alive the research interests in tall buildings design. Ali and Moon (2007) discuss the evolution of tall building's systems and the technological driving force behind tall building developments. They categorize interior structures as rigid frames, braced hinged frames, shear wall/hinged frames, shear wall-frame interaction system and outrigger structures, and exterior structures – tube, diagrid, space truss structures, spaceframes and exo-skeleton. Fawzia and Fatima (2010) discuss the use of belt truss and outrigger systems in controlling deflections. A three-dimensional finite element model of a 60-storey composite building is used to investigate the performance (deflection control) of the building subjected to wind loads. One, two and three outrigger levels are used to show that significant reduction in lateral deflections and inter-story drifts can be obtained in comparison to a model without any outrigger system. A method for determination of preliminary member sizes in the context of diagrid systems is presented in Moon et al. (2007). The developed methodology is used to size the diagrid members in building ranging from 20 to 60 stories. With an aspect ratio of 7, for 60-story diagrid structures, the optimal range of diagrid angle is from about 65^0 to 75^0. With an aspect ratio of 5, for 42-story buildings, the range is lower by 10^0 indicating that the angle is a function of the building dimensions. At the preliminary as well as the detailed design stages, the use of a designer guided system is indispensable. Design optimization tools provide such a system helping take over the mundane task of finding the best possible design once the problem formulation is set and the basic finite element and design models are established. Several researchers have addressed design optimization of building systems – cost-revenue conceptual design of high-rise buildings (Grierson and Khajehpour, 2002), multiple design criteria (Ng and Lam, 2005), evolutionary methods (Manickarajah et al., 2000; Kameshki and Saka, 2001; Kicinger et al., 2005), optimality criteria (Chan and Chui, 2005), optimum design of steel structures with openings using sizing, shape and topology design variables (Lagaros et al., 2006), numerical design optimization tools (Baker et al., 2008), preliminary

design optimization (Jayachandran, 2009), and topology optimization (Liang et al., 2000; Stromberg et al., 2012). Through the use of principal stress trajectories, evolutionary structural optimization and gradient-based and population-based techniques, conceptual development of innovative structural and architectural topologies can take place [Baker et al., 2008]. Principal stress trajectories are described in terms of partial differential equations and then solved to yield diagrid systems. In another approach, gradient-based method is used to find the optimal shape of a tall building by minimizing the displacement at the top of the building when subjected to constant wind pressure. The structural elements are assumed to be located only on the exterior face of the tower when height, enclosed volume and base are constrained. For verification, a similar problem is also solved using genetic algorithm where the best solution is similar to that obtained by the gradient-based technique. Topology optimization provides another means of finding a better design. Liang et al. (2000) developed a methodology for finding the optimal layout of members in a bracing system subjected to multiple lateral loading conditions. The objective function is the weight and the performance constraint places an upper limit on the mean compliance of the structure. The unbraced (skeletal) structure is modeled with beam elements and the continuum between the beams and columns are modeled with plane stress elements. The final continuum topology is used as a guide for placing the bracing elements. Similarly, Stromberg et al. (2012) address the task of finding an efficient planar lateral bracing system via topology optimization that is based on combining beam and continuum finite elements where, though unstated, the final topology is a reasonable guess for the exploration of a diagrid system.

The main objective of this paper is to develop a framework for the optimal design of tall buildings. The framework allows for investigating the design efficiencies of different building systems, e.g. rigid frames, belt truss and outrigger systems, diagrid systems etc. The design framework starts with a general design problem formulation that allows for finding the sizing variables (essentially cross-sectional dimensions and properties), shape variables (location of structural members and joints), and topology variables (presence, absence and location of members). The performance and serviceability constraints include normal stress, shear stress, displacement, inter-story drifts, buckling, and natural frequencies. An optimization toolbox is tightly integrated with a function and gradient evaluation system that includes a finite element analysis system and computer code to compute the function and gradient values. The problem formulation and the evaluation of function and gradient values are discussed in the next section. This is followed by several design examples that show how the framework is used to investigate the design space.

OPTIMAL DESIGN PROBLEM FORMULATION

Design problems involving buildings can be posed several different ways. The formulations are motivated by the need to find optimal solutions at the preliminary design stage so that an exhaustive search of the design possibilities can take place accurately and efficiently. The objective is to design buildings with m stories having n structural steel members, assigned to p cross-section property groups $\left(p \le n \right)$. The skeletal framework is assumed to be made of steel.

Design Problem Formulation – Minimum Weight Design (MWD)
This is a minimum weight design problem and the problem is posed as follows.

Find $$\mathbf{x} = \left\{ \mathbf{x}_c, \mathbf{b} \right\} \tag{1}$$

Minimize $$W\left(\mathbf{x} \right) = \sum_{i=1}^{n} A_i L_i \gamma_i \tag{2a}$$

Subject to $$\sigma_{\max,i}^{t,c} \le \sigma_a^{t,c} \quad (i = 1, 2, ...n) \tag{3}$$

$$\tau_{\max,i} \le \tau_a \quad (i = 1, 2, ...n) \tag{4}$$

$$\left(D_i \right)_{\max}^{T} \le D_a \tag{5}$$

$$\frac{D_j - D_{j-1}}{h_j} \le \left(D_{ij} \right)_a \quad (j = 1, 2, ..., m) \tag{6}$$

$$\frac{\pi^2 EI}{(kL)^2} \le (P_{cr})_a \tag{7}$$

$$\lambda^B \ge \lambda_a^B \tag{8}$$

$$\mathbf{x}_c^L \le \mathbf{x}_c \le \mathbf{x}_c^U \qquad (c = 1,2,..,p) \tag{9a}$$

$$b_l \in \{0,1\} \qquad (l = 1,2,...,r) \tag{9b}$$

where *W* is the total weight of all the structural elements, γ_i is the weight density of material, L_i is the length and A_i is the cross-sectional area of member *i*. Eqns. (3-4) are used to impose stress constraints where $\sigma^t_{\max,i}$, $\sigma^c_{\max,i}$, $\tau_{\max,i}$ are the maximum tensile, compressive and shear stress, and the subscript *a* denotes the allowable value. Eqn. (5) defines the constraints imposed on the maximum lateral drift $(D_i)^T_{\max}$ in longitudinal and transverse directions of the building. Eqn. (6) defines the inter-story drift constraints for the structure where D_j and D_{j-1} are the drifts of j^{th} and $(j-1)^{th}$ story respectively and h_j is the height of j^{th} story. Buckling constraints are imposed via Eqn. (7) in the form of Euler buckling and via Eqn. (8) in the form of overall buckling of the structure where $(P_{cr})_a$ is the allowable buckling capacity of the member and λ^B is the lowest eigenvalue from the buckling eigenvalue problem and λ_a^B is the allowable value. Eqn. (9a) is used to denote either discrete design variables (selected from a predetermined table of cross-sectional shapes) or continuous design variables as explained later. Eqn. (9b) denotes boolean design variables that are used to select or deselect bracing members $(r < n)$.

Finite Element Analysis

Finite element analysis is used during function evaluation necessary to compute the objective function and constraints. Three sets of linear algebraic and eigenproblems are solved as follows.

$$\mathbf{K}_{d\times d}\mathbf{D}_{d\times lc} = \mathbf{F}_{d\times lc} \tag{10}$$

$$\mathbf{K}_{d\times d}\mathbf{\Phi}_{d\times d} = \mathbf{\Lambda}_{d\times d}\mathbf{M}_{d\times d}\mathbf{\Phi}_{d\times d} \tag{11}$$

$$\mathbf{K}_{d\times d}\,\phi_{d\times 1} = \lambda^B \mathbf{K}^{\sigma}_{d\times d}\phi_{d\times 1} \tag{12}$$

where $\mathbf{K}_{d\times d}$, $\mathbf{M}_{d\times d}$ and $\mathbf{K}^{\sigma}_{d\times d}$ are the structure stiffness matrix, mass matrix and geometric stiffness matrix respectively. In addition, *d* is the total number of degrees-of-freedom in the finite element model, *lc* is the number of load cases, λ^B is the buckling load factor for the lowest mode. Eqn. (11) is typically solved in a smaller space as $\hat{\mathbf{K}}_{q\times q}\mathbf{\Phi}_{q\times q} = \mathbf{\Lambda}_{q\times q}\hat{\mathbf{M}}_{q\times q}\mathbf{\Phi}_{q\times q}$ since only the lowest few *q* eigenpairs are of interest $(q \ll d)$. Further explanations involving the problem formulation are presented next.

Performance Constraints

Performance-based design includes strength and serviceability requirements as discussed below.

Stress Constraints: Allowable Stress Design (ASD) requirements are imposed where the requirement is that the allowable strength of each structural component equals or exceeds the required strength. As per AISC Specification (2005), the allowable tensile/compressive stress for gross steel cross section is $0.6f_y$ and the allowable shear stress for gross steel cross section is $0.4f_y$ where f_y is the yield strength of the steel material. In the finite element analysis, the magnitude of the maximum beam element stresses are computed conservatively as follows (x-y-z denote the longitudinal axis and the two transverse directions, respectively) at the two ends and at the quarter-points of each beam finite element.

Normal stress:

$$\sigma^t_{\max} = \max\left(\frac{N_x}{A} + \frac{|M_y|}{S_y} + \frac{|M_z|}{S_z}, 0\right) \tag{13}$$

$$\sigma^c_{\max} = \min\left(\frac{N_x}{A} - \frac{|M_y|}{S_y} - \frac{|M_z|}{S_z}, 0\right) \tag{14}$$

Shear stress:

$$\tau^y = \frac{|V_y|Q_y}{I_y t_y} \qquad \tau^z = \frac{|V_z|Q_z}{I_z t_y} \qquad \tau^T = \frac{|T_x|}{T_J} \tag{15}$$

$$\tau_{\max} = \max\left\{\tau^y + \tau^T, \tau^z + \tau^T\right\} \tag{16}$$

where $\left\{A, S_y, S_z, Q_y, Q_z, t_y, t_z, I_y, I_z, T_J\right\}$ are the cross-sectional properties and dimensions, i.e. area, section moduli, first moments of the area, widths resisting shear, moments of inertia and torsional constant, respectively, $\{N_x, V_y, V_z\}$ are the normal and shear forces in the element's local x, y, z directions, and $\left\{T_x, M_y, M_z\right\}$ are the torsional and bending moments in the element's local x, y, z directions.

Displacement Constraints: Two types of displacement constraints are imposed – Eqns. (5) and (6). First, the displacements in the two transverse directions are limited to 1/600 to 1/400 of the total building height [ASCE, 1998]. Second, the inter-story drift is another serviceability criterion for design requirements is taken to be less than 1/500 of the story height [Ng and Lam, 2005].

Buckling Constraints: In addition of the strength requirements imposed via stress constraints, in performance based designs, structural instability must be prevented. Member buckling is controlled via the imposition of Euler buckling constraint (Eqn. (7)). Buckling behavior of the structure is determined by solving the eigenproblem shown in Eqn. (12) where λ^B is the buckling load factor that needs to be much greater than 1 to prevent buckling under the action of the applied loads, i.e. all load cases. Other instabilities such as buckling of flanges, torsional buckling etc. are not considered.

Design Variables

Selection of the design variables help define the problem as sizing, shape and/or topology design optimization problem [Rajan, 1995].

Sizing Variables: To meet the high strength requirements of the beams, braces and columns, we assume that custom sections are needed. Using continuous design variables, each element cross section is taken as a custom wide flange section and the web height of the section is used as the primary design variable. A group of heavy 130 wide flange sections from the AISC database was examined for generating relationships among the four dimensions of a typical wide flange section - web height, h_w, flange width, w_f, web thickness, t_w, and flange thickness, t_f. A sample relationship is shown in Fig. 1.

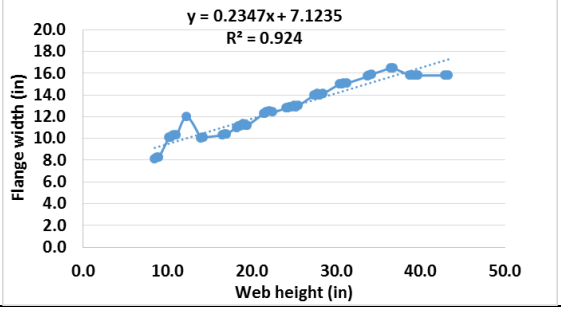

Figure 1. Flange width versus web height relationship

The linear relationships obtained from this exercise are as follows (the R^2 values for the three fits are 0.924, 0.956, 0.553) [Sirigiri et al., 2015]

$$w_f = 0.235h_w + 7.12 \tag{17}$$

$$t_f = 0.492t_w + 0.106 \tag{18}$$

$$t_f = 0.0406w_f + 0.118 \tag{19}$$

where the implied units are inches. The low R^2 value for the flange thickness and flange width relationship is due to the wide range of available flange thicknesses (0.4"-0.8") for a given flange width (8.0"-17.0"). It should be noted that other commonly used cross-sectional shapes can be

easily incorporated in the problem formulation, and that the wide-flange sections are used in this study to readily illustrate the design concepts.

Topology Variables: Diagonal bracing members are often used to brace steel frameworks to maintain lateral drifts within acceptable limits. The optimal layout design of bracing systems is a challenging task for structural designers because it involves a large number of possibilities for the arrangement of the members. In the absence of an efficient optimization technique, the selection of lateral bracing systems for multi-story steel frameworks is undertaken by a designer based on a trial-and-error process or previous design experiences. In topology optimization of a structure, boolean design variables are assigned to structural elements. The value of ***1*** for the variable implies that the element exists in the structure and ***0*** implies that element is removed from the structure [Rajan, 1995].

Finite Element Analysis

The FE analysis necessary to compute the function and gradient values in the problem formulations are carried out using the GS-USA© Frame3D program [Sirigiri and Rajan, 2013]. A small strain, small displacement, linear elastic finite element analysis is carried out by the computer program. The responses from the FE analysis that can be used in the problem formulations include nodal displacements, beam element nodal forces, beam element maximum tensile, compressive and shear stresses, thin plate/shell stresses and structural lowest frequencies. The frequency analysis is carried out using the stiffness and mass of the structural elements plus the mass of the nonstructural elements and a fraction (25%) of the live loads.

Numerical Optimization Techniques

The design optimization toolbox used for optimal design has several optimization techniques that can be invoked depending on the problem type.

Gradient-based Techniques: Gradient-based techniques are particularly useful when designing with continuous design variables and continuous and differentiable objective and constraint values. In particular, the Method of Feasible Directions (MFD) [Rajan et al., 2006] is used in this study. Typical problems with about 25-50 design variables can be solved in about 10-15 iterations involving less than a hundred function evaluations and about 10-15 gradient evaluations. The active set strategy is used in order to make the storage space and computations efficient.

Population-Based Global Optimization Techniques: When the design variables are not continuous (e.g. discrete, boolean), or the objective and constraint functions are not differentiable, or if there is a need to find several distinct local optima and possibly, the global optimum, population-based techniques are desirable. In particular, the Genetic Algorithm is used in this study [Rajan, 1995; Rajan and Nguyen, 2004]. Typical problems involving 25-50 design variables require several hundred function evaluations to yield high quality solutions.

In the next section, details of a case study are presented showing how the developed design optimization methodology is used for the design of tall buildings.

NUMERICAL RESULTS

The numerical results are obtained by executing the developed program, GS-USA© Frame3D, on a Dell Precision Workstation T5400 with Intel Xeon E5440-2.83 GHz processor, 8 GB RAM running Windows 7-64 bit operating system.

Design Optimization with Planar Frame Models

The developed design methodology is tested using a 40-story building that has a *fs* ft by *s* ft rectangular floor layout (Fig. 2) where *s* is the spacing between the frames and *f* is the number of frames in the (strong) y-direction. The height of the first floor containing the lobby is 16 ft. All the other floor heights are 13 ft. The total height of the building is 523 ft. The floor system consists of a composite metal deck slab (3" cellular steel deck with 2.5" concrete slab), supported on the steel joists. All the degree-of-freedom at the bottom of the columns are restrained. All the models with bracing elements considered in this study are assumed to be symmetrical.

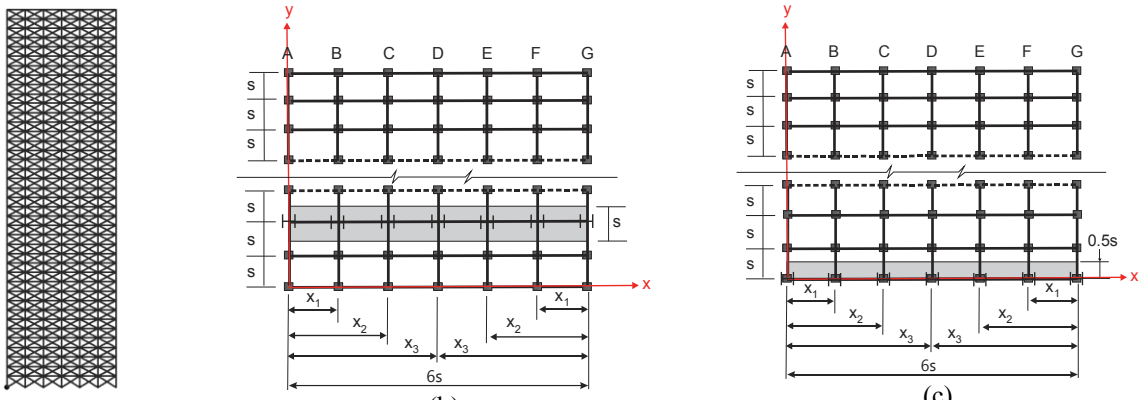

Figure 2. (a) Initial 40-floor planar frame layout (b) Typical floor plan (x-y plane; z: gravity direction) showing interior frame (c) End frame

In the rest of this section, the frame shown in Fig. 2(a) and corresponding to the interior frame with the shaded area in Fig. 2(b), is used during design optimization. Three different frames are considered with $s = 20', 25', 30'$ and are labeled 120-WF, 150-WF and 180-WF frames. There are 287 nodes, 1000 beam finite elements and 840 effective degrees-of-freedom in the initial planar finite element model.

Material Properties and Loads

The steel columns, beams and bracings of the building are assumed to be of grade A992/A992M. The floor slabs and elevator shaft walls are assumed to be of high strength reinforced concrete. Table 1 summarizes the material properties.

Table 1. Material Properties

Material	Structural elements	Mass Density	Elastic Modulus
Steel, Grade 992/A992M	Columns, beams, and bracings	$15.24\, slug/ft^3$	$29000\, ksi$
Concrete	Slab, curtain walls & elevator shaft walls	$0.39\, slug/ft^3$	$4600\, ksi$

The dead loads are due to the steel deck and floor finishes. Assuming that the building is for office use, the live load on the floors and roof are as per the specification in Table 4-1, ASCE-7-10 [ASCE, 2010]. Wind pressure loads are computed as per Chicago City Code Table 16 (13-52-310). Tributary area concept is used to compute the loading on the planar frame. Table 2 summarizes the key loading values.

Table 2. Load Values

Location	Item	Load
Floors	Dead load	144 psf
Floors	Live load	100 psf
Columns (ground level-top floor)	Wind load	20-31 psf

Allowable Stress Design (ASD) Load Combinations

In ASD, the combinations of service loads are evaluated for maximum stresses and compared to allowable stresses. ASCE-7-2010 combinations of loads are shown below.

1. LC 1: Dead load
2. LC 2: Dead load + Live load
3. LC 3: Dead load + 0.6 Wind Load
4. LC 4: Dead load + 0.75 Live Load + 0.75(0.6 Wind Load)

Design Variables

The floors were grouped together into 20 groups, 2 floors per group. The cross section properties of columns, beams and bracing members are varied along the height so that the properties are the same in any group. In this study, the two end columns and the interior columns are not treated differently and are assumed to have the same properties in a particular floor group. The web height of the wide flange section assigned for each of these groups is defined as a continuous sizing design variable with an upper limit as a function of the story height. Twenty belt trusses were created

along the height of the planar frame by grouping the bracings of two floors together. A boolean value of ***1*** for L_1 indicates that the bracing exists along the entire floor of the building. The locations of the interior columns (along B and C) are allowed to vary. Equality constraints are used to impose symmetry so that columns B and E, and C and F are symmetrically placed about D. Thus, there are 62 continuous design variables and 20 boolean design variables in each design model as shown in Table 3.

Table 3. Description of Design Variables in Planar Frame Models

Variables	Variable type	Number	Description
C_1 to C_{10}	Continuous (Sizing)	20	Web height of column cross-section for the 20 groups of floors
LB_1 to LB_{10}	Continuous (Sizing)	20	Web height of longitudinal beam cross-section for the 20 groups of floors
BT_1 to BT_{10}	Continuous (Sizing)	20	Web height for belt truss bracing member cross-section for the 20 groups of floors
L_1 to L_{10}	Boolean (Topology)	20	Bracing pattern for belt trusses for the 20 groups of floors
x_1 and x_2	Continuous (Shape)	2	Location of the two interior columns. The end columns and the center column remain fixed.

For problem involving only continuous design variables, MFD was used for a maximum of 50 iterations with a relative and absolute convergence tolerance of 10^{-4}. Otherwise, GA was used with a population size of 500 for 50 generations.

Design Optimization Solutions

Initially, models were created with no bracing elements. These models were executed to find a baseline optimal design for comparative purposes. However, no feasible solution could be found for two of the three models - the 150' wide and the 180' wide frames. The addition of bracing elements via belt trusses produced acceptable designs in those two cases. It should be noted that the weight of each member was calculated center-to-center without accounting for connections. The values of some of the key structural parameters are shown in Table 4 (ton denotes 2000 pounds).

Table 4. Key Structural Parameters

	120-2D	**120-2D-BT**	**150-2D-BT**	**180-2D-BT**
Total weight of all beams, columns and bracing members, *ton*	865	860	1405	1935
Initial location of the interior columns (x_1, x_2, x_3) (see Fig. 2), *in*	(240, 480, 720)	(240, 480, 720)	(300, 600, 900)	(360, 720, 1080)
Final location of the interior columns (x_1, x_2, x_3) (see Fig. 2), *in*	(205, 449, 720)	(204, 448, 720)	(287, 587, 900)	(344, 700, 1080)
Lowest frequencies, *Hz*	(0.18, 0.45, 0.80)	(0.18, 0.45, 0.80)	(0.15, 0.64, 0.96)	(0.17, 0.72, 1.03)
Smallest Buckling Load Factor, λ^B	15.7	16.2	17.9	17.8

The optimal designs are summarized in Tables 5-6. Table 5 shows the weight distribution of the structural elements. The summary of the structural response is shown in Table 6. The normalized weight (weight per designed unit area) is computed by assuming a square building with 49 frames as

$$W_N = \frac{7W + 42W_B + 3W_X}{\text{Total covered area}} = \frac{7W + 42W_B + 3W_X}{40\left(36s^2\right)} \tag{20}$$

where W is the total weight on one frame (see Table 4), W_B is the weight of all the remaining beams and W_X is the weight of all the remaining bracing elements. The final shape and topologies of the optimal designs are shown in Fig. 3 along with the plots of the highest compressive stress (blue denotes highest value and red the lowest value) for LC 4, the governing load case.

Discussion: As expected, increasing the span from s=20' to s=30' makes it much more challenging and difficult to obtain a feasible design. A simple moment-connected frame appears to be the optimal design when the span is relatively small (s=20') – both 120-2D model (solved via MFD) and 120-2D-BT model (solved via GA) lead to very

similar final designs. However, when the span is increased, it becomes necessary to combine a rigidly-connected frame with belt trusses. Even with the use of these structural elements, the columns dictate the design requiring a relaxed upper bound on the web height. Interestingly enough, the columns with the highest stresses are the interior columns at the base of the belt trusses (Fig. 3(c)-(d)). However, a large number of members have their max. compressive (columns and beams) and tensile stress (beams) close to the limit of 30,000 psi for both LC 2 and LC 4 indicating that the design is near optimal and efficient. Displacement, shear stress, buckling (Euler and buckling load factor) and the lowest frequencies of the structure are not close to controlling the design. The lowest three frequencies are well spaced. The largest displacement value occurs on the top floor of the structure and is about 4% of the typical floor height. In every model, the interior columns move outward thereby reducing the outermost spans and increasing the interior spans. From an office space usage viewpoint, this may be desirable since larger uninterrupted spans are available for use as conference or meeting rooms. The normalized weight shows a wide range between 51.5-76.4 psf. It is possible that the 150-2D-BT and 180-2D-BT models can be improved (are not the global optimum solutions) and that with a better solution, a lower normalized weight can be found. We will discuss the difficulty of finding solutions in the Boolean-continuous design variable space later in the paper. The wall clock time (WCT) for one function evaluation is about 0.11 s so that the total WCT for a GA-runs (the belt truss models) is about 2800 s and about 250 s for the MFD-solved model (120-2D).

Design Using Braced Tube - Diagrids

The building design problem from Section 3.1 is used in the context of braced tube-diagrid building form. To facilitate the automatic selection of the two end nodes for the bracing elements, a list of potential nodes was used for each

element – these discrete design variables were added to the list of design variables (Eqn. (1)) as $\mathbf{x} = \{\mathbf{x}_c, \mathbf{b}, \mathbf{x}_d\}$. The new problem formulation has a total of 38 design variables. The C_1 to C_{10} design variables were applied to columns B, C, E, F. The LB_1 to LB_{10} design variables were applied to all beams not connected to the primary braced tube-diagrid system, and x_1 and x_2 design variables were used as before. Using information from a preliminary design study of this configuration, new design variables were introduced to handle the diagrid system - 4 continuous design variables were introduced for columns A, D and G, 4 continuous design variables for the longitudinal beams, 4 design variables for the bracing members, and 4 discrete design variables were introduced to take care of the end nodes of the bracing members. Possible bracing configurations are shown in Fig. 4 where the thick lines denote columns, beams and bracing members that are part of the diagrid system. Symmetry of the structure is enforced with the nodes of the bracing elements being placed on columns A, D and G as shown in Fig. 4. This approach is perhaps preferable to the use of continuum element-beam element model as those shown in previous research work [Liang et al., 2000; Stromberg et al., 2012] since the modeling and design approach fits in with the optimal design problem with no additional assumptions or limitations. The problem data are the same as those used in Section 3.1 The optimal design results are shown in Tables 7-9. The final shape and topology of the building is shown in Fig. 5.

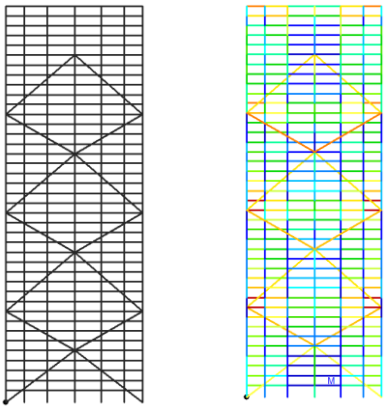
180-2D-D	0.92 (8)	29600 (99)	29700 (99)	9980 (50)

Discussion: Both the compressive/tensile stress and buckling load factor control the design. The reason why the latter controls the design is because of the extremely long bracing members. In practice one would attach the intermediate points in the bracing members to appropriate points in the intersecting columns and beams. Such connections are not generated in the model in the current research since this would involve finding the intersection of the beams and columns during the optimization run, thereby requiring new nodes and elements to be generated. Finally, it should be noted that the bracing members help reduce the lateral displacement from 3.8" to just 0.78".

CONCLUSIONS

A simultaneous sizing, shape and topology optimization methodology is developed and used for the optimal design of tall buildings modeled as planar frames. The developed framework allows for investigating the design efficiencies of different building systems using planar finite element models. Continuous, discrete and Boolean design variables are used in the context of sizing, shape and topology optimization. The computed results yield important building

parameters such as cross-sectional dimensions and properties, location of structural joints, and member layout via presence, absence and location of members. The performance and serviceability constraints include normal stress, shear stress, displacement, inter-story drifts, buckling, and natural frequencies.



(a) (b)

Figure 5. (a) Final design (b) Compressive stress plot (LC 4)

Results show that efficient planar models can be obtained that satisfy performance requirements in a reasonable amount of time. Finally, it should be noted that the results from a geometrically nonlinear analysis yielded almost the same results as that obtained from linear analysis justifying the use of linear analysis. While planar frames provide a wealth of knowledge, the understanding is limited by the limitations of the model. Buildings are three-dimensional and planar frames typically do not contain some of the important structural elements – floors, walls, specialized system such as tubes or cores etc. A tributary area approach in computing equivalent planar model loads is approximate. In addition, planar models do not account for behavior found only in three-dimensional systems such as member bending and shear about two axes, torsional moments, and torsional eigenmodes. A logical extension of the framework discussed in this paper is to build and use a three-dimensional finite element model for design optimization. One of the numerical optimization challenges is the difficulty in finding solutions in the Boolean-continuous design variable space encountered when sizing and shape continuous design variables are mixed with topology design variables that are either Boolean or discrete or both. The computational challenge is to reduce the overall compute time so as obtain solutions in a reasonable amount of time. One of the easily implementable strategies to improve the computational throughput is through parallel computations. In the gradient-based solutions, the computation of numerical derivatives and those during line search can be parallelized [Rajan et al., 2006]. The reduction in the objective function is typically much greater in the initial few iterations after which the reduction are relatively much smaller. Hence using a coarse convergence criteria can cut down on the computational cost without an unacceptable loss of accuracy. In population-based solutions, the parallelization is an embarrassingly parallel problem [Rajan and Nguyen, 2004]. The GA solutions required involving topology optimization required a larger probability of mutation. In this research, repeating chromosomes [Chen and Rajan, 2000] were not detected so as to avoid carrying out a previous function evaluation. Implementing this option would cut down the computational cost since later generations typically contain a large number of identical members.

ABSTRACT

The resilience of a community is defined as its ability to prepare for, withstand, recover from and adapt to the effects of natural or human-caused disasters, and depends on the performance of the built environment and on supporting social, economic and public institutions that are essential for immediate response and long-term recovery and adaptation. The performance of the built environment generally is governed by codes, standards, and regulations, which are applicable to individual facilities and residences, are based on different performance criteria, and do not account for the interdependence of buildings, transportation, utilities and other infrastructure sectors. The National Institute of Standards and Technology recently awarded a new Center of Excellence (NIST-CoE) for Risk-Based Community Resilience Planning, which is headquartered at Colorado State University and involves nine additional universities. Research in this Center is focusing on three major research thrusts: (1) developing the NIST-Community Resilience Modeling Environment known as NIST-CORE, thereby enabling alternative strategies to enhance community resilience to be measured quantitatively; (2) developing a standardized data ontology, robust data architecture and data management tools in support of NIST-CORE; and (3) performing a comprehensive set of hindcasts on disasters to validate the data architecture and NIST-CORE.

KEYWORDS

Community resilience, hazards, investment optimization, post-disaster recovery, resilience performance metrics, risk-informed decision.

INTRODUCTION AND MOTIVATION

Disaster resilience has been defined many ways, but one major commonality exists in virtually all definitions: the ability to rebound following a shock or major disruption. Presidential Policy Directive (PPD) 8: National Preparedness (2011) defines resilience as the ability to "adapt to changing conditions and withstand and rapidly recover from disruption due to emergencies." This definition was expanded in Presidential Policy Directive (PPD) 21 (2013) which defines resilience as the ability to "prepare for and adapt to changing conditions and withstand and recover rapidly from disruptions." The ability of a community to recover from a disaster is a function of many factors including pre-event planning, preparation, mitigation, infrastructure type, complexity, condition, individual and collective experiences prior to the disaster and the ability to mobilize resources afterward. Prior to the disaster, a community may contain a heterogeneous mix of populations and institutions of varying degrees of vulnerability. Following the occurrence of an extreme event, there is a rapid drop in community functional capacity, followed by a period of response and recovery, leading to a "new normal" state for the community. For example, the most vulnerable communities may have a diminished "new normal," in which the community functions at a level that is below where they were prior to the event because they were only able to build back based on pre-impact or diminished capabilities; an example of this is the City of New Orleans, Louisiana, USA shown flooded in Fig 1a following Hurricane Katrina in 2005, particularly in the lower

9th ward. Conversely, communities may achieve a "new normal," in which their community functions at a higher level following the event, in what has been termed a "build back better" scenario. An example of this is Greensburg, Kansas, USA following the 2007 EF5 (> 320 kph winds) tornado, in which 95 % of the city was destroyed as shown in Fig 1b.

Figure 1 (a) New Orleans, LA during flooding following hurricane Katrina in 2005 (Ed Levine, NOAA); (b) Greensburg, KS following the EF 5 tornado in 2007 which destroyed 95 % of the city (Greg Henshall, FEMA)

The performance of the built environment in the United States, which is a key factor in community resilience, is largely determined by codes and standards, which are applicable to individual facilities and residential structures, and have the primary objective of preserving life safety under severe events. Current codes do not address the period of recovery following an event. Moreover, design of interdependent transportation systems, utilities and communication systems currently is based on different performance criteria. As a consequence, there currently is no assurance that all systems required for community resilience will perform at a necessary or consistent level following an extreme event. Uncertainties in the demands placed on a community by extreme natural hazards and in the response of community infrastructure to withstand those demands are very large. Furthermore, science-based measurement tools to evaluate performance and resilience at the community scale, fully integrated supporting databases, and risk-informed decision frameworks to support optimal life-cycle technical and social policies aimed at enhancing community resilience do not exist. The NIST-CoE will focus on creating these science-based measurement tools over the next five years. These tools will allow researchers and planners to assess strategies quantitatively for optimizing resiliency subject to a community's technical, economic and social constraints. The risk-informed decision framework and unique set of science-based measurement tools will help communities to better assess, visualize and potentially achieve resilience goals while managing life-cycle costs, thus making it possible to establish, for the first time, a business case agreed upon by a communities multiple constituencies, for achieving community resilience.

OVERVIEW OF THE CENTER FOR RISK-BASED COMMUNITY RESILIENCE PLANNING

The NIST-CoE at Colorado State University, funded by the National Institute of Standards and Technology (NIST), will develop systems-level models and databases that will provide the technology for enhancing community resilience in a research and development program. In addition to faculty at CSU, the team members include noted experts in resilience from the California Polytechnic University Pomona, Oregon State University, Rice University, Texas A&M University, Texas A&M University-Kingsville, the University of Illinois at Urbana-Champaign, the University of Oklahoma, the University of South Alabama, and the University of Washington. The Center's research program is organized along three major thrust areas.

Thrust 1 will develop a multidisciplinary computational environment with integrated supporting databases, known as NIST-CORE (NIST-Community Resilience Modeling Environment), that will enable the factors (and their inter-relationships) that determine community resilience to be better understood. This environment is being implemented as a risk-informed decision framework that permits the effectiveness of alternative strategies for addressing resilience to be measured quantitatively. A distinctive feature of Thrust 1 is its emphasis on multiple hazards and inter-dependent physical systems, which may have significant cascading effects. This will include consistent handling of and propagation of uncertainties throughout the analysis. Furthermore, nontechnical systems that are essential for the recovery and vitality of a community – housing, businesses, healthcare, schools,

and civic organizations – are being integrated into NIST-CORE, creating a nexus between social and technological infrastructure networks intended to narrow the gap between engineering and social science aspects of resilience planning and to facilitate risk communication among stakeholders. Finally, optimization strategies for enhancing community resilience involving advanced intelligent decision algorithms are being integrated, and are based on performance metrics such as time to recovery, number of mortalities, number of morbidities, and other metrics to be identified.

Thrust 2 will produce a CoE standardized data ontology, a robust data architecture, and effective data management. This includes tools to support the computational environment developed in Thrust 1 and to permit databases from stakeholders representing multiple domains of engineering and social sciences to be integrated to the decision process. The data architecture and data management tools in NIST-CORE will be customized to help users incorporate, manage, query, visualize and share data.

Finally, Thrust 3 will validate the resilience data architecture through a series of testbeds that stress the process of data collection, its integration into the computational modeling environment, and decision algorithms. The NIST-CoE research thrusts seek to align with those of NIST, with synergies and opportunities for collaborative research, staff exchanges, development of partnerships with the private sector, and for participating in collaborative field studies that can be used to validate and improve the computational environment and its supporting databases.

THRUST 1 - COMPUTATIONAL MODELING ENVIRONMENT FOR COMMUNITY RESILIENCE: DEVELOPMENT OF NIST-CORE

The NIST-CORE architecture is depicted in Fig 2. When fully developed, NIST-CORE will have the capability of computing proposed resiliency assessment measures at the user-specified community level (described to the right in Fig 2) and utilizing the data architecture (summarized at the bottom of Fig 2), thereby producing performance metrics, performance requirements, and risk-informed decision tools for community resilience. This section addresses some of the immediate challenges that Center investigators are addressing.

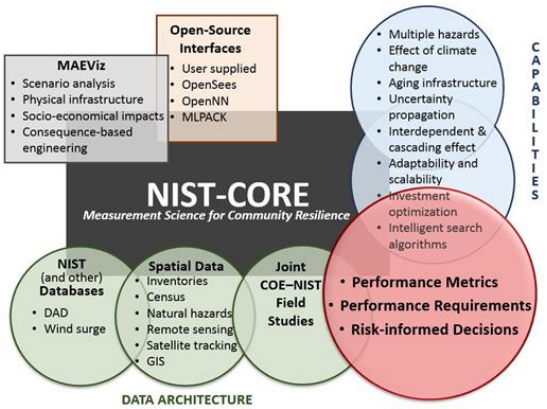

Figure 2 The architecture of the NIST Community Resilience (NIST-CORE) Modelling Environment

Hazards and Climate Change

The treatment of hazards, including earthquake, earthquake aftershock, coastal and riverine flooding, tornado including wind and debris, hurricane wind and debris, hurricane surge and wave, wildfires and their interface with urban areas, tsunami, and landslide, is a major part of the NIST-COE. The risk formulation for some individual hazards is reasonably mature; for other hazards, there is a need for improved characterization of intensity and damage potential for the computational resilience modeling environment. For example, wind speeds resulting from tornadoes are not well developed but have been recently updated by, for example, Standohar-Alfano and van de Lindt (2014) by combining earlier methodologies. Relative to seismic and wind hazards, the hazards due to surge, waves, and water-borne debris for hurricanes and severe coastal storms have been identified as a critical research gap (NIST 2014), not only for characterizing the probable inundation levels and wave conditions but also for identifying the joint distributions of wind and wave effects for multi-hazards scenarios. Moreover, recent research (Tamiczek et al 2014) following Hurricane Ike has shown that water depth

alone is often a poor predictor of damage to structures. Each of these cases requires special consideration with regard to the specific multi-hazard models for: a) multi-hazard characterization, b) modeling infrastructure fragilities when subjected to concurrent or time lag events; and c) restoration modeling.

In addition to consideration of hazards, the NIST-CoE will include methods to estimate the effect of climate change on hazards when applying them within NIST-CORE. During the past three decades, evidence has grown that global climate change may affect both the frequency and severity of extreme events resulting from natural hazards (e.g., IPCC 2013). The severity of extreme climatic events is characterized by changes in the climate variables such as wind speed, precipitation, temperature or flooding. However, practically all risk assessments for civil infrastructure to date have been based on the assumption that the hazard-imposed demands on the system can be modeled as stationary random processes. This assumption becomes untenable when the effects of global climate change are considered (Lee and Ellingwood 2013). Stochastic models of natural hazard demands from hurricanes, surge and coastal flooding that incorporate nonstationarity due to changes in sea surface temperatures and other manifestations of climate change are also being developed.

Modelling the Built Environment

Five key components of the built environment are being modeled, including buildings, transportation infrastructure, water and wastewater networks, energy systems, and telecommunication networks. Performance objectives for individual buildings are required to enable a building inventory to support community resilience goals (McAllister 2013). For example, the SPUR Program in San Francisco (Poland 2011) established a set of performance objectives for buildings (e.g., hospitals, school, emergency operation centers, residences, businesses) in different performance categories exposed to different earthquake intensities (i.e. routine, expected, and extreme) and with different functionality needs (i.e., immediate recovery within 72 hrs., short-term recovery within 60 days, and long-term reconstruction).

While the SPUR Program provides an example of building performance criteria linked to community resilience planning for one hazard (earthquake), more general metrics, criteria and guidelines for building performance that are based on measurement science are required for disaster planning for communities with different hazard exposures, social needs and resources. Resilience assessment of buildings, as implemented by structural engineers for extreme events, has focused on minimizing direct and indirect losses through enhanced system robustness as well as more effective recovery strategies (e.g., Bruneau, et al. 2003).

Transportation infrastructure is comprised of a number of multi-modal systems, such as bridge and roadway networks, heavy and light rail, airports and port and maritime systems. Common themes for characterizing transportation system resilience include the need to assess component reliability under multiple hazards, model connectivity within the network, evaluate the recovery trajectory and quantify the associated impacts on community functions. A significant body of work exists on modeling the fragility of transportation infrastructure to aging, with emphasis placed on resilience assessment of bridge networks (e.g., Bocchini & Frangopol 2013), but with only limited work on other modes of transportation. In the transportation network developed within the NIST-CoE, temporal effects (e.g., aging, time lag in multiple events, sequence of restoration) will be captured along with spatial considerations across a regionally distributed network (e.g., damage correlations).

Water systems are regarded as a “lifeline” infrastructure crucial for minimizing the societal impact of extreme events. These networks are large, distributed interdependent systems and their failure can be significant, since residential, commercial, industrial, and other users depend on the network: supply (ground and surface), transmission, treatment, pumping, and storage.

Electric power delivery systems are comprised of generation, transmission and distribution subsystems and are central to the proper functioning and operation of most other infrastructure and again critical for social systems in general and business survival in particular. Thus, they have been examined in greater detail than have natural gas, liquid fuel, or geothermal systems, and models of resilience for electric power delivery networks have been developed. Most of these models focus on the resilience of the physical systems comprised of generation facilities, transmission towers, substations and transformers, poles and towers that comprise the bulk of the distribution lines.

Innovative approaches to modeling resilience and interdependency include agent-based modeling, input-output models, mathematical models and game theory. Physics-based models (as opposed to regressive models) for assessing resilience and reliability of electric power delivery include system-level fragility functions based upon multiple hazards, expanded system reliability indices as defined by IEEE 1366 (2012); post-event restoration

models; functionality and inoperability models with associated metrics of "vulnerability", "rapidity" and "recovery" and mechanical analog single degree of freedom system models used to characterize the properties of the underlying system and to determine how these properties may be used minimize outage times (e.g., Reed et al. 2009).

Modelling Economic and Social Systems and Networks

Economic models can inform a portfolio of risk management investment decisions, including mitigation, warning and evacuation systems, as well as recovery and reconstruction efforts (Gilbert 2010). In short, these models can show how investing or failing to invest in resilience-enhancing interventions generate direct and cascading effects in economic systems that can alter a regional (or community) economy's long-term trajectory. Two complementary economic impact modeling approaches are being utilized within the CoE to estimate the direct and multiplier effects of assorted disaster shocks. First, *applied econometric models* examine community resilience across a variety of economic outcomes (e.g., gross regional product, government revenue, employment growth, wages, births and deaths, and migration flows) over hazard events of varying intensity (i.e., fatalities, injuries, destruction of capital stock), given varying regional attributes and levels of investment in hazard resilience. Specifically, the objective is to quantify the economic impacts of disasters in the US over the last 50 years to determine the level of resilience that has been achieved across regions. Second, *computable general equilibrium (CGE) models* capture economic dynamics during and after major shocks, analyzing how hazard losses manifest themselves in the economy of a region through industry-specific losses in capital stock, damage to critical infrastructure, and human capital stock deterioration through out-migration (Rose 2009). These models will be integrated into the intelligent decision algorithms for optimizing investments in community resilience.

The impacts of disasters on human populations (mortality, morbidity, and psychological) and social systems (disruption, displacement, failure, change), while set into motion by the particular disaster agent, are nevertheless heavily influenced by pre-existing inequalities related to physical vulnerabilities in the built and natural environment and social vulnerabilities generated within economic and social systems. Linking these physical and social vulnerabilities is key to understanding community disaster resilience. Socially vulnerable populations within communities that are residing in hazard-prone locations and vulnerable structures before a disaster often are most likely to experience disproportionate losses, higher damage rates, and housing losses (Highfield et al. 2014). Loss of housing resulting in short- and long-term displacement, jeopardizes employment, business survival, food security, educational attainment, and access to transportation and local support networks, thus placing households in even more precarious and difficult recovery trajectories (Peacock et al 2014). Variations in socio-economics results in clusters of households and businesses facing similar direct and cascading effects, leading to increased probabilities of local business disruption and subsequent failure. The ability to model cascading effects requires that these preexisting social vulnerabilities of populations and social systems characterized in terms of age, race and ethnicity, gender, income/poverty, including relative access to potentially scarce resources such as health care, food, education, employment and housing will be modeled (Van Zandt et al 2012). The way in which hazards losses manifest and cascade among these populations and social systems, such as the dependencies between housing loss, population displacement and local business and neighborhood disruption (Xiao and Van Zandt, 2013) is being modeled for synthesis into NIST-CORE.

Treatment of Interdependency, Aging Infrastructure, and Uncertainties

Community resilience is highly affected by the mutually interdependent nature of buildings, transportation, water and wastewater, power, and communications (Reed 2009). Interdependency is defined herein as "the multi or bi-directional reliance of an asset, system, network, or collection thereof, within or across sectors, on input, interaction, or other requirement from other sources in order to function properly" (CIKR 2008). Most available approaches to modeling interdependency only support a portion of the simulation (i.e., response phase, failure cascading phase, or recovery phase) involved in the resilience analysis (Ouyang 2014). Within the NIST-CoE a combination of methods to achieve a uniform interdependency modeling framework *in both time and geographic scale* for the overall resilience analysis in NIST-CORE will be used. Data obtained from remote sensing, satellite tracking, and geographical information systems at various scales will be integrated into NIST-CORE, which will include a combination of topological approaches, network flow models, and empirical methods. The data-rich history which currently exists (and will be continually updated and housed within NIST-CORE) in empirical methods and statistical learning will inform the topological representation and thereby improve the accuracy of the interdependencies captured by the model.

Physical infrastructure facilities may deteriorate due to exposure to extreme conditions (e.g., excessive loading or harsh environments), weathering, routine use and accidents. The past two decades have seen considerable research on time-dependent reliability of deteriorating structures (e.g., Mori and Ellingwood 1993; Frangopol, et al. 2004). To model the life-cycle of a facility, including time to failure under random occurrences of loads or number of loads until failure occurs (e.g., operational and extreme loads), stochastic models of the deterioration processes and the dependencies between these processes will be included in NIST-CORE. The models will utilize a novel framework that accounts for 1) both shocks and a gradual deterioration process; 2) the effect of deterioration on both capacity of and demand on infrastructure components; and 3) the possibility of both types of failures. The stochastic framework will be used in a novel renewal theory-based life-cycle analysis (RTLCA) model for deteriorating infrastructure components, which accounts for both functional and ultimate failures.

Significant uncertainties exist in every phase of community resilience evaluation – in the condition of the built environment prior to the occurrence of the extreme event, in the loss of functionality immediately after the event, and in the time and degree of post-disaster recovery. Essential components of uncertainty analysis include physical system-based uncertainties that mainly affect the community robustness (e.g., stemming from performance of individual facilities, building portfolios and infrastructure systems as a whole) and socioeconomic uncertainties that affect the extent of societal impact and community recovery (e.g., those associated with social, economic and political institutions within the community, human responses and available external resources.) Such socioeconomic uncertainties will be considered (Murphy et al 2011).

Resilience assessment methods developed within the last decade do not address the spatial and temporal correlations in the response of building portfolios and infrastructure systems as an integral part of the community resilience; nor do they address the uncertainties in the recovery trajectory, which depend on the residual strength of key community institutions following the disaster. NIST-CORE will incorporate simulation-based algorithms for propagating uncertainties in individual and competing natural hazards, in facility response and capacity, and in structural modeling through the risk analysis. The uncertainties in the effect of aging on capacity and demand and the effect of climate change on the intensity/frequency of natural hazards will also be addressed. Coupling and linkage of engineering and social science models of displacement and housing recovery, for example, introduce additional issues in the modeling of uncertainties that will be addressed within NIST-CORE.

THRUST 2 - DATA STANDARDIZATION, USER REQUIREMENTS, AND MANAGEMENT TOOLS

Thrust 2 will develop a standardized data ontology, a robust data architecture and effective data management tools to support the computational environment. Thrust 1 encompasses multiple domains of science and it is therefore critical to first understand all user needs prior to data standardization. Existing ontology, data types and data formats for communities and stakeholders will be integrated into the data standards for NIST-CORE. Finally, the data architecture and data management tools will be customized to help users ingest, manage, query, visualize and share data effectively.

The existing ontology, data types, and data formats identified for the communities and stakeholders involved will be reviewed and integrated into the standards for NIST-CoE. For example, an existing earthquake loss modeling environment may have approximately 200 data types and about 10 data formats for seismic risk assessment; thus it is envisioned that as many as 500 to more than 1000 data types may be required in NIST-CORE. These will be reviewed and integrated according to the user requirements. This will utilize the extension of GML (Geospatial Markup Language) to define the data types and metadata of the datasets.

The core component of the data architecture will be the NIST-CORE data middleware layer, the place where the processing/curation of data occurs. In other words, the raw data, such as hazards, fragility curves for infrastructure, structure inventory, utility network, socio-economic data, etc., will be curated according to the data ontology, data types and data formats developed as described above. This layer has four components: 1) metadata extraction, 2) format conversion, 3) user curation, and 4) data publishing. The metadata extraction component automatically captures/processes the metadata from the raw data according to the data ontology. The format conversion provides the conversion service of the data format with information about data loss from the conversion. The user curation component then allows users to finalize the curation process with extracted metadata. Finally, the curated data will be published to the NDS. The curated data from the middleware layer will be stored in distributed data repositories. The data repositories will have secure access control allowing user(s) to have private repositories, if needed for security reasons.

Defining Resiliency Baselines, Resilience Metrics for Recovery, and Performance Improvements in Resiliency

A critical element in the impact-recovery model is the recognition that *resiliency planning and actions* can have direct consequences on physical impacts and social consequences, as well as influencing the nature and speed of recovery. The adoption of comprehensive mitigation policies (e.g., building codes and effective land-use planning) can reduce physical vulnerabilities and exposure, ensuring that buildings are kept out of high hazard areas or that buildings constructed there are better able to meet potential risks. Recovery planning can help ensure that rebuilding and repair lessens preexisting vulnerabilities, expedites debris removal, ensures capitalization of post disaster public sector activities, addresses vulnerable population needs and lessens post-disaster risks. The NIST-CORE environment, as a comprehensive community decision support tool, will address broad based resilience planning activities by helping communities understand 1) their baseline levels of resilience in relation to existing vulnerabilities and potential impacts, 2) associated recovery outcomes, and 3) resilience enhancements through the adoption and implementation of policies during recovery or as a function of resilience planning.

To capture direct and cascading impacts, the linkage between direct physical damage to the built environment (buildings and infrastructure) and broader socio-economic impacts will be refined to capture and specify damage to housing in its various forms (owner vs rental, single family, duplexes, multi-family and concomitant loss of housing units), to businesses, and to critical facilities. The focus is initially translating direct physical damage to structures and infrastructure systems to the associated disruptions caused by dependencies of social systems on the built environment. Additionally, social impacts and cascading effects for a set of hazards of varying levels and intensities will be modeled. Resilience metrics will assess impacts in the form of the loss of different forms of housing, loss and disruption of various forms of businesses, critical facilities (health, and institutional entities (hospitals, education, childcare, etc.), These in turn will be employed to model further social consequences related to population dislocations, food and health security, etc. The consequences of disaster impact for each sector cannot be defined based on a single metric (damage state(s), life safety, economic loss, etc.) or value due to differences in initial conditions, community expectations, and unequal consequences. Thus, within the NIST-CoE, an impact-performance matrix will be developed for building, infrastructure systems, and social systems, for a number of hazards.

While recovery is still one of the most understudied areas in disaster research (NRC 2006; Peacock et al. 2008; McAllister 2013), recent years have seen new research on long-term recovery and modeling approaches based on empirical and expert knowledge (e.g., Chang et al. 2014; Peacock et al, 2014). Drawing on these findings and research undertaken by the NIST team, the CoE is developing a series of algorithms that will model recovery trajectories for infrastructure, housing, businesses, and populations. They will consider not only technical aspects of repair, replacement, lifecycle and interdependence, but also broader socio-economic factors and policies that can influence recovery. The results will provide recovery-timing assessment for various sectors and sub-populations, the overall community, and a reassessment of vulnerabilities and risk given the new post disaster end-state. A goal will be to parameterize models assessing recovery under scenarios such as *expedited recovery* without policy changes or *policy driven recovery* based on recovery and mitigation planning policies.

As part of comprehensive resiliency planning, activities stakeholders may undertake performance improvement analysis as part of a recovery scenario or simply to reflect the adoption and implementation of new resiliency policies by their community or sector. The NIST-CORE environment will model performance changes (both increases and decreases) given changes or modifications in codes, standards, and policies relative to the baseline resiliency impact-performance matrix. It will be critical that the modeling environment be flexible to adapt to user, stakeholder, and community defined scenarios to allow communities to consider alternative solutions and various scenarios, such as *business as usual*, *progressive intervention*, or some other scenario. Furthermore, a long-term goal will be forecasting scenarios capturing *what-if-outcomes* given specific policy changes and *how-to* scenarios whereby stakeholders establish a resilience goal (i.e., reduced damage probabilities or recovery rates) and the model will offer optimal resiliency changes (mitigation investments, policies, etc.) needed to reach goals. This will allow users to understand the effect of changing one performance metric in the grand scheme and allow performance metrics to be refined and selected. To test this approach, numerous simulations and sensitivity studies will be performed.

THRUST 3 - SENSITIVITY, VALIDATIONS, AND FIELD STUDIES

Investment Optimization and Decision Algorithms

Considerable research has been conducted on the topological analysis and optimal flow of single networks (Newman et al. 2006). On the other hand, the mathematical modeling and optimization of interdependent networks – a fundamental component of community resilience –is relatively new. A key distinction between the two paradigms is that a network component identified as minor importance from the perspective of an isolated network may be critical when the network is considered from an interdependent framework. Failures of links or nodes in interdependent networks may lead to cascading effects and system-wide failure. Variation in the failed links or nodes will affect the speed at which a community recovers from a disaster as well as the extent of recovery. The size and complexity of a community-level model require novel algorithmic approaches that produce accurate solutions efficiently. Intelligent search algorithms based on meta-heuristics are being developed and applied to effectively search the solution space (defined by classical modeling techniques), identify critical interdependent components, develop strategies to reduce time to recovery, and determine near-optimal network designs which improve community resilience. These algorithms are being incorporated into NIST-CORE.

Engineering and economic investments to improve community resilience are being evaluated against a no-action (*laissez faire*) benchmark. More specific, investment expenditures meant to boost resilience to hazard shocks involve reallocation of resources away from *normal* expenditures in the economy. The net short-run economic impact of reallocating resources is negative. However, insofar as these investments are resiliency-enhancing, they will function to mute initial losses (*robustness*) and speed return to pre-shock equilibrium (*rapidity*), thus enhancing *resourcefulness* going forward (Bruneau et al 2003). The negative short-term costs of investments, both direct and indirect (from system efficiency losses), will be compared to the long-term losses averted by community resilience for various investment options as part of this optimization.

To summarize, NIST-CORE will model how a natural hazard impacts the functioning of commercial and residential buildings, transportation, utilities (water), telecommunications and energy. A Computable General Equilibrium (CGE) model will be used to estimate the economic impact of all these effects. The CGE model can estimate the initial downturn in the economy and also estimate the economic resilience of the economy depending on the resilience of the five engineering scenarios. Alternative mitigation policies that can reduce the impact of the hazard with a focus on the costs and benefits of each policy will be developed.

Infrastructure Evaluations

NIST-CORE will be evaluated for individual infrastructure systems (e.g., buildings, transportation), coupled infrastructure systems (e.g., power-water, power-buildings-water), and the fully coupled model (all components including economics and social structures). Observations from Hurricane Ike will be used to validate the individual system models. Hurricane Ike is particularly suitable for this because damages were confined to a relatively small region (Houston, Galveston). For initial validation of the fully coupled system, observations and data from both the Northridge earthquake and Hurricane Ike will be used.

NIST-CORE Architecture and Ontology Validation Studies

Data for Hurricanes Ike and the Northridge earthquake will be used to perform beta testing approximately every 4 to 6 months as the full NIST-CORE architecture is being developed during Year 2 and into Year 3 of the Center. This will allow a systematic validation of each of the integration steps for databases, open source environment communication, search algorithms, and investment optimization. Validation of the NIST-CORE computational environment architecture and forecasts of risk and community resilience based on available computational models and supporting databases will contain significant unavoidable uncertainties. In any application of NIST-CORE (validation or forecasting), the question of paramount importance is whether the models and databases embedded (or interfaced) in it are sufficient to assess infrastructure risk or forecast community resilience with a level of accuracy (or confidence) sufficient for rational decision-making. Within NIST-CORE this critical research challenge is being addressed by structuring the decision analysis module within the environment within a machine learning shell that will enable NIST-CORE to “learn” from the data provided to it, recognizing specific patterns or capturing statistical characteristics during the course of the resilience forecast, and advising the analyst or the decision-maker as to whether the forecasts are likely to be useful.

Field Studies

Field studies will be conducted to enable validation of NIST-CORE for individual systems, interdependencies and cascading effects if present, and the fully integrated data architecture. Mid-term (30 days to 6 months) and long-term field studies will help validate NIST-CORE accuracy in computing recovery trajectory. Data will be collected to characterize the hazard, damage to infrastructure and social systems, and recovery by the community.

ABSTRACT

Studies of hurricane damage to residential buildings confirm that the risk of wind and/or water damage related losses can be mitigated via retrofit solutions. However, adoption of appropriate retrofits by homeowners has been limited despite its obvious benefits. For several reasons, including high cost of retrofitting, the practical difficulty of implementing upgrades, and other homeowner priorities, the level of structural retrofits remain low. This paper proposes a performance-based design approach to retrofitting, targeted for residential homeowners (and their construction team) to advise on incremental retrofits that ultimately result in desired performance targets for wind-resistant houses. To specifically engage the homeowner, a user-friendly smartphone application is developed that evaluates the wind resistance and vulnerability of existing homes. The app provides each homeowner an individualized vulnerability assessment, while engaging and educating them on the effects of structural systems and building characteristics on damage and on the options for retrofits and costs associated with the work. The vulnerability assessment is determined using a database of fragility curves, developed originally for the FEMA's HAZUS-MH program, and adapted for this use. The analysis yields the top three recommended retrofits for each house as-is, and its expected hurricane-induced economic losses compared against the predicted loss if all the retrofits were conducted. Beta trials of the mobile app will be conducted in at-risk coastal communities in Florida, USA. The authors suggest that direct engagement of homeowners in identifying wind mitigation techniques and solutions may yield more positive outcomes than traditional communication approach and it may eventually increase the number of building retrofits.

INTRODUCTION

The use of performance-based design (PBD) is recognized in the engineering community as the most rational means of assessing and reducing the risks of engineered buildings subject to natural disasters (Ciampoli et al. 2011). PBD requires the designers to go beyond code prescriptions and accurately predict how a structure will respond to its environment, often during extreme events. To make these predictions often requires sophisticated structural analysis using state-of-the-art computer software, and sometimes requires laboratory testing. The objective of PBD is to assess the adequacy of a structural system based on a set of decision variables (DV). Each DV is typically a (quantitative) measure of the structural performance that can be defined in terms of interest to the stakeholder. In the case of cyclone-resistant housing construction, building codes have historically focused on life safety. In the wake of extreme economic losses following cyclones over the last 25 years, wind engineering has become increasingly focused on reducing insured loss to structures. Thus vulnerability to wind and water-ingress damages has become an appreciable DV for residential structures. Considering the bulk of housing stock constructed prior to more recent enhancements of building code provisions, a mechanism is need to assess the vulnerability of existing housing (which is specific to each structure) on a large scale. ResilientResidence™ aims to facilitate this mechanism in creating a platform by which homeowners can self-assess vulnerability based on the utilization of research-based vulnerability models (e.g., HAZUS).

BACKGROUND

The damage caused by hurricanes to coastal infrastructure in the U.S. averages about $5.3 billion per year (PCS 2014). In Florida specifically, the inflation-adjusted thirty-year catastrophe losses (including all hazards) between 1983 and 2013 were $66.8 billion, 14% of the total catastrophe losses for the entire United States over the same period (PCS 2014). Within this 30-year period, Florida suffered from the Category 5 Hurricane Andrew in 1992 that destroyed over 25,000 homes and damaged 100,000 others. This single event caused $23 billion (in 2013 dollars) in insured losses, over a third of the 30-year catastrophe losses in Florida. That disaster prompted major changes in how we build, including the adoption of wind-resistance provisions in the 2001 Florida Building Code that addressed many of the structural vulnerabilities exposed by Hurricane Andrew. The effectiveness of this code was put to the test in 2004, when four hurricanes impacted the state of Florida: Charley in the southwest, Ivan in the panhandle, and Frances and Jeanne on the East coast. Statistical analysis of the post-storm damage assessments showed that homes built to the 2001 building code performed significantly better than pre-2001 homes in nearly every area surveyed (ARA 2008; Gurley and Masters 2011). However, while the current building code assures that new homes are safer and less likely to experience severe damage, homes built prior to the code remain vulnerable to future damage. Further, analysis of public county records from the Florida Geographic Data Library (FGDL 2015) indicate that 80% of Florida's 5 million detached, single family homes were built before 2002, as shown by county in Figure 1.

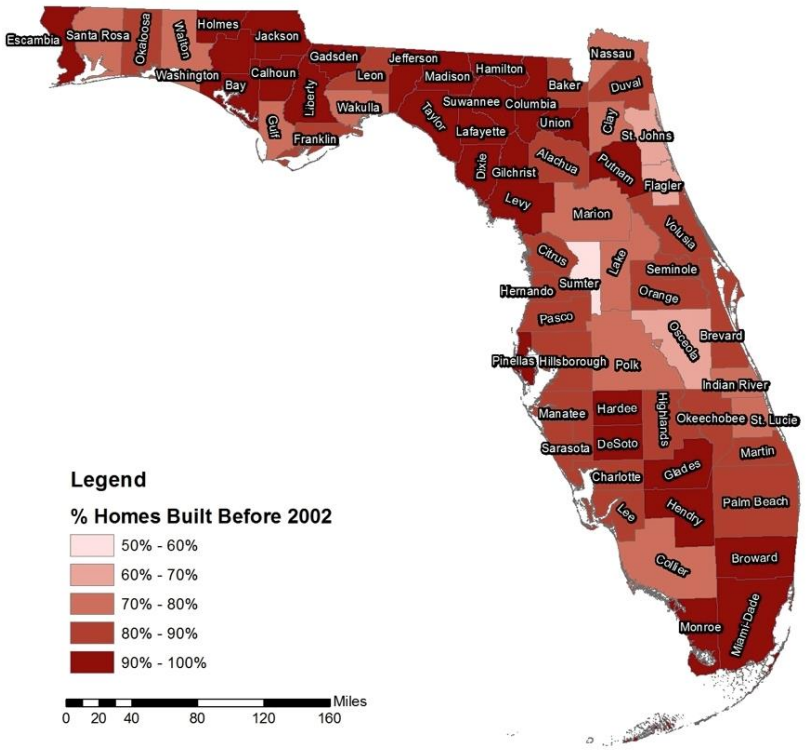

Figure 1. Percentages of homes built prior to 2002 in each Florida county. Data obtained from public county records in Florida (FGDL 2015).

Despite significant advances in knowledge and more efforts to implement stringent wind-resistant building codes in Florida over the past few decades, the majority of houses in Florida may still suffer disproportionately large structural damage from future hurricanes. The existing structural systems in Florida's homes lack wind-resistant details and adequate structural load paths that prevent brittle failures of the structures, and at less than design level wind speeds. The situation is exacerbated by the 80% proportion of the state's insured homes, (approximately $2.8 trillion) that are located in coastal (hurricane-prone) regions (Insurance Information Institute 2014). Together these data demonstrate that Florida's vulnerability to hurricane impacts remains high, despite a strengthened building code ranked second in the US by the Insurance Institute for Business and Home Safety (IBHS 2015) and more than 20 years of better building construction following Hurricane Andrew. Wind engineers have identified a number of cost-effective protection measures that can be retrofitted to existing homes. Despite efforts by state officials, and NGOs to promote mitigation through information and economic incentives, these retrofit techniques have not been widely adopted by Florida homeowners. Unless the implementation of these techniques is

substantially increased in older homes, continued storm damage may erode market values of the surviving homes and discourage community investment in rebuilding.

Dissemination of hurricane risk to the general public has occurred on a broad scale, but it has been difficult to engage the homeowner to understand and act on their personal risk (Wood et al. 2012). A population's ability to perceive risk and consequences of events beyond the immediate event is low (Fischer et al. 2015). Studies show that homeowners understandably devote more thought to the immediate effects of natural disasters than the long-term effects and therefore are more concerned with survival actions (e.g. first aid kits, water supply) than mitigation actions (Fischer et al. 2015). However those homeowners are often unaware of the solutions that can mitigate their losses from natural disasters. Historical evidence suggests that experiencing a disaster may be the strongest public motivator to prepare/mitigate for the next event, albeit coming after the event. However, the window for action quickly closes as the memory of experiencing an event declines as time passes. Weinstein (1989) found that the perceptions of safety reemerge and rise back to pre-event levels, typically within a two-year period.

As a result, the general public is disconnected from the hurricane risks and the majority of solutions proposed to mitigate future damage. In general, the public often assumes that insurance will protect against any losses and that the period of recovery will be short and relatively painless. However, hurricane damage deductibles (i.e. excess) are high (from 2- 5% of the value of the home), and insurers have prerogative to reject claims where long-term aging effects and hurricane-related damages are indistinguishable. Many homeowners do not appreciate that post-hurricane reconstruction is more expensive, and generally requires a longer timeline. Further, homeowners seldom consider that hurricane-induced wind and water damage may require temporary housing for weeks or months, resulting in considerable long-term disruptions to their lives.

Hence, the residents of vulnerable homes may possess unrealistically high expectations of personal safety stemming from a lack of exposure to the disparities in construction practices between older and newer Florida homes. Fischer et al. (2015) found that the top two reasons homeowners did not take earthquake mitigation actions was because they had not thought about it or did not believe it necessary for their home. Additionally, an overabundance of information on hazard risk (e.g. news reports, TV Specials) rather than preparedness actions hinders the implementation of mitigation solutions (Wood et al. 2012). In general, two prominent preparedness adoption barriers commonly noted in previous literature are risk perception, and lack of clarity regarding the benefits of preparedness actions (Bourque 2013; Ge et al. 2011; Wood et al. 2012). Both of these barriers can be addressed through a performance-based design approach. As described by van de Lindt (2009), this design approach specifies specific performance objectives and safety goals that a community or building owner desire to achieve, and a probabilistic evaluation of design alternatives against the performance objectives for a given hazard level. This paper describes the framework for a mobile app entitled ResilientResidence™ (ResRe) (www.resilientresidence.com) that provides a personalized wind risk assessment of a user's home, including the expected losses that would occur in a scenario event, using a performance-based design approach.

DEVELOPMENT OF A MOBILE APPLICATION

The concept for the ResRe mobile application was developed in 2013 by a team of engineering doctoral students (Daniel Smith, David Roueche, and Austin Thompson) supervised by Associate professor David Prevatt. Though a number of mediums are available for conveying risk information, the development and near ubiquitous adoption of smartphones in the US (as shown in Figure 2) make it an ideal platform for a decision aid.

Research has established the effectiveness of smartphones as mobile education devices (Song et al. 2012) and has proposed the use of smartphones in disaster communication (Meltzer et al. 2015; Riddell et al. 2011) and as decision support tools in building energy conservation strategies (Leslie 2012).

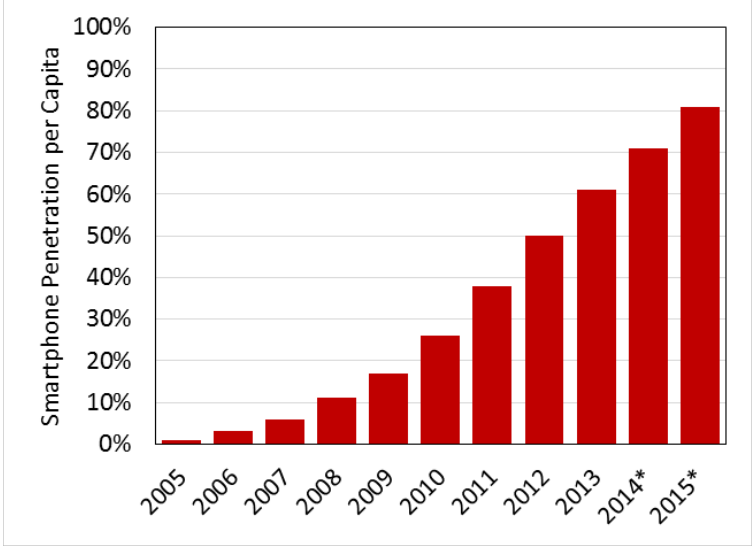

Figure 2: Current and projected(*) smartphone ownership in the United States from 2005 – 2015 (eMarketer 2014)

The personalized risk and vulnerability assessment of ResRe requires an engineering-based loss model to establish the relationship between wind speed and expected monetary losses for a given residential structure type. This is publicly available in the HAZUS-HM hurricane catastrophe model, a peer-reviewed, multi-hazard catastrophe model distributed by Federal Emergency Management Agency (FEMA) (Vickery et al. 2006). A primary component of HAZUS-HM is a library of loss functions that relate hurricane wind speed and expected building losses (normalized to the value of the home) for various building types. The loss functions are extensive, including 1,024 different configurations of residential buildings. When a specific home is defined within ResRe, it is matched to a specific loss function in the HAZUS-HM library. The expected losses for that home are determined for a given wind speed based upon the value of the home. The benefits of retrofitting are then evaluated by comparing the expected losses for the same home configurations with added mitigation features to the expected losses of the original home. The methodology is illustrated by Figure 5. In this example, the difference in building loss ratios of 0.18 for a Category 1 hurricane suggests that for a home valued at $200,000, the retrofitted home would have ~$36,000 less damage than the unretrofitted home.

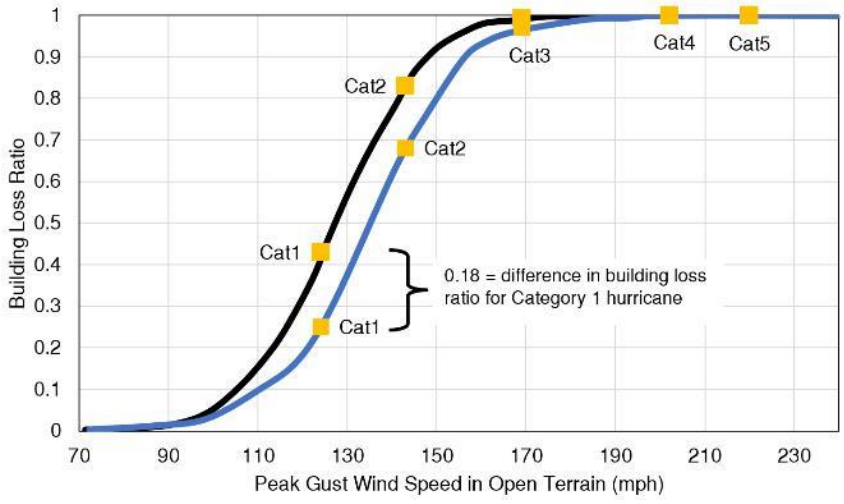

Figure 3. Illustration of building loss functions for a woodframe, one story, gable home without retrofits (black) and retrofitted with hurricane straps and stronger roof sheathing fasteners (blue). Gold-colored squares represent the maximum 3-second gust wind speed associated with Category 1-4 hurricanes and a representative value for a Category 5 hurricane.

It is understood that HAZUS-HM loss functions represent generalized structures and therefore have limited accuracy at house-level resolution. However, these curves can be used to provide a rational basis for comparative

analysis between wind-resistant building features. Their use in this application also enables meaningful risk communication to homeowners through dollar figure loss estimations.

PROGRAM LOGIC

The customized analysis of a ResRe user's home is completed by a program coded into the background of the app, behind the guided user interface (GUI). The program completes a vulnerability assessment and retrofit optimization for the user based on the input data collected by the GUI. The data collected from the user includes: [a] building characteristics (e.g., location of the home, year of construction, roof shape, wall material, number of stories, appraised home value) and [b] current protection levels for building components (e.g., roof cladding, roof to wall connections, wind protection, roller door rating, roof framing) that affect the vulnerability of a residential structure. The protection levels for each component (e.g. strong, medium, weak) are determined by the user within the GUI through a questionnaire that aims to extract the need technical information while remaining simplified and easy to use. Figure 4 provides an overview of the application logic.

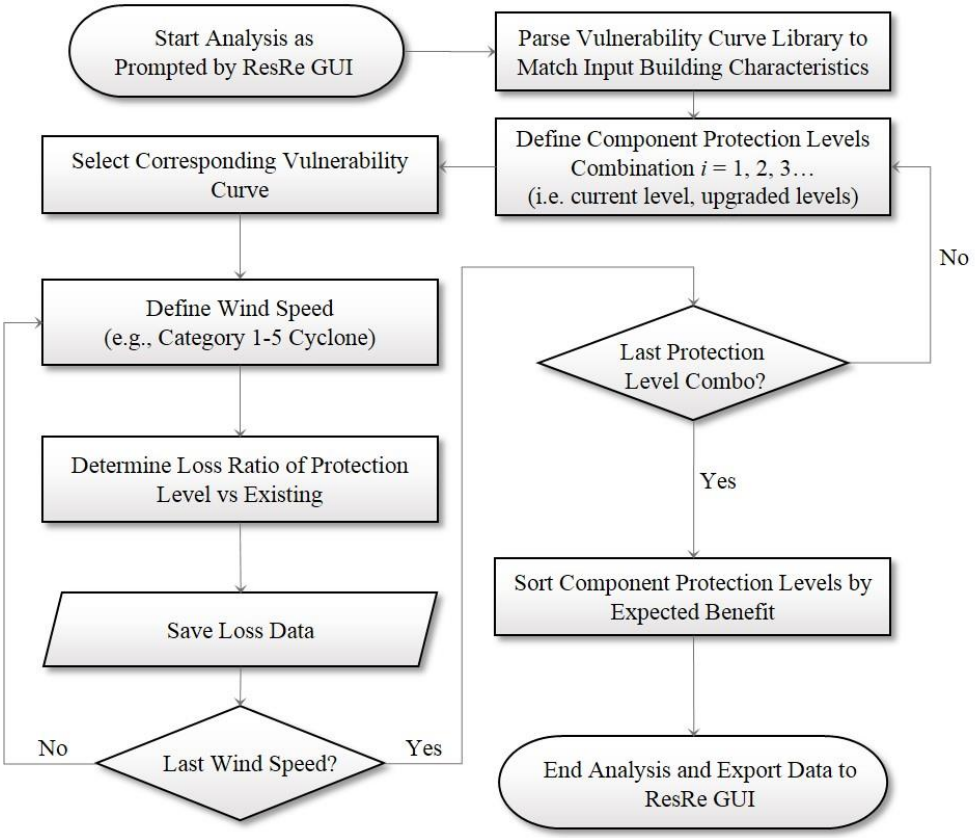

Figure 4. Vulnerability assessment and retrofit optimization program logic for ResilientResidence™

GRAPHIC USER INTERFACE (GUI)

While the technical engine for ResRe is critical to ensuring useful information is available to the user it must be coupled with a user interface that the majority of homeowners can use if the education and engagement goals of the app are to be realized. Ideally such an interface would be intuitive, seamless and easy to use, with minimal opportunities for user input errors, and minimal potential sources of frustration for a user who is likely to be unfamiliar with many of the concepts being explored (Leslie 2012). An initial app flow design that addresses these criteria has been developed into a prototype. In the prototype, the user launches the application from their smartphone device and is greeted with a homepage that serves as the base station for their experience. First time users are prompted to register an account and accept a legal disclaimer. All users are provided three options on the homepage (a) assess a new house, (b) review/update my existing houses, and (c) interact with the ResRe team.

If the user chooses to assess a new home, they proceed to start a new assessment of a home. If the user opts to review or update an existing house, the summary outputs from previous home assessments are provided, and the

user is given the opportunity to edit their inputs, if necessary. The 'Interact with the ResRe Team' gives the user the opportunity to visit the social media pages associated with ResRe and email the ResRe team with questions or comments. This will allow the user to directly engage the researchers with questions or comments, as well as provide the user with up-to-date information about upcoming application updates, relevant research, and new findings. Providing this direct link between interested users and the research community is important to further facilitate the transfer of knowledge.

When assessing a new home, the user is prompted to: a) allow access to GPS coordinate capabilities available in the device to locate the house or b) manually input the address of the house being assessed. Once input, the user is guided through a series of screens that prompt the user for key baseline parameters describing the general aspects of the house. Examples include the age of home, number of stories, roof shape, and wall construction type. When available, this information will be automatically parsed from the local property appraiser database. If the user is unsure of any inputs, they are provided helpful content (e.g., illustrations of common roof types, or hints on how to determine the exterior wall material). Once baseline parameters of the home are defined, users are shown a graphical building representing the general characteristics of their home (Figure 5). Each dot point on the figure represents a critical building component within the vertical load path for wind hazards (e.g., roof covering, roof-to-wall connections, windows, entry doors and garage doors). Advanced options will also be available to allow selection of roof sheathing fasteners and gable-end bracing (if applicable). As shown in the figure, red circles will represent components that have not been defined by the user. Conversely, green circles with check marks will represent components that have been defined by the user.

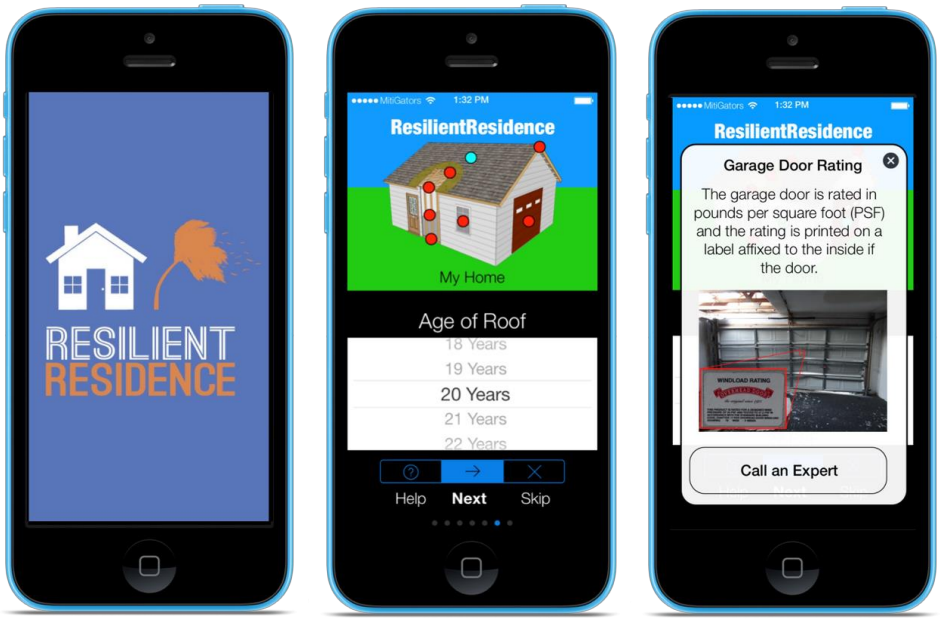

Figure 5. Screen capture of current wire-frame version of ResilientResidence™ including building attribute selection (center) and attribute help screens (right)

In scenarios for which the user is unable to define the component, the program will default to the baseline values established by the home's location, wall type, age, number of stories and roof type. Although accuracy of the results is maximized when the user is able to define all input parameters, the user is not precluded from receiving the vulnerability and mitigation outputs if components are not defined.

Upon successful definition of all components, the user is prompted to submit their home for assessment. Once selected, the user is provided an output report (Figure 6) consisting of:

1. The vulnerability of their current home to wind-related damage as monetary loss
2. Three optimized retrofit strategies that most effectively reduce damage potential
3. The expected monetary loss of the retrofitted home for a given wind-speed intensity level.

Figure 6. Screen capture of current wire-frame version of ResilientResidence™ output display

The three recommended mitigation methods are expressed on the screen as separate options that the user can select, either individually or in combination, to see how implementing the mitigation techniques reduces the vulnerability of their current home. The user can also see how effective the retrofits are for different hurricane scenarios, from Category 1 to Category 5 intensity. This aspect of the performance-based analysis allows the user to choose the performance they desire (economic losses) for a specific hazard level. When coupled with visualizations of hazard probabilities (not shown in current prototype), this becomes an even more powerful tool, allowing the user to make informed, engineering-based decisions on hazard mitigation levels with minimal training or expertise. The user is also presented with the option to send the full report, which includes all inputs and outputs, to outside stakeholders (i.e. insurance providers, etc.).

After completing the assessment users are provided several resources to guide in the implementation of the retrofit methods. These resources include, but are not limited to: the Federal Alliance for Safe Homes, Florida Department of Emergency Management, and the Insurance Institute for Business & Home Safety.

DISCUSSSION

Two parallel efforts in Florida (via David Prevatt and the University of Florida) and Queensland (via Daniel Smith and James Cook University) will commence in 2016 to identify drivers of homeowner engagement in each of these cyclone prone regions. The findings will be used to develop effective methods of incentivising homeowner engagement for use within Florida- and Queensland-based versions of the ResRe app. An alpha version of the decision-support tool will be constructed and tested for effectiveness in both locations. A comprehensive set of vetted vulnerability functions (e.g. HAZUS) does not currently exist in the public domain for Australia, however, these functions are currently in development at James Cook University in collaboration with Geoscience Australia and the Bushfire and Natural Hazards Cooperative Research Center. These functions will replace the HAZUS functions in the Queensland version of the application. The graphical interface will also be adapted to suit Queensland homeowners. Beyond direct benefits (i.e. increasing mitigation behavior, educating homeowners, informing risk-based pricing for insurance, etc.), widespread use of the application will generate large quantities of data on the age, location, building components, retrofit usage, etc. of the homes in these regions. This information will be used in aggregate form (with privacy filters) for a variety of research purposes, including identifying regions of higher vulnerability, etc. to inform public policy and emergency response and recovery.

ABSTRACT

This paper investigates the intra-building and inter-building aerodynamic correlations of linked buildings (LBs, i.e., adjacent tall buildings structurally connected by links such as skybridges, skypools and skygardens). Spatiotemporal wind pressure data on a few typical LBs with different gap distances are used to examine the two aerodynamic correlations. The intra-building aerodynamic correlation is examined using correlation coefficients and trajectories between wind force components on the building. Results show that the intra-building aerodynamic correlations for the LBs differ considerably from that for the isolated building, especially in the correlation between along-wind and torsional force components. The inter-building aerodynamic correlation is then presented in terms of the correlation coefficients between local wind force components and between generalized force components of the two buildings. The along-wind inter-building correlation is found to decrease with increasing gap distance, whereas the variation of cross-wind inter-building correlation is more complicated. In addition, it is illustrated that the wind-induced response of the LB is related positively to the correlation coefficient between the generalized force components of the two buildings in the associated unlinked case.

KEYWORDS

Inter-building force correlation; intra-building force correlation; wind force; wind-induced response; linked buildings; tall buildings.

INTRODUCTION

There is a growing trend to join tall buildings in close proximity by linking through horizontal structural links such as skybridges, skypools and skygardens. They are usually built to great heights in order to achieve a grand appearance, so wind-resistance is one of primary concerns in design practice, particularly in typhoon-prone areas. Because LBs are usually not far away from each other, wind flow around in their surroundings is susceptible to the interference effect (Kareem, 1987; Khanduri et al., 1998; Kim et al., 2011). In addition to modification of wind force magnitude on an LB, therefore, the correlation between wind force components within each building likely differs from that for an isolated building. This correlation, which is related to the combination of the resulting directional structural response (Thoroddsen et al., 1988; Tamura et al., 2001; Tamura et al., 2008; Tamura et al., 2014), is termed the intra-building aerodynamic correlation in this work. Furthermore, the existence of the structural link can couple the vibrations of the two connected buildings by transferring internal forces. Due to this link-induced structural coupling, wind forces on all the connected buildings should be taken into consideration simultaneously to accurately reflect the true nature of wind-excited LBs and calculate the resulting structural responses (Xie and Irwin, 2001; Lim and Bienkiewicz, 2007; Song and Tse, 2014). This involves summing wind force components of all the connected buildings. For instance, the generalized force for a mode is the summation of generalized force components of all the connected buildings. The correlation in wind force components between the connected buildings, termed the inter-building aerodynamic correlation, plays an important role in determining the summation.

The effects from the presence of adjacent building(s) on the wind force magnitude and wind-induced response of a principal building have already been studied extensively, in terms of the interference effect (McLaren et al., 1971; Lee and Fowler, 1975; Bailey and Kwok, 1985; Taniike and Inaoka, 1988; Khanduri et al., 1998; Lam et al., 2008; Kim et al., 2011; Hui et al., 2013). For instance, the interference effect was quantitatively examined for a principal building that was surrounded by one or more interfering buildings located at different locations, in terms of an interference factor (Bailey and Kwok, 1985; Sakamoto and Haniu, 1988; Taniike, 1992; Yahyai et al., 1992; Thepmongkorn et al., 2002; Mara et al., 2014). It should be mentioned that in these studies, usually only the principal building was equipped with instrumentation to measure wind forces and the interfering

buildings were just dummy blocks to provide interference effect. As far as the authors of this paper know, very few studies examine the aerodynamic correlation of buildings in close proximity (Lim et al., 2011; Lim and Bienkiewicza, 2014), although the aerodynamic correlation for wind force components on a single building has been systematically investigated by Kareem (1982) and Tamura et al. (2000; 2001; 2008; 2014).

Therefore, there clearly remains a need to investigate both the intra-building and inter-building aerodynamic correlations of LBs, which provides the motivation for this study. In this study five LB models with designed determined gaps were fabricated to provide different intra-building and inter-building aerodynamic correlations. Fluctuating wind pressures on each face of the buildings in each model were simultaneously measured in a wind tunnel. Then, the intra-building and inter-building aerodynamic correlations were separately examined in detail. The main findings were summarized in the concluding section.

EXPERIMENTAL MEASUREMENT

The tests were carried out in the boundary layer wind tunnel of the CLP Power Wind/Wave Tunnel Facility at the Hong Kong University of Science and Technology. Five cases of LBs with different gap distances (S) were considered. In each case, two buildings which were connected by a top link were set to be identical, as shown in Fig. 1. A typical square building model, 160 m tall and 30 m × 30 m in plan (prototype scale), was chosen for each building. Considering common arrangements of LBs, gap distance S was set to be in the range of 10 m to 45 m in the prototype scale. The specially-designed gap distance and ratio S/B for each case are listed in Table 1. For comparisons, the single isolated building case was also tested (labeled case 0). Allowing for the requirements of the block ratio and easy operation, a typical length scale of 1: 400 was selected for the models in the wind tunnel. One tested model in the wind tunnel (i.e., case 4, S/B = 1) is shown in Fig. 2.

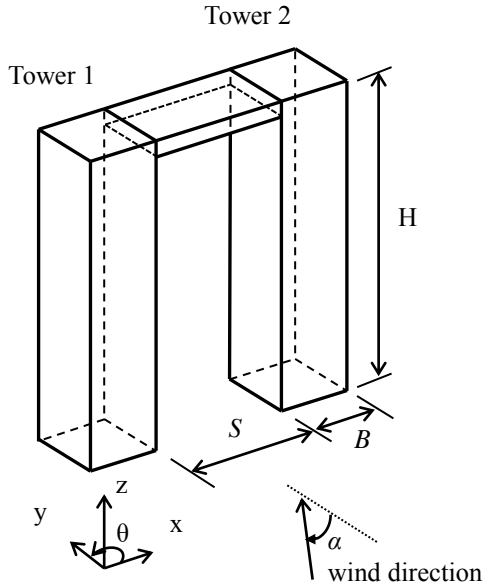

Figure 1 Setup of two square buildings, wind direction, and coordinate

Table 1 Gap distance (S) and ratio (S/B) for each case

Gap distance (S) and ratio (S/B)		cases					
		case 0	case 1	case 2	case 3	case 4	case 5
S	model scale (mm)	-	25	37.5	50	75	112.5
	prototype scale (m)	-	10	15	20	30	45
	S/B	-	1/3	1/2	2/3	1	3/2

The design mean wind speed and the longitudinal turbulence intensity at the top of the building (160 m) were 42.8 m/s and 13.9%, respectively. The approaching flow was simulated in the wind tunnel as natural wind over an open terrain with a power law exponent of 0.2 for the horizontal mean wind velocity profile. Both mean wind speed and turbulence intensity profiles were calibrated and the calibration results are shown in Fig. 3.

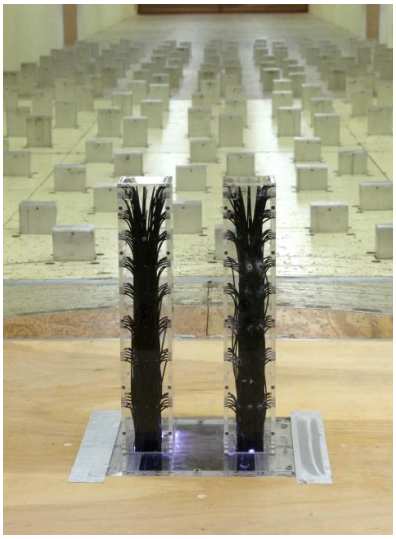

Figure 2 Model (case 4, S/B = 1) in the wind tunnel

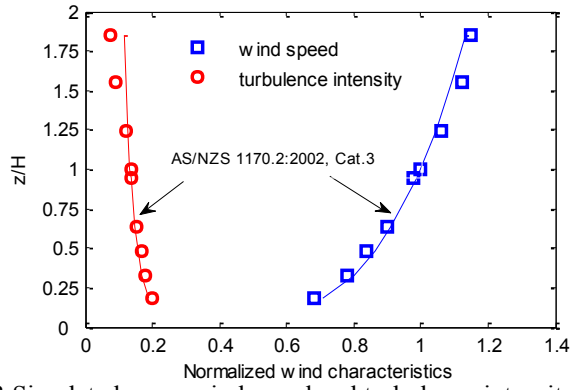

Figure 3 Simulated mean wind speed and turbulence intensity profiles

Pressures on the side faces of the model were measured employing a synchronous multi-pressure measuring system (SMPMS) with 9 levels of pressure taps on each face and 5 taps per level (360 taps in total). After fluctuating wind pressure data on all faces were synchronously collected, the time histories of local wind forces at each floor, two base overturning moments, and the base torque were determined by integrating over the associated wind pressure field.

INTRA-BUILDING AERODYNAMIC CORRELATION

The intra-building aerodynamic correlation, i.e., the correlation between wind force components on each building, is related to the combination of resultant directional wind-induced responses (Chen and Huang, 2009; Tamura et al., 2014). As mentioned in the introduction, the correlation may differ significantly from that for a single building. Therefore, the intra-building aerodynamic correlation is examined in this section. In this study, we focus on results for a critical wind direction, $\alpha = 0^{o}$. For $\alpha = 0^{o}$, the oncoming wind is normal to the face of the LBs and the two buildings are in a side-by-side symmetric arrangement (refer to Fig. 1). Therefore, the statistical characteristics of the aerodynamic forces on the two buildings are the same, and hence only results from the building on the right (Tower 2) will be discussed.

Trajectories of Base Moment Components

The correlation between wind forces components is first investigated by examining the trajectories of base moment coefficients of Tower 2 (i.e., C_{MD}, C_{ML}, and C_{MD}), which are defined as

$$C_{MD} = \frac{M_D}{\frac{1}{2}\rho_{air} V_H^2 BH^2} \qquad C_{ML} = \frac{M_L}{\frac{1}{2}\rho_{air} V_H^2 BH^2} \qquad C_{MT} = \frac{M_T}{\frac{1}{2}\rho_{air} V_H^2 B^2 H} \tag{1}$$

where M_D, M_L, and M_T are the along-wind base moment, cross-wind base moment, and base torque of Tower 2, respectively. ρ_{air} is the air density; and V_H is the velocity at the top of the building. In addition to examining the trajectories for the five LB cases, the trajectories for the associated single building are also presented for comparison.

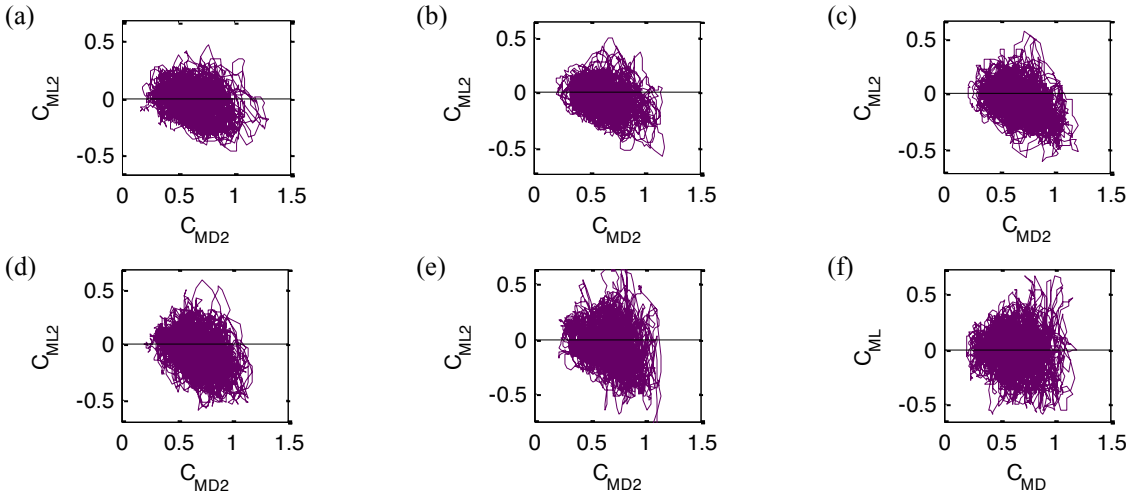

Figure 4 Trajectories for the along-wind and cross-wind base overturning moments: (a) S/B = 1/3; (b) S/B = 1/2; (c) S/B = 2/3; (d) S/B = 1; (e) S/B = 3/2; (f) single

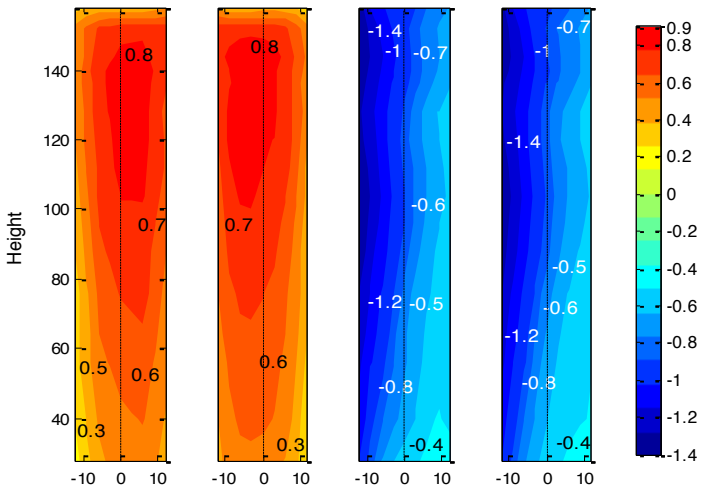

Figure 5 Contours of mean pressure on (a) windward face of Tower 1; (b) windward face of Tower 2; (c) inside face of Tower 1; and (d) inside face of Tower 2 for case 2

The trajectories for the along-wind and cross-wind forces of all cases are shown in Fig. 4. For the single building, envelope of the trajectory (shown in Fig. 4f) is half-elliptic. This half-elliptic envelope is very similar to that reported in (Tamura et al., 2014), which in part suggests validation of the measured data. Unlike the symmetric trajectory for the single building, however, those for the LB cases shown in Fig. 4a to e are negatively inclined, clearly indicating a negative correlation between the along-wind and cross-wind forces. The negative correlation can be explained by the pressure contours shown in Fig. 5. Due to the channeling effect caused by the inter-building gap, the wind that flows through the gap accelerates. As a result, the pressure on the area of the windward faces close to the gap of is increased. Meanwhile, suction on the area of the two inside faces near the windward edges is also enhanced, as shown in Fig. 5. For Tower 2, pressure on its windward face is along the positive direction while suction on the inside face is along the negative direction, which causes the negative correlation between the along-wind and cross-wind forces. As channeling effect becomes relatively small when the gap distance is large, it can be seen that the trajectory for S/B = 2/3 is no more significantly inclined and becomes close to that for the single building.

The trajectories of the along-wind and torsional base moment are presented in Fig. 6. The trajectory for the single building shows a normal elliptic envelope, almost the same as that reported in (Tamura et al., 2014) for a square building with a similar aspect ratio. In contrast, the trajectories for the LBS cases (Fig. 6a to e) are rather contracted and negatively-inclined, clearly suggesting a strong correlation between along-wind base moment and torque. This is because the distribution of pressure on the windward faces in an LB is usually skewed (as shown in Fig. 5 where the distribution shifts inward), instead of being symmetric. In addition to causing the along-wind forces, the pressure with asymmetrical distribution will bring about torsional forces on the LBS. Therefore, the trajectories (shown in Fig. 6a to e) for the LB cases cluster within in a rather narrow zone, although the zone becomes relatively wider when S/B is large, such as when S/B = 3/2. Furthermore, the shape of the trajectories for LB shows that it is highly probable that maximal along-wind force coincides with maximal torsional force. Therefore, although the correlation between along-wind and torsional forces on a single building is weak and usually ignored, the correlation between the two wind force components on an LB is considerable and cannot be disregarded without careful consideration.

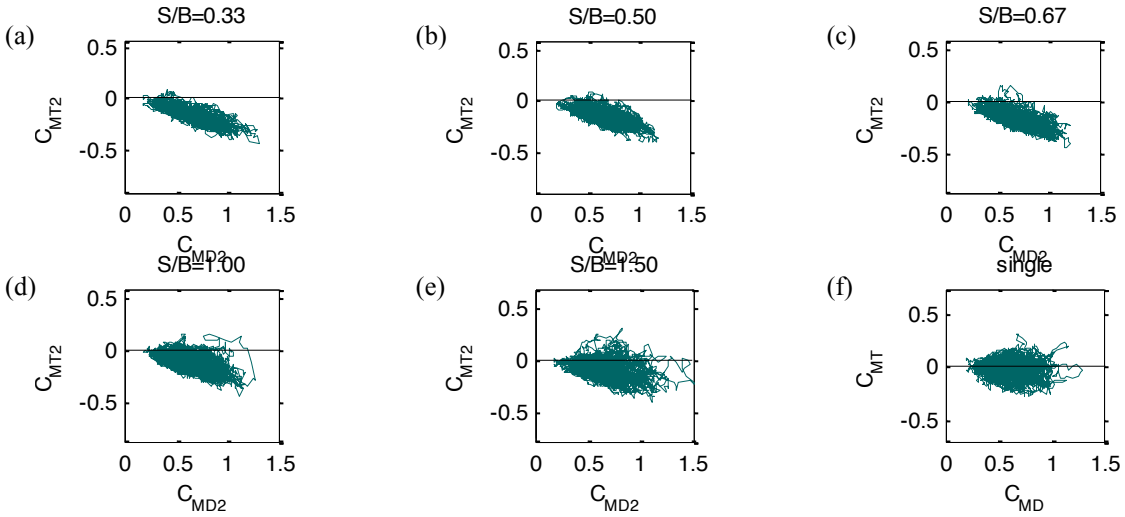

Figure 6 Trajectories for the along-wind and torsional base moments for α = 0°: (a) S/B = 1/3; (b) S/B = 1/2; (c) S/B = 2/3; (d) S/B = 1; (e) S/B = 3/2; (f) single

Trajectories for cross-wind base moment and torsional moment are presented in Fig. 7. It is usually believed that the cross-wind force and the torsional moment on a single building are well correlated, since they are both largely caused by the wake dynamics. As a result, the trajectory for a single building shown in Fig. 7f is an inclined ellipse, rather than a normal one. For the same reason, the trajectories for LBs also show similar envelopes to that for single building, indicating that the correlation between cross-wind and torsional force is similar for an LB and a single building. In addition, it can be observed that the gap distance ratio S/B has no significant effect on the trajectories.

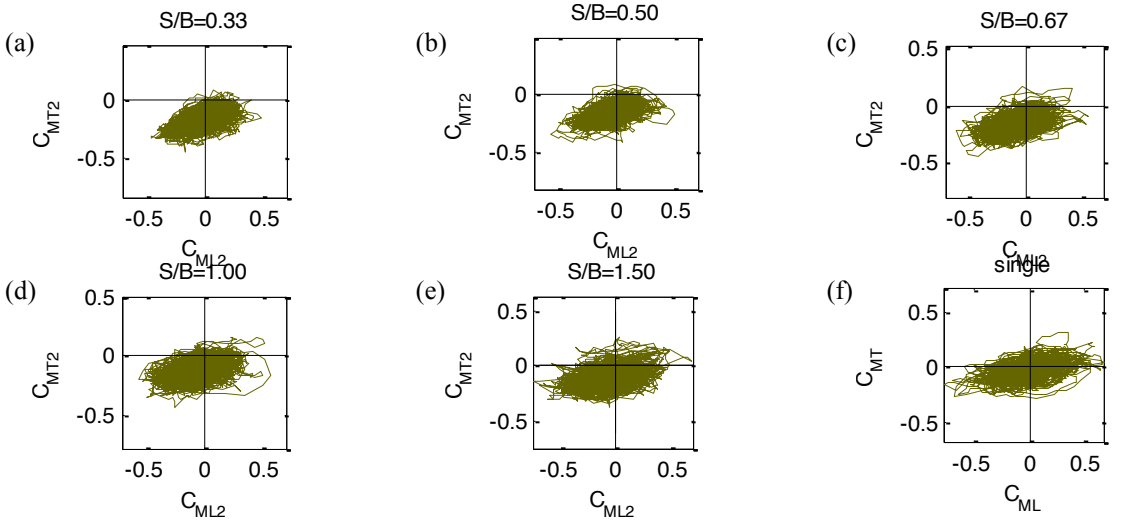

Figure 7 Trajectories for the cross-wind and torsional base moments for α = 0°: (a) S/B = 1/3; (b) S/B = 1/2; (c) S/B = 2/3; (d) S/B = 1; (e) S/B = 3/2; (f) single

INTER-BUILDING AERODYNAMIC CORRELATION

As indicated in the introduction, the inter-building correlation plays an important role in summing the wind force component of each building. This is because if the wind forces on two connected buildings are positively correlated, the summed generalized force for the whole LB system is relatively large and hence the response. However, if the wind forces are negatively correlated, the resultant general force is likely to be relatively small. In this section, the inter-building correlation is investigated quantitatively, to show how the correlation varies with gap distance.

Inter-building Correlation between Local Wind Force Components

The inter-building aerodynamic correlation is calculated in terms of the correlation coefficient between local wind force components, which is defined as

$$\rho_{Fc1,Fc2} = \frac{E\left[\left(F_{c,1}(z,t)-\mu_{Fc,1}\right)\left(F_{c,2}(z,t)-\mu_{Fc,2}\right)\right]}{\sigma_{Fc1}\sigma_{Fc2}} \tag{2}$$

where $F_{c,q}(z, t)$ is time histories of the force component on tower q (q = 1, or 2) at the elevation z, in which $c = D$ or L, denoting the along-wind and cross-wind force, respectively; $\mu_{Fc,\,q}$ and $\sigma_{Fc,\,q}$ are the mean value and standard deviation of the force component $F_{c,q}$; E is the expectation operator; and $\rho_{Fc1,Fc2}$ is the associated correlation coefficient.

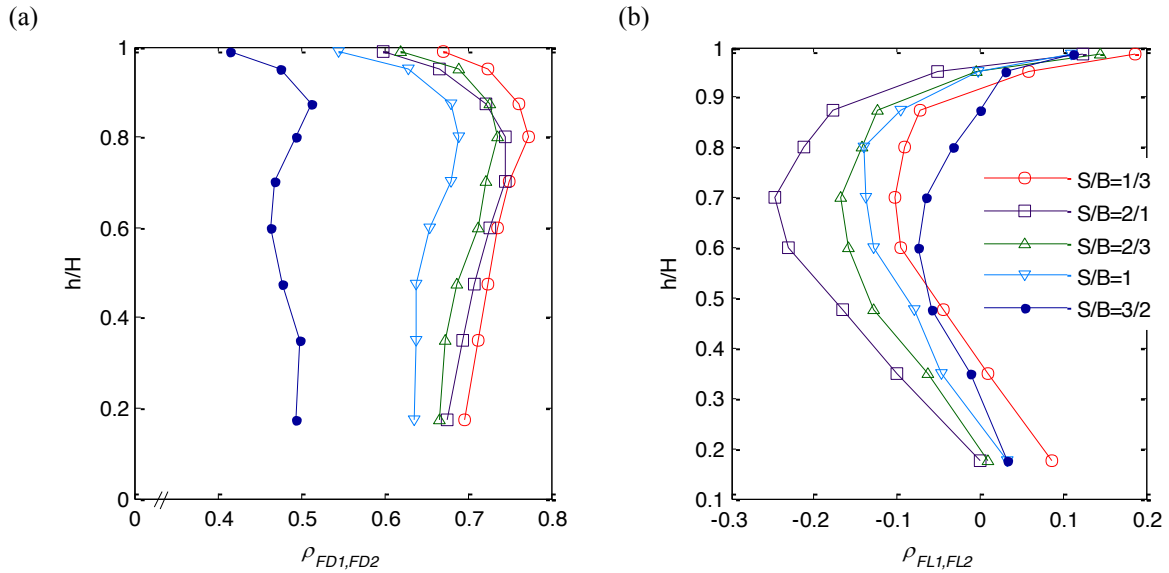

Figure 8 Correlation coefficients between two wind force components on Towers 1 and 2 at the same level for α = 0°: (a) along-wind; (b) cross-wind

Fig. 8 shows the correlation coefficients between the local wind forces on the two buildings of the five cases for α = 0°. It can be observed from Fig. 8a that in most levels, the correlation coefficients of the along-wind forces decrease with increasing S/B. This decreasing trend can be explained by the fact that along-wind forces are mainly attributed to the approaching wind, the correlation of which decays with an increase in the lateral separation distance. Therefore, it can be anticipated that for α = 0°, when S/B is very large (> 3/2), the correlation between along-wind forces on two buildings will become relatively weak. However, it should be noted that the wind forces at high levels (h/H > 0.8) for S/B = 1/2 and 2/3 do not stringently follow this trend. This strange variation could be attributed to the complicated 3D flow (tip flow) around the building top. When S/B increases from 1/2 to 2/3, the 3D flow may increase the correlation between suction forces on the two leeward faces, to some extent delaying the decrease of the correlation between the forces on the two windward faces and hence resulting in the correlation coefficients not decreasing significantly from S/B = 1/2 to 2/3.

Unlike the inter-building correlation between along-wind forces, the correlation between cross-wind forces does not continuously decrease or increase with gap distance, as shown in Fig. 8b though a week trend exists. In the range 0.3 < h/H < 0.9, the absolute values of the correlation coefficients increase with increasing S/B from 1/3 to 1/2, whereas further increasing S/B from 1/2 to 3/2 leads to gradual decrease in the absolute value of the correlation coefficients. The increase in the correlation coefficient can be explained by the increased gap flow—

accelerated wind passing through the gap may increase the correlation between the two suction forces on the two inner faces. The decrease in the correlation coefficient, on the other hand, is due to the fact that increases in S/B above 1/2 can gradually allow the shear layers from the two inner edges to roll up into the rear region of the two towers through the gap, interrupting the original cross-wind correlation in S/B = 1/2. In addition, within the range 0.3< h/H < 0.9, almost all the correlation coefficients are negative, indicating that vortex shedding is dominant. At the top and bottom (i.e., h/H > 0.9 and h/H < 0.3), in contrast, the correlation coefficients for cross-wind forces are positive. This is because the flow around the top is complicated, which can be attributed to downwash from the tip flow which disrupts the organized structure of wake fluctuations, resulting in the positive, albeit slight, correlation. Similar trends were noted by Ayoub and Karamcheti (1982) and Kareem et al. (1989). Consequently, the negative correlation around the top of the building is weak, even becoming positive. Similarly, vortex shedding around the bottom region is not fully formed, so cross-wind forces at the bottom of the two buildings are slightly positively correlated (also observed in Kareem et al. 1989).

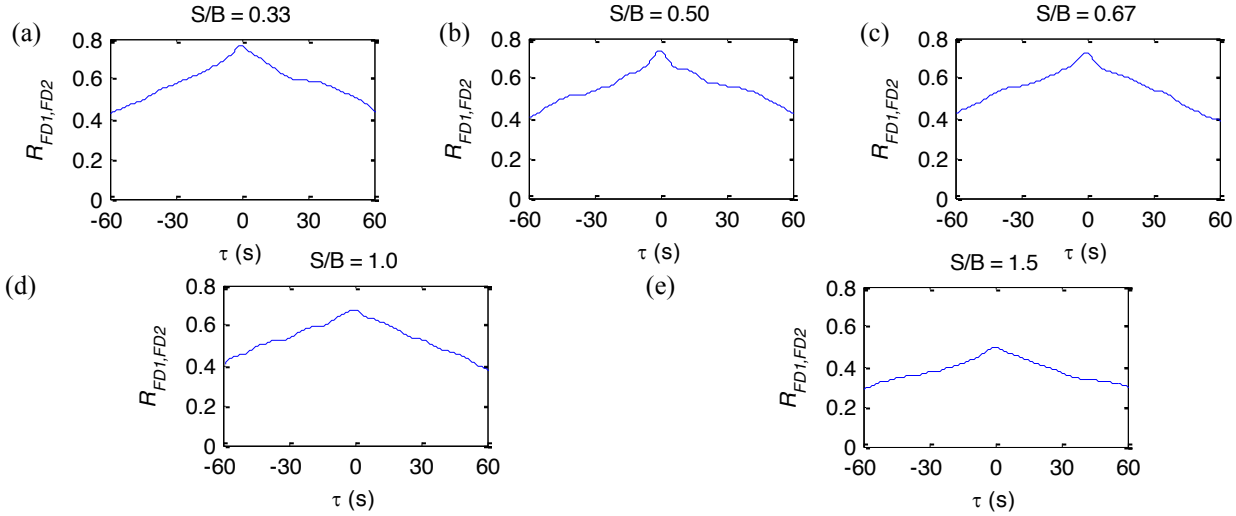

Figure 9 Inter-building correlation function between along-wind forces at 0.8H for α = 0°: (a) S/B = 1/3; (b) S/B = 1/2; (c) S/B = 2/3; (d) S/B = 1; (e) S/B = 3/2

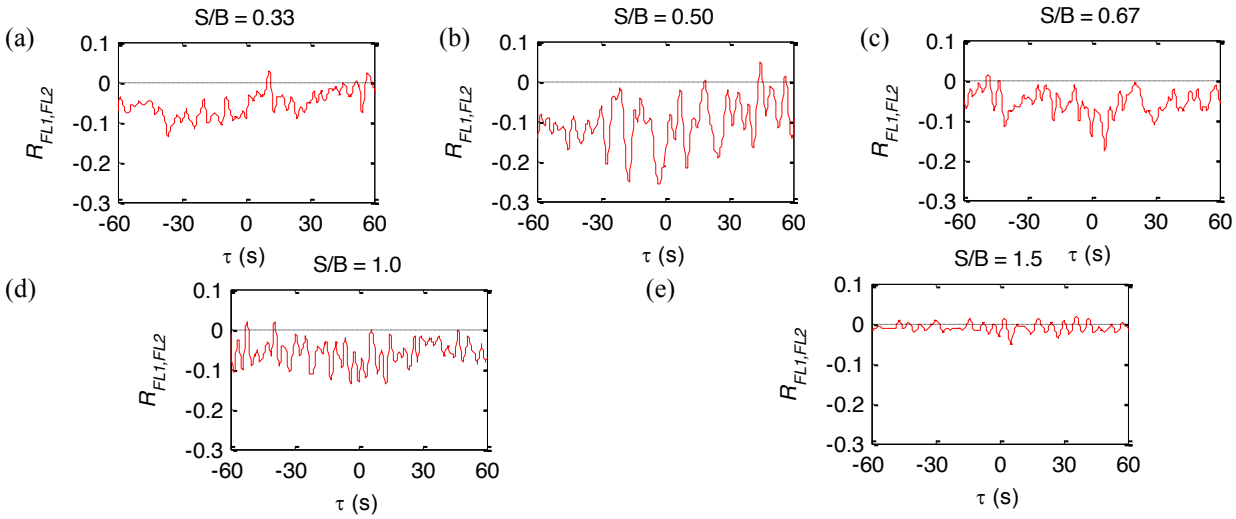

Figure 10 Inter-building correlation function between cross-wind forces at 0.8H for α = 0°: (a) S/B = 1/3; (b) S/B = 1/2; (c) S/B = 2/3; (d) S/B = 1; (e) S/B = 3/2

In addition to the spatial correlation coefficient, the inter-building temporal correlation function R for time lag τ is also calculated for the local wind forces at a representative height of 0.8H, as shown in Figs. 9 and 10. For the along-wind forces, it can be observed from Fig. 9 that for all cases, the zero time lag has the largest value and the correlation decays significantly with increasing time lag τ. Furthermore, for most of the time lags, the value of the associated correlation function decreases with increasing gap distance ratio S/B, which agrees with the trend shown in Fig. 8a. However, the correlation function for the cross-wind forces shows a rather complicated pattern, as shown in Fig. 10. As can be seen, the largest correlation does not occur at the zero time lag and the correlation does not monotonically decay with increasing time lag. For instance, the largest correlation shows at τ = -2.4s and 6.6s, for S/B = 1/2 and 2/3, respectively. More interestingly, it can be observed that the correlation

function R has embedded periodicity, albeit rather weak. Although there is no perfect coherent periodic vertex shedding in the LSs, the pressures on two outer side faces of the LBs still introduced some periodicity in the inter-building correlation between cross-wind forces.

Effect of Correlation on the Wind-induced Responses of LBs

In this section, the effects of inter-building correlation on the wind-induced responses of LBs are examined. Five LBS cases with different gap distances are considered. In order to highlight the effects from inter-building wind load correlation, modal properties of the five LBS cases are assumed to be identical to those in case 2 (S/B = 1/2). In this way, the structural coupling due to the link is equal in these five cases and thus the difference between the resulting responses can be attributed only to aerodynamic forces. The structural system for case 2, which is the same as that in Song and Tse (2014). The first three frequencies of the system are 0.239 Hz (x direction), 0.239 Hz (y direction), and 0.297 Hz (θ direction). A damping ratio of 2% is set for all modes.

Due to the link-induced structural coupling, the two connected towers in an LBS behave as a whole to resist the external wind forces. Therefore, the wind forces on both towers should be considered simultaneously to precisely determine their wind-induced responses. For example, the j-th generalized force F^*_j on the overall LBS is the summation of generalized force components from both towers, so,

$$\begin{aligned} F_j^*(t) &= F_{j,tower1}^*(t) + F_{j,tower2}^*(t) \\ &= \sum_{i=1}^{m} F_{c,1}(z_i,t)\Phi_{tower1,j}(z_i) + \sum_{i=1}^{m} F_{c,2}(z_i,t)\Phi_{tower2,j}(z_i) \end{aligned} \tag{3}$$

where $\Phi_{tower1,\,j}$ and $\Phi_{tower2,\,j}$ are the j-th mode shape components of Tower 1 and Tower 2, respectively; and $F^*_{j,\,tower1}$ and $F^*_{j,\,tower2}$ are the generalized wind force components of Tower 1 and Tower 2, respectively. Clearly, the inter-building correlation between the generalized force components of the two towers (i.e., $F^*_{j,\,tower1}$ and $F^*_{j,\,tower2}$) implicitly presents in Eq. 3 and plays an important role in the summation and hence has an influence on the related wind-induced responses.

Fig. 11 shows the inter-building correlation coefficients ρ_{F^*in} between the generalized force components of the two towers without a link (i.e., the unlinked case) for the first in-phase modes in along-wind and cross-wind directions. It can be observed that the correlation coefficient ρ_{F^*in} for the along-wind forces decreases gradually as the gap distance increases, because the correlation between along-wind forces on the two towers (i.e., $F_{tower1}(z,\,t)$ and $F_{tower2}(z,\,t)$) decays with the increase of gap distance, as shown in Fig. 8a. However, ρ_{F^*in} for cross-wind forces does not vary in the same manner with the gap distance ratio S/B. This is because cross-wind forces result from the pressure fluctuations under the separated shear layer from the side faces and hence the associated correlation may not bear a direct relationship with gap distance. Other tertiary influences also play a role like the turbulence from building edges. Similar to the variation shown in Fig. 8b, the correlation for the cross-wind forces increases when S/B increases from 1/3 to 1/2, whereas decreases when S/B increases from 1/2 to 3/2.

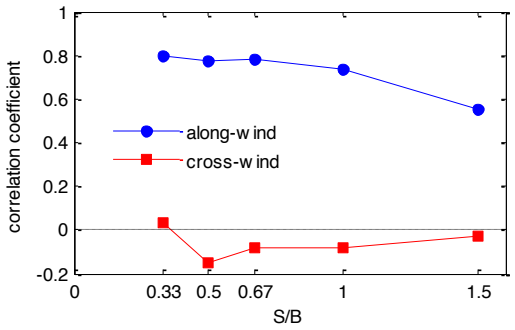

Figure 11 Correlation coefficient ρ_{F^*in} for all LB cases

In order to quantify the effect of the inter-building aerodynamic correlation on the wind-induced responses, a ratio $r_{response}$ is introduced, which is defined as

$$r_{response} = \frac{\sigma_{acc,link}}{\sigma_{acc,nolink}} \tag{4}$$

where $\sigma_{acc,\,link}$ is the standard deviation of the top acceleration response in the case of an LBS; $\sigma_{acc,\,nolink}$ is that in the associated unlinked case.

The relationship between the inter-building correlation coefficient ρ_{F^*in} and $r_{response}$ is illustrated in Fig. 12. Clearly, for both along-wind and cross-wind responses, $r_{response}$ increases with increasing ρ_{F^*in}. This indicates that when ρ_{F^*in} is large in the unlinked case, installing a link (even with large stiffness) does not significantly decrease the response in the associated LBS. This is because large value of ρ_{F^*in} means that the resulting in-phase generalized force component is relatively large, whereas the resulting out-of-phase generalized force component is relatively small. It has been confirmed in (Song and Tse, 2014) that link's stiffness only increases the frequency of the out-of-phase mode and thus only decreases the out-of-phase response component. Therefore, if the out-of-phase generalized force component is small (i.e., ρ_{F^*in} is large), the minor decrease in the out-of-phase modal response component will not lead to significant reduction in the total response. However, when ρ_{F^*in} is small, the response in the associated LBS can be reduced significantly, because in this case the out-of-phase response component is relatively considerable. For instance, the value of ρ_{F^*in} for along-wind response in S/B = 1/3 is large (0.8) so the value of $r_{response}$ is up to 90%, indicating that for this case installing a link has no significant effect on the reduction of response in the along-wind response. In contrast, the value of ρ_{F^*in} for along-wind response in S/B = 3/2 is relatively small (0.56), and so the $r_{response}$ is decreased to 70%. This indicates that in this case, the along-wind response in the LB is decreased by 30%, compared to the response in the associated unlinked case. In addition, it can be observed that reduction in cross-wind response is more significant than that in along-wind response, because the correlation coefficient ρ_{F^*in} between cross-wind forces is much smaller than that between along-wind forces. All these results clearly emphasize that the inter-building correlation plays a significant role in determining the reduction in the response of LBs.

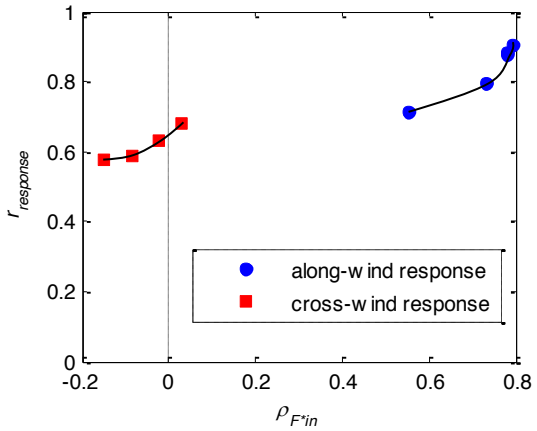

Figure 12 Relationship between the inter-building correlation coefficient ρ_{F^*in} and the response ratio $r_{response}$

CONCLUSIONS

This study investigated the intra-building and inter-building aerodynamic correlations of linked buildings and their effects on their wind-induced response by employing spatiotemporal wind pressure data measured from a series of SMPMS wind tunnel tests. The intra-building correlation for LBSs was compared with that for a single building. The correlation between along-wind and torsional wind force components on the single building is negligible, whereas the correlation for the LBSs is noteworthy, due to the channeling effect. For smaller ratios of S/B the correlation is more pronounced. It was shown that for the examined wind direction (i.e., $\alpha = 0^o$) and the building configurations considered, the inter-building correlation between two along-wind forces decays with the increase of gap distance, whereas that between the cross-wind forces does not show a similar relationship with the gap distance. In addition, it was illustrated that inter-building correlation has an important effect on the wind-induced response of LBSs. For the same link, if the inter-building correlation coefficient ρ_{F^*in} is high, there is no significant reduction in the response of the associated LBSs (compared to the two buildings without a link). However, if the correlation coefficient ρ_{F^*in} is low, the associated LBSs can show significant reduction in the response. In short, there is a positive relationship between the correlation coefficient ρ_{F^*in} and the wind-induced response of LBSs.

ABSTRACT

Modal identification is a technique that can assess modal properties of structures based on vibration data. This technique can be categorized into known and unknown input modal identification. Known input modal identification, e.g. forced vibration tests, is more economically demanding because of the need of special devices to generate artificial loading but the data obtained has higher signal-to-noise ratio. Unknown input modal identification, e.g. ambient vibration, could be performed economically with structures under working conditions. This study employs a fast Bayesian FFT method to not only identify the modal parameters, such as natural frequencies and damping ratios, but also quantify the uncertainties associated with the modal identification results. This provides a tool to investigate the uncertainties in the modal identification. In this study two numerical examples are used to generate synthetic data for investigating and comparing the uncertainties in the known and unknown input modal identification.

KEYWORDS

Known input, unknown input, modal identification, uncertainty, Bayesian, FFT.

INTRODUCTION

Modal identification is a process to assess the actual dynamic properties, such as the natural frequencies, damping ratios and mode shapes, of structures using vibration data. It is one of the important components in vibration control and structural health monitoring. Modal identification can be classified into known and unknown input excitation condition. The former usually refers to force vibration test (Edwin 2000; Au and Ni 2013) using artificial input loading, in which both loading and response of structures are simultaneously measured during the test. The latter (Brownjohn 2003; Au 2011; Au 2012; Au et al. 2013; Au and Zhang 2016) usually refers to a case where only response is measured during the test, e.g. unknown loading from wind acting on buildings.

The known input excitation modal identification requires special devices, such as shaker or impulse hammer, to generate the artificial input loading, and hence, it is more economically demanding. However, this approach is usually able to achieve a good signal-to-noise (s/n) ratio for the measured vibration data. The unknown input excitation modal identification can be performed economically. It assumes the loading is statistically random, and hence, it does not require specific knowledge of loading, special device to generate the artificial input loading, and can be carried out with structure under working condition. Since the loading is not measured, the process of modal identification is more sophisticated.

In the literature different methods have been developed to identify the modal parameters from vibration data for known and unknown input excitation modal identification. For the known input excitation condition, half-power bandwidth method (Zembaty and Kowalski 2000) and least-square fitting of frequency response function (Maia et al. 2003) have been used to determine the modal parameters from vibration data consisting of the input loading and responses of structures. For the unknown input excitation condition, natural excitation technique (James et al. 1995) and stochastic subspace identification method (Reynders et al. 2007) have been developed for ambient modal identification in the literature.

There are a number of challenges in determining the modal parameters in practical situation through vibration data, such as the limited number of sensors, limited frequency bandwidth in response, modelling error and measurement noise. There are always uncertainties associated with the identified modal parameters. Recently a Bayesian system identification approach has been proposed to address these challenges (Beck and Katafygiotis 1998; Papadimitriou et al. 2001; Beck 2010). Time-domain Bayesian formulation for system identification with known input excitation data (Yuen and Katafygiotis 2002) and ambient data have been developed in the literature (Yuen and Katafygiotis 2001). However, a frequency-domain formulation can provide a more robust approach in stochastic modelling of the prediction error that account for the discrepancy between the model and measured data. In addition it also allows the modal identification carried out using only the spectral data in a selected frequency band dominated by the contributing modes of interest, and hence, it can improve the accuracy in the modal identification. In frequency-domain, a Bayesian approach (Yuen and Katafygiotis 2003) using fast Fourier transform of vibration data has been developed for unknown input excitation modal identification previously. Recently efficient algorithm that allows practical implementation in the modal identification has been proposed for known and unknown input excitation condition. The fast Bayesian modal identification approach for modal identification of structures has been developed for known single-input force vibration (Au and Ni 2013) and unknown input excitation condition (Au 2012). Although methods have been developed to quantify the uncertainties associated with the identified modal parameters, the relationship between known and unknown input excitation conditions and insights into the uncertainties associated with the identified modal parameters are still unclear.

The objective of this study is to investigate the uncertainties associated with identified modal parameters of structures under known and unknown input excitation condition. In this study the fast Bayesian approaches for known and unknown input excitation condition have been employed to not only identify the modal parameters, but also the associated uncertainties. The next section first presents the Bayesian formulations for known and unknown input excitation condition, which includes the Bayesian fast Fourier transform (FFT) formulation for known and unknown input condition, calculation of posterior uncertainties and definition of modal s/n ratio. After that a numerical case study is carried out identify the modal parameters and quantify the associated uncertainties. Finally, conclusions are then drawn.

BAYESIAN FFT MODAL IDENTIFICATION THEORY

Bayesian FFT Formulation

In this study the fast Bayesian FFT modal identification approach (Yuen et al. 2002; Au 2012; Au and Ni 2013) is employed to not only identify the modal parameters but also their associated uncertainties. The following sections briefly explain methods for known and unknown input condition in the modal identification. In the context of modal identification, the measured acceleration $\{\hat{\ddot{\mathbf{x}}}_j \in R^n : j = 1,...,N\}$, where N is the number of samples per measurement channel, is modeled as

$$\hat{\ddot{\mathbf{x}}}_j = \ddot{\mathbf{x}}_j(\theta) + \varepsilon_j \tag{1}$$

where $\ddot{\mathbf{x}}_j(\theta)$ is the model acceleration response given by a set of modal parameters . $\{ _j \quad R^n\}$ is the prediction error that is the discrepancy between the measured response and the model response. Taking FFT on Eq. (1), the prediction error model in the frequency domain is

$$\hat{\mathcal{F}}_k = \mathcal{F}_k(\theta) + \varepsilon_k \tag{2}$$

where $\mathcal{F}_k(\theta)$ is the FFT of the model acceleration response corresponding to frequency $f_k = (k \quad 1)/N \quad t$. $_k \quad C^n$ is FFT of the prediction error at frequency f_k and assumed has a flat PSD in the frequency band of interest. The FFT of the measured acceleration response $\hat{\mathcal{F}}_k$ is defined as

$$\hat{\mathcal{F}}_k = \sqrt{\frac{2\Delta t}{N}} \sum_{j=1}^{N} \ddot{\mathbf{x}}_j \exp\left[-2\pi \mathbf{i} \frac{(k-1)(j-1)}{N} \right] \quad \text{for} \quad k = 1,...,N \tag{3}$$

where t is the sampling interval and $\mathbf{i}^2 = \quad 1$. For $k = 2,3,...,N_q$, the FFT corresponds to frequency $f_k = (k \quad 1)/N \quad t$, where $N_q = \text{int}[N/2] + 1$ is the frequency index at the Nyquist frequency and int[×] denotes the integer part of its argument. The scaling factor $\sqrt{2 \quad t / N}$ is defined such that the spectral density is one-sided with respect to the physical frequency in Hz rather than circular frequency in rad/s. In the modal identification the values for $k = 1$, $N_q + 1$, $N_q + 2,...,N$ are ignored because the former simply gives a scaled sample average of the signal due to the voltage offset of the measurement channel; the latter are the conjugate mirror image of those values at $k = 2,3,...,N_q$, hence, providing no addition information. Thus only $(N_q \quad 1)$ FFT values are used in the modal identification. In practice only FFT data within the selected resonant frequency band covering the modes of interest are used for modal identification as remaining band contains only

negligible or irrelevant information, which tend to increase the error in the modal identification. Hence, the FFT data used in the modal identification only over N_f frequencies in the selected resonant frequency bands.

Known Input Modal Identification

For modal identification with measured acceleration response and known input force, the modal parameters to be identified consist of the natural frequencies $\{f_i : i = 1,...,m\}$, damping ratios $\{\ _i : i = 1,...,m\}$ mode shapes $\{\ (i)\ \ R^n : i = 1,...,m\}$, modal mass $\{M_i : i = 1,...,m\}$ and the power spectral density (PSD) of prediction error S_e. Let $\mathbf{Z}_k = [\mathrm{Re}\,\mathcal{F}_k(\theta), \mathrm{Im}\,\mathcal{F}_k(\theta)]^T \in R^{2n}$ and $\hat{\mathbf{Z}}_k = [\mathrm{Re}\,\hat{\mathcal{F}}_k, \mathrm{Im}\,\hat{\mathcal{F}}_k]^T \in R^{2n}$ are an augmented vector comprising the real and imaginary part of $\mathcal{F}_k(\theta)$ and $\hat{\mathcal{F}}_k$, respectively. Using the Bayes' theorem and assuming a non-informative prior distribution, the posterior probability density function (PDF) of given the FFT of the measured data is given by

$$p\left(\ \middle|\left\{\hat{\mathbf{Z}}_k\right\}\right) \mu\ p(\ )\, p\left(\left\{\hat{\mathbf{Z}}_k\right\}\middle|\ \right) \tag{4}$$

where $p(\ )$ is the prior PDF that reflects the plausibility of in the absence of data. A non-informative prior is common condition because the variation in the posterior PDF is often dominated by the likelihood function with large amount of data, hence, the posterior PDF $p(\ |\{\hat{\mathbf{Z}}_k\})$ is directly proportional to the likelihood function $p(\{\hat{\mathbf{Z}}_k\}|\ )$. The likelihood function in individual frequency is given by (Au and Ni 2013)

$$p\left(\left\{\hat{\mathbf{Z}}_k\right\}|\ \right) = \prod_k \frac{1}{(2\ )^n \det\left(\mathbf{C}_{ik}\right)^{1/2}} \exp\left[\ -\frac{1}{2}\left(\hat{\mathbf{Z}}_k\ \ \mathbf{Z}_k\right)^T \mathbf{C}_k^{\ 1}\left(\hat{\mathbf{Z}}_k\ \ \mathbf{Z}_k\right)\right] \tag{5}$$

where $\mathbf{C}_k$ is the covariance matrix of $\hat{\mathbf{Z}}_k$. Since it is assumed that the sample size N is large, the $\mathrm{Re}\,\hat{\mathcal{F}}_k$ and $\mathrm{Im}\,\hat{\mathcal{F}}_k$ of $\hat{\mathbf{Z}}_k$ are asymptotically independent and have a variance of $S_e/2$. The likelihood function can be simplified and its compact form is

$$p\left(\left\{\hat{\mathbf{Z}}_k\right\}|\theta\right) = (2\pi)^{-nN_f}\left(\frac{S_e}{2}\right)^{-nN_f} \exp\left[-S_e^{-1}\sum_k \left[\hat{\mathcal{F}}_k - \mathcal{F}_k(\theta)\right]^* \left[\hat{\mathcal{F}}_k - \mathcal{F}_k(\theta)\right]\right] \tag{6}$$

where

$$\mathcal{F}_k(\theta) = S_k \sum_{i=1}^{m} h_{ik}\Phi_r(i) \tag{7}$$

and $h_{ik} = [(\ _{ik}^{\ 2}\ \ 1) + \mathbf{i}(2\ _{\ i\ \ ik})]^{\ 1}$ is the (complex) transfer function of the ith mode evaluated at frequency f_k. $_{ik} = f_i / f_k$ is a frequency ratio. S_k is FFT of the measured acceleration of the moving mass of the shaker at frequency f_k. S_e is the spectral density of the prediction error and $_r(i) = r_i\ \ (i)$. In this study the mode shape is normalized such that it is equal to unity at the input degree-of-freedom (dof) I, and hence, $_r(I,i) = r_i$.

It is more convenient to work with the negative log-likelihood function (NLLF), so that

$$p\left(\ \middle|\left\{\hat{\mathbf{Z}}_k\right\}\right) \propto \exp[\ \ L(\ )] \tag{8}$$

where

$$L(\theta) = nN_f \ln\pi + nN_f \ln S_e + S_e^{-1}\sum_k \left[\hat{\mathcal{F}}_k - \mathcal{F}_k(\theta)\right]^* \left[\hat{\mathcal{F}}_k - \mathcal{F}_k(\theta)\right] \tag{9}$$

For globally identifiable case under the condition of high sampling rate and long duration of data in the modal identification, the posterior PDF can be well approximated by a Gaussian PDF, which is equivalent to second order approximation of $L(\ )$. Let $\hat{\ }$ be the most probable value (MPV), which maximises the posterior PDF, and hence, minimises the NLLF. Consider the second-order Taylor series about

$$L(\ )\ \ L\left(\hat{\ }\right) + \frac{1}{2}\left(\ \ \hat{\ }\right)^T \mathbf{H}_L\left(\hat{\ }\right)\left(\ \ \hat{\ }\right) \tag{10}$$

where $\mathbf{H}_L(\ )$ is the Hessian of Eq. (9) at the MPV. Substituting Eq. (10) into Eq. (8), the posterior PDF becomes a Gaussian PDF

$$p\left(\ \middle|\hat{\mathbf{Z}}_k\right) \propto \exp\left[\ -\frac{1}{2}\left(\ \ \hat{\ }\right)^T \hat{\mathbf{C}}^{\ 1}\left(\ \ \hat{\ }\right)\right] \tag{11}$$

where $\hat{\mathbf{C}}$ is the posterior covariance matrix and is given by

$$\hat{\mathbf{C}} = \mathbf{H}_L\left(\hat{\ }\right)^{\ 1} \tag{12}$$

It can be seen that the Gaussian PDF is completely characterised by the MPV and the covariance matrix, hence, a fast computation of these quantities is important for practical implementation of the Bayesian method

Unknown Input Modal Identification

In unknown input modal identification, the prediction error and modal forces can be modelled as independent and identically distributed (i.i.d.) Gaussian white noise and stationary process with a constant spectral density matrix, i.e. independent of k, respectively. The modal parameter to be identified consists of natural frequencies $\{f_i : i = 1,...,m\}$, damping ratios $\{ _i : i = 1,...,m\}$, mode shapes $\{ (i) \ R^n : i = 1,...,m\}$, Hermitian PSD matrix of modal forces $\mathbf{S} \ R^{m \ m}$, and power spectral density of prediction error S_e. For large N and small time step in the data acquisition, $\hat{\mathbf{Z}}_k$ are asymptotically independent at different frequencies and their real and imaginary part follow a Gaussian distribution (Yuen and Katafygiotis 2003). The likelihood function $p(\hat{\mathbf{Z}}_k| \ )$ is then given by

$$p\left(\left\{\hat{\mathbf{Z}}_k\right\}| \ \right) = (2 \ )^{nN_f}\left[\prod_k \det \mathbf{C}_k(\ )\right]^{\frac{1}{2}} \exp\left[\ \frac{1}{2}\sum_k \hat{\mathbf{Z}}_k^T \mathbf{C}_k(\ )^{1} \hat{\mathbf{Z}}_k\right] \tag{13}$$

where $\det(\times)$ denotes the determinant. The sum and product are over the N_f frequencies in the selected frequency band. $\mathbf{C}_k$ depends on , and is given by

$$\mathbf{C}_k = \frac{1}{2}\begin{bmatrix} \left(\mathrm{Re}\,\mathbf{H}_k\right)^{T} & \left(\mathrm{Im}\,\mathbf{H}_k\right)^{T} \\ \left(\mathrm{Im}\,\mathbf{H}_k\right)^{T} & \left(\mathrm{Re}\,\mathbf{H}_k\right)^{T} \end{bmatrix} + \frac{S_e}{2}\mathbf{I}_{2n} \tag{14}$$

where the first and second term account for the contribution from the model response and prediction error, respectively. $= [\ (1),..., \ (m)] \ R^{n \ m}$ is the mode shape matrix confined to the measured dofs. $\mathbf{I}_{2n}$ is the $2n \ \ 2n$ identity matrix. $\mathbf{H}_k$ is the theoretical spectral density matrix of the model response with (i,j) entry given by

$$\mathbf{H}_k(i,j) = S_{ij} h_{ik} h_{jk}^* \tag{15}$$

where S_{ij} is the cross spectral density between the ith and jth modal force. The posterior PDF $p(\ |\hat{\mathbf{Z}}_k)$ in terms of the NLLF $L(\ )$ as

$$p\left(\ |\hat{\mathbf{Z}}_k\right) \propto \exp[\ L(\ )] \tag{16}$$

where the log-likelihood function $L(\ )$ is defined as

$$L(\ ) = \frac{1}{2}\sum_k \left[\ln \det \mathbf{C}_k(\ ) + \hat{\mathbf{Z}}_k^T \mathbf{C}_k(\ )^{1} \hat{\mathbf{Z}}_k\right] \tag{17}$$

For a sufficiently large amount of data, the posterior PDF can be well-approximated by a Gaussian PDF centred at the most probable value. Considering the second order Taylor series about $\hat{}$ with the first term vanishes due to optimality of $\hat{}$, it can be shown that the posterior covariance matrix is equal to the inverse of the Hessian of $L(\ )$ evaluated at the most probable value.

Posterior Uncertainties

In known and unknown input forced modal identification, the MPV of the modal parameters are determined by maximizing $p(\ |\hat{\mathbf{Z}}_k)$, which is equivalent to minimizing NLLF. The posterior covariance matrix is then approximated by the inverse of the Hessian of the NLLF. In this study, coefficient of variation (c.o.v.) is used as an indicator of the uncertainties associated with the identified modal parameters. The c.o.v. is calculated as the ratio of the square root of variance, which is the corresponding diagonal element of the posterior covariance matrix, to the MPV value.

Modal Signal-to-noise Ratio

This section defines the modal s/n ratio, and hence, to provide an indication of the quality of the data for modal identification and assist interpreting the identification results. A modal s/n ratio is defined as the PSD of acceleration response to the PSD of the prediction error as

$$= \frac{S}{4S_e^{\ 2}} \tag{18}$$

This is organically defined in the case of unknown input forced modal identification. In the case of known input force modal identification, $S = S_F r^2 \| \ \|^2 \ \ _I^2$ where S_F is the PSD of the shaker acceleration within the selected frequency band and $_I$ is the mode shape value at the shaker dof.

NUMERICAL CASE STUDIES

Effect of Modal Signal-to-noise Ratio

A two-story shear building was considered to study the effect of different levels of measurement noise on uncertainties associated with the identified modal parameters. The height of the first and second story of the shear building is 4 m and 3 m, respectively. The shear building has uniform mass 5600 kg, and the inter-story stiffness of the first and second story is 1.769×10^7 N/m and 1.244×10^7 N/m. The natural frequencies are 3.261 Hz and 11.211 Hz. The damping ratio is assumed to be 1% in all modes. It is assumed that an accelerometer was installed at each story to measure the acceleration responses in horizontal direction. The measured responses are assumed with sampling rate at 100 Hz. It is assumed that the measured acceleration was contaminated by i.i.d. Gaussian white noise with a root PSD of 1×10^{-6} $g/\sqrt{Hz}$. Pseudo-random excitation with different magnitudes and having a flat root PSD from 0.1 Hz to 20 Hz frequency band is applied to the second floor of the shear building. The excitation signal was generated by band-passing a Gaussian white noise signal through a second order Butterworth filter. 185 s acceleration responses were measured, which covers 10 s before the shaker is turned on, 140 sec pseudo-random excitation, and 35 s free vibration after the shaker is turned off.

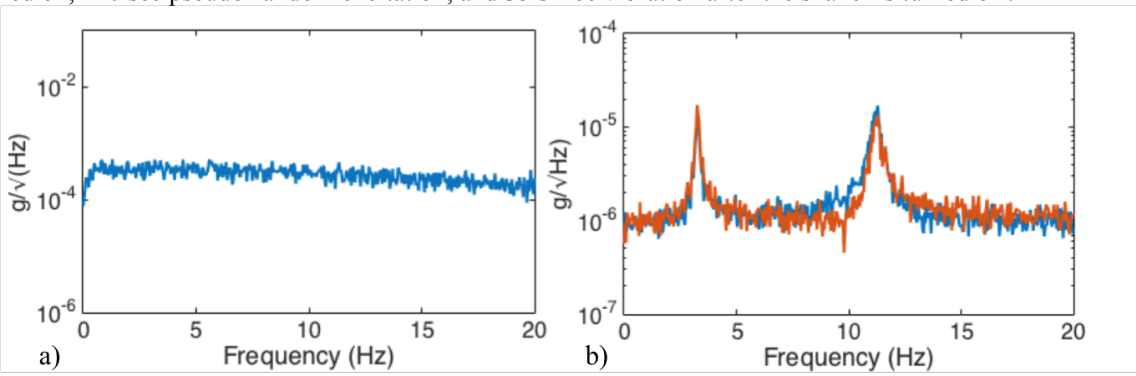

Figure 1 a) Root PSD spectrum of shaker mass applied on the two-storey shear building and b) corresponding root PSD spectrum of acceleration data

Figure 1a shows one of the considered Pseudo-random excitations applied on the second floor of the two-story shear building. The root PSD spectrum of the measured acceleration responses at the first and second story of the two-story shear building are shown in Figure 1b. Figure 1b shows that two modes are adequately excited with their resonance peaks apparent. The known and unknown input fast Bayesian FFT modal identification are used to identify the modal parameters, i.e. natural frequencies and damping ratios, and quantify the associated uncertainties. In the case of the unknown input modal identification, the two-story shear building is subjected to the same excitation as the known input case. However, the measured input loading is not used, and hence, it is output-only modal identification. Two modes are identified separately with a single mode (m=1) assumed within each band. In this study the FFT data within frequency bands (3.065 – 3.457 Hz) and (10.539 – 11.884 Hz) are used to identify the 1st and 2nd mode, respectively.

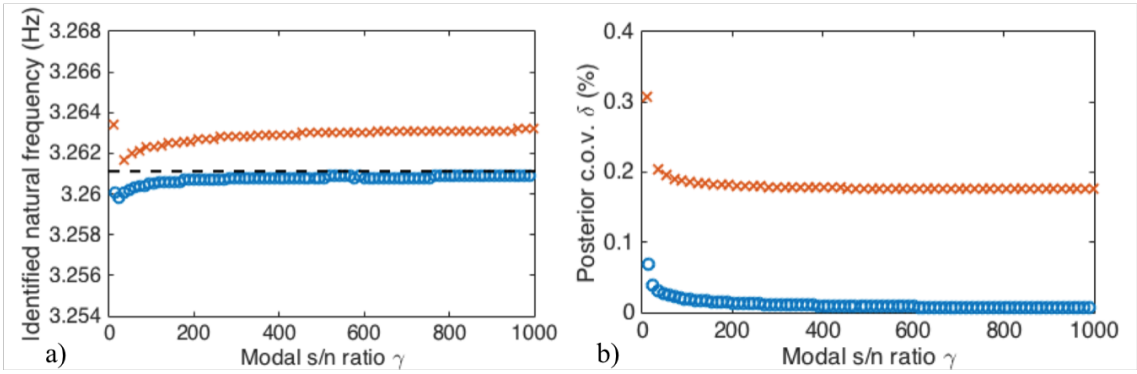

Figure 2 a) Identified 1st mode of natural frequency and b) corresponding posterior c.o.v. versus modal s/n ratios (circles: known input; crosses: unknown input; dashed line: true value)

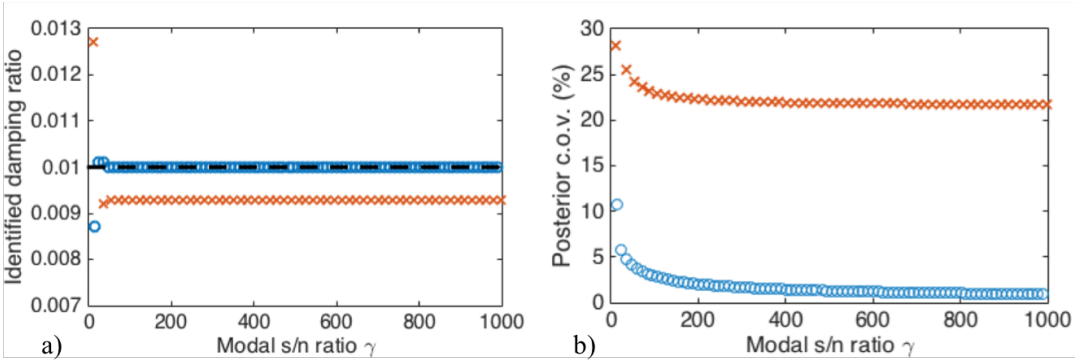

Figure 3 a) Identified 1st mode of damping ratio and b) corresponding posterior c.o.v. versus modal s/n ratios (circles: known input; crosses: unknown input; dashed line: true value)

Figures 2a and 3a show the identified 1st mode natural frequencies and damping ratios using known and unknown input modal identification. The modal s/n ratio rather than the excitation magnitude is shown, as it is dimensionless and more informative. The results show that the natural frequencies and damping ratios identified by known and unknown input modal identification are close to the true value. However, the natural frequencies and damping ratios identified by the known input modal identification have better agreement with the true value than the unknown input modal identification. Figures 2b and 3b shows the posterior c.o.v. of the identified natural frequencies and damping ratios, respectively. It can be seen that the value of the posterior c.o.v. decreases with the increase in the modal s/n ratio. For the case of unknown input modal identification, the posterior c.o.v. of natural frequency and damping ratio tend to be a constant at 0.174% and 21.635%, respectively, which are much higher than the posterior c.o.v. in the known input excitation modal identification (0.003% and 0.491% for natural frequencies and damping ratios). The reason is that the unknown input modal identification does not have the loading information, and hence, it always has larger uncertainty associated with the identified natural frequencies and damping ratios. The identified natural frequencies and damping ratios and the associated posterior c.o.v. for the 2nd mode versus different modal s/n ratios are also shown in Figures 4a and 5a, and Figures 4b and 5b, respectively. A similar phenomenon is observed in the results for 2nd mode.

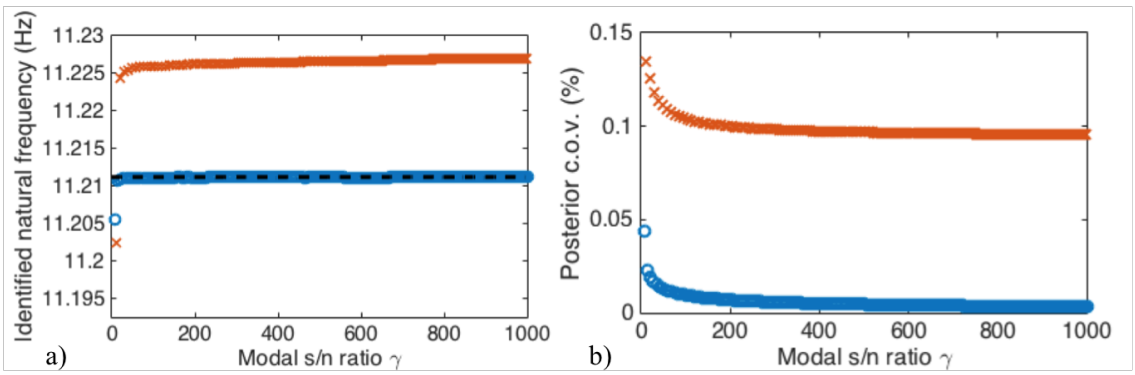

Figure 4 a) Identified 2nd mode of natural frequency and b) corresponding posterior c.o.v. versus modal s/n ratios (circles: known input; crosses: unknown input; dashed line: true value)

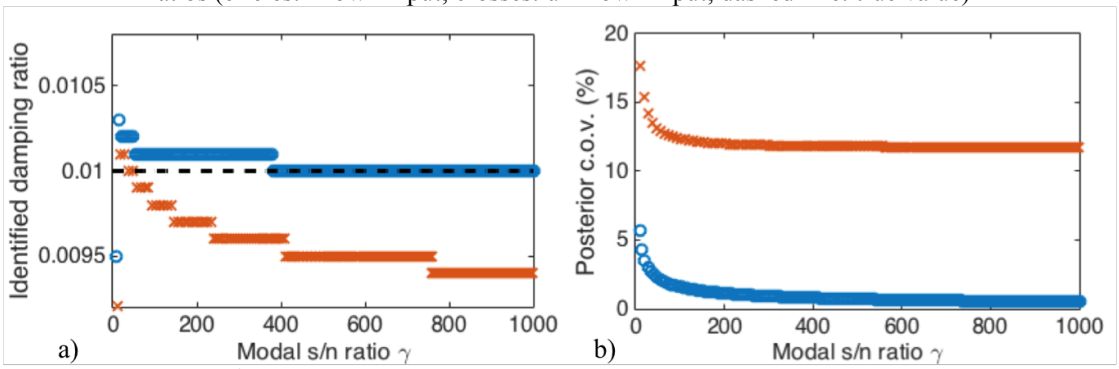

Figure 5 a) Identified 2nd mode of damping ratio and b) corresponding posterior c.o.v. versus modal s/n ratios (circles: known input; crosses: unknown input; dashed line: true value)

Effect of Measured Number of Degrees-of-freedom

The second example is a ten-story shear building. It was used to study the effect of measured number of dofs. The ten-storey shear building has uniform floor mass of 100 ton, inter-story stiffness of 177 kN/mm and damping ratio of 1% in all modes. The natural frequency of the first two modes are 1 Hz and 2.98 Hz. It is assumed that a shaker is installed on the top of the building to generate horizontal excitation. The excitation signal is a pseudo-random excitation with a flat root PSD from 0.1 Hz to 20 Hz. This example considers increasing number of accelerometers installed from the top to the bottom of the ten-story shear building. The sampling rate of each accelerometer is 100 Hz in the simulation and the data is contaminated by i.i.d. channel noise with a root PSD of $1\times10^{-6}\ g/\sqrt{Hz}$. The data covers 50 s before the shaker is turned on, 500 s forced vibration during the shaker is turned on, and 50 s free vibration after the shaker is turned off. Table 1 summarized the number of measured dof and the locations for the ten-story shear building.

Number of measured dof *n*	Floors with accelerometer installed
2	10/F, 9/F
3	10/F, 9/F, 8/F
4	10/F, 9/F, 8/F, 7/F
5	10/F, 9/F, 8/F, 7/F, 6/F
6	10/F, 9/F, 8/F, 7/F, 6/F, 5/F
7	10/F, 9/F, 8/F, 7/F, 6/F, 5/F, 4/F
8	10/F, 9/F, 8/F, 7/F, 6/F, 5/F, 4/F, 3/F
9	10/F, 9/F, 8/F, 7/F, 6/F, 5/F, 4/F, 3/F, 2/F
10	10/F, 9/F, 8/F, 7/F, 6/F, 5/F, 4/F, 3/F, 3/F, 2/F, 1/F

Table 1 Summary of the number of measured dof *n* and locations for the ten-story shear building (shaker located at 10/F)

Figure 6 shows the mode shapes for 1st and 2nd mode of the ten-story shear building. The study focuses on identifying the natural frequency and damping ratio of the 2nd mode. The reason is that the value of the mode shape component at the 7th floor is almost close to zero, which means the accelerometer installed at 7th floor does not contain much information of the 2nd mode. This is used to study the effect of the modal information measured by each accelerometer on the uncertainties associated with identified natural frequencies and damping ratios.

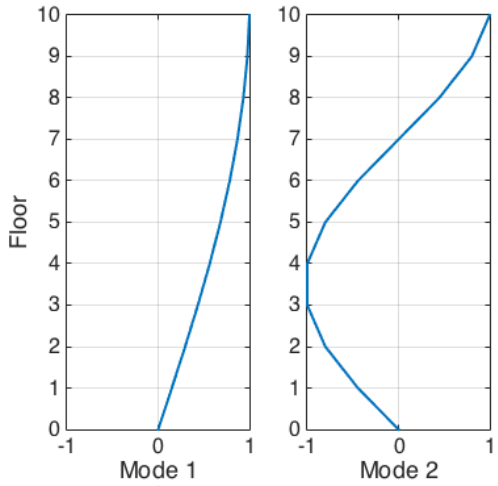

Figure 6 1st and 2nd mode shape of ten-story shear building

Figure 7 shows the modal s/n ratio versus different number of measured dofs for 1st and 2nd mode. For the 1st mode, the modal s/n ratio increases with diminishing rate as *n* increases. This is because the increasing number of accelerometers are placed from the top to the bottom on the ten-story shear building and the information measured for 1st mode at each dof increases with diminishing rate as evidenced by the mode shape of the 1st mode in Figure 6. Different to 1st mode, the modal s/n ratio of the 2nd mode does not increase much even an accelerometer is added on 7th floor. The reason is that the mode shape of the 2nd mode having an almost zero value component at this floor, which means the accelerometer installed at this floor does not provide much information of the 2nd mode.

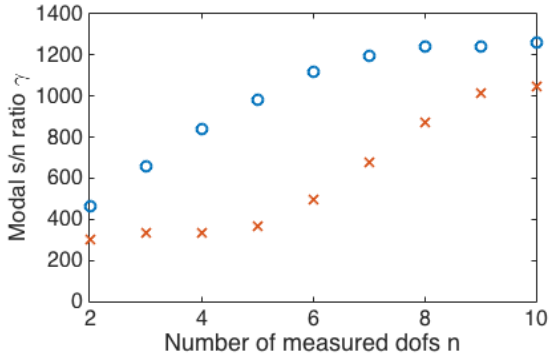

Figure 7 Modal s/n ratio versus the measured number of dofs for ten-story shear building (circles: 1st mode; crosses 2nd mode)

Figures 8 and 9 show the posterior c.o.v. of the identified natural frequencies and damping ratio for the 1st mode under known and unknown input excitation condition. As expected, the posterior c.o.v. of the identified damping ratio is much larger than the identified natural frequency. Comparing the posterior c.o.v. in known and unknown input modal identification, the uncertainty associated with the identified modal parameters is always larger than that in known input modal identification. This is because the input excitation information is not provided, and hence, there is less information available in the modal identification process. Figures 8a and 9a show that the posterior c.o.v. of the identified natural frequencies and damping ratios in known input modal identification decrease with diminishing rate as the n increases, which is consistent with modal s/n ratio as shown in Figure 7. However, the posterior c.o.v. in the unknown input modal identification is insensitivity to n as shown in Figures 8b and 9b.

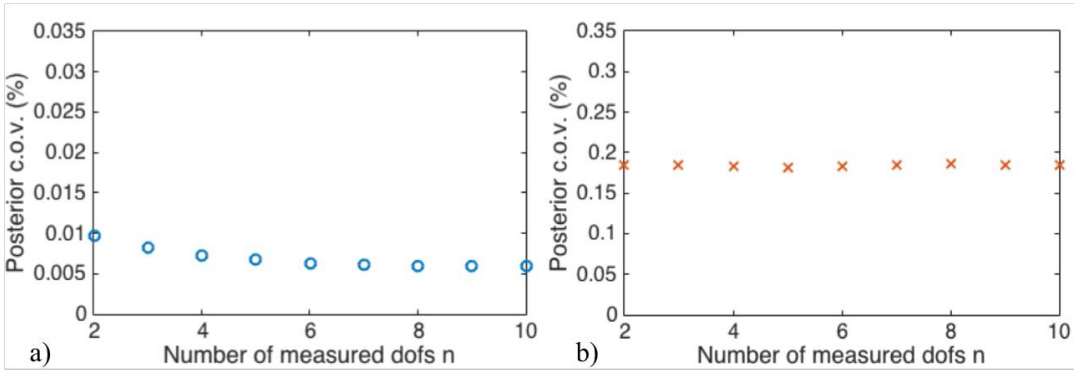

Figure 8 Posterior c.o.v. of the identified 1st mode natural frequency using a) known and b) unknown input modal identification for ten-story shear building

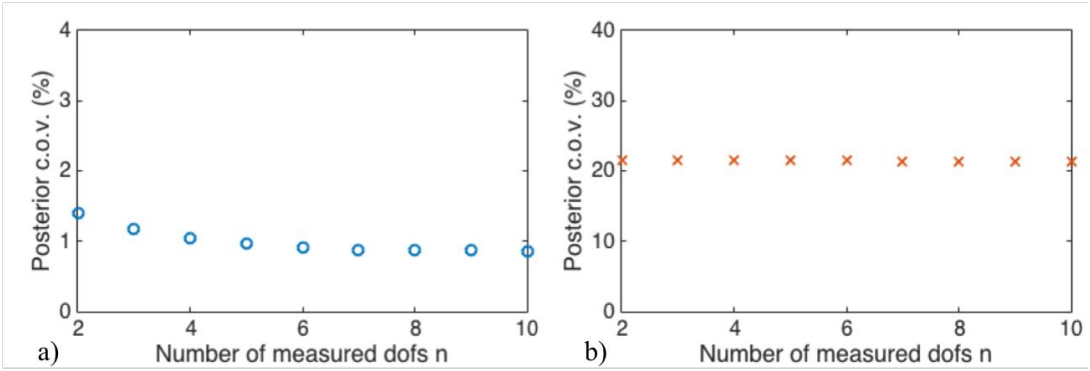

Figure 9 Posterior c.o.v. of the identified 1st mode damping ratio using a) known and b) unknown input modal identification for ten-story shear building

Figures 10 and 11 shows the identified 2nd mode natural frequency, damping ratio and the corresponding posterior c.o.v. using known and unknown input modal identification. As shown in Figure 7, the modal s/n ratio of the 2nd mode does not increase much as the 4th accelerometer (n = 4) is added to the 7th floor, where the value

of the mode shape component is almost close to zero, and hence, the accelerometer at the 7th floor does not provide much information about the 2nd mode. This is consistent with the posterior c.o.v. of the identified 2nd mode natural frequency and damping ratio under known input modal identification as shown in Figures 10a and 11a. Both figures show that the values of the posterior c.o.v. of the identified natural frequency and damping ratio do not reduce after the 4th accelerometer was added at the 7th floor. For unknown input modal identification, the values of the posterior c.o.v. are not as sensitive as the results of known input modal identification to *n*.

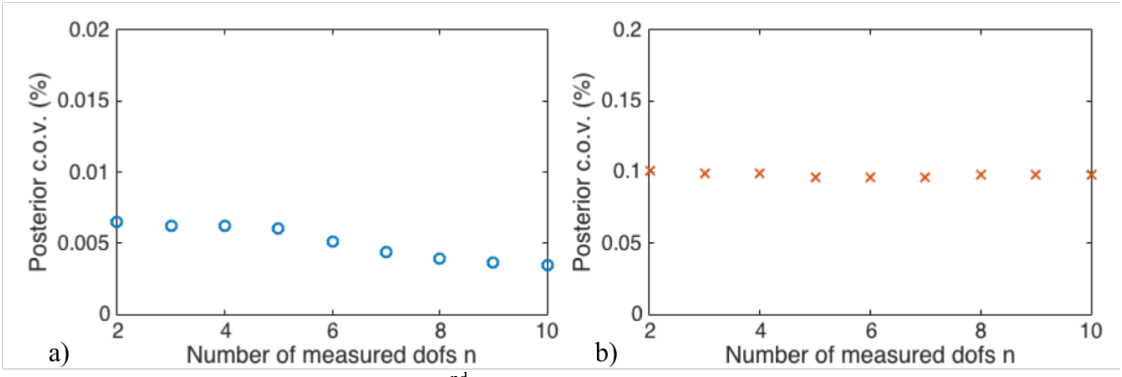

Figure 10 Posterior c.o.v. of the identified 2nd mode natural frequency using a) known and b) unknown input modal identification for ten-story shear building

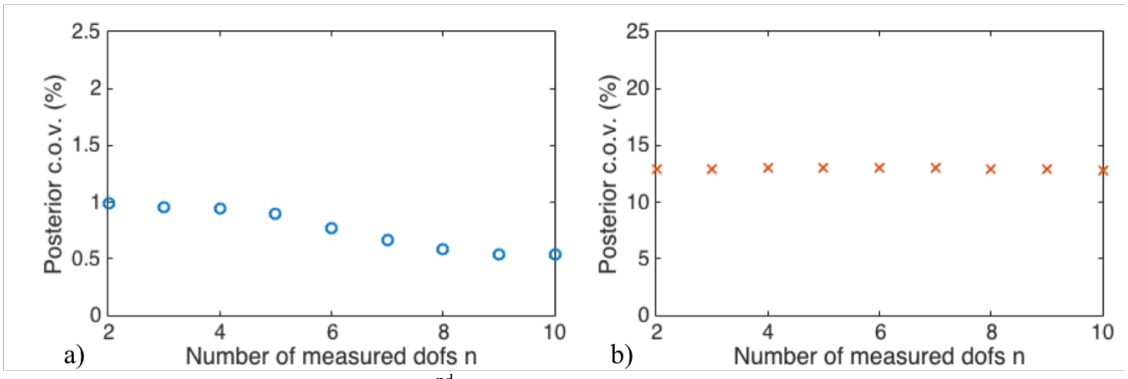

Figure 11 Posterior c.o.v. of the identified 2nd mode damping ratio using a) known and b) unknown input modal identification for ten-story shear building

CONCLUSIONS

A comparison of the uncertainties associated with the modal parameters in modal identification has been presented in this paper. The study employs a frequency-domain fast Bayesian FFT method to identify the modal parameters, such as natural frequencies and damping ratios, from vibration data. In addition to identifying modal parameters, the fast Bayesian FFT method also quantifies the associated uncertainties in modal identification. This study has analysed and compared the uncertainties in known and unknown input condition. In general the uncertainties associated with the modal parameters in unknown input modal identification is much larger than and as not as sensitive as known input modal identification to modal s/n ratio. This study has compared and provided insights on the uncertainties of known and unknown input modal identification.

A FEASIBILITY STUDY ON THE USE OF BAYESIAN MODEL UPDATING AND VIBRATION PREDICTION FOR STRUCTURAL DIAGNOSTIC

Heung-Fai Lam [1,*] and Jia-Hua Yang [1]
[1] Department of Architecture and Civil Engineering, City University of Hong Kong, Hong Kong, China

ABSTRACT

This paper puts forward a feasibility study on the use of Bayesian model updating and vibration prediction for structural diagnostic when the level of modeling error is relatively high. The proposed method consists of two parts. In the first part, the Markov chain Monte Carlo (MCMC)-based model updating is employed to calculate the posterior PDF of uncertain model parameters conditional a set of measurement and a given model class. Modeling error is the key problem to be addressed in the practical implementation of structural model updating or damage detection. Apart from very simple structures, model updating of real structures is usually not globally and locally identifiable. Therefore, MCMC simulation is employed in the proposed method in generating samples in the important region(s) for the approximation of the posterior PDF. In the second part, the probabilities for the vibrations of the structure to exceed a list of threshold limits (i.e., the failure probabilities) were calculated using the MCMC samples. It is believed that the failure probabilities for the damaged structure are higher than those for the undamaged one. A 3-dimensional scaled transmission tower model was tested under laboratory conditions for verifying the proposed method. To test the robustness in the detection of damage existence, artificial modelling error was introduced to the model class in the numerical case study. The numerical case study results were positive implying the feasibility of the proposed method.

Bayesian model updating, Bayesian vibration prediction, Markov chain Monte Carlo, failure probability, structural health monitoring.

INTRODUCTION

Due to rapidly aging and intense loading from earthquakes and typhoons, structures will be potentially damaged and structural failure may happen. Structural health monitoring (SHM) is critical to save human lives and prevent huge economic loss. One promising way to implement SHM is to carry out model updating of the target structure based on measured vibration data. For model updating, the mathematical model (i.e., the class of models) of the target structure is firstly established. The structural model parameters are then updated utilizing measured data. The structural properties and performance can be assessed with the updated structural model. Model updating can be categorized into deterministic (Titurus *et al*. 2003; Lee *et al*. 2014) and probabilistic (Katafygiotis *et al*.1998; Zhang and Mahadevan 2000; Beck 2010) approaches. Deterministic model updating tries to pinpoint one single solution. However, there are usually multiple equivalent solutions for model updating of complex systems (especially when the quality and quantity of measurement are not high). Under such situation, deterministic model updating needs to introduce some ad hoc constraints such that one single solution is kept and all others are discarded. The structural responses predicted from this kind of model updating result may be seriously biased. To avoid this problem, probabilistic model updating is followed in the proposed method. In order to address measurement noise and modeling error, uncertain model parameter vector $\boldsymbol{\theta}$ of the structure is considered as a random variable and the posterior PDF of $\boldsymbol{\theta}$ conditional on measured modal data $\mathbf{D}$ and the model class $\mathbf{M}$, $p(\boldsymbol{\theta}|\mathbf{D},\mathbf{M})$, is derived following Bayesian theory. Instead of pinpointing the "true" model of the structure, the relative plausibility of a set of models (in $\mathbf{M}$) is considered through updating $p(\boldsymbol{\theta}|\mathbf{D},\mathbf{M})$ (Beck and Katafygiotis 1998). Multiple models are included to perform the posterior prediction with each model weighted by $p(\boldsymbol{\theta}|\mathbf{D},\mathbf{M})$.

Identifying the posterior PDF is a challenging task. If the uncertainty is small and $\boldsymbol{\theta}$ is globally identifiable, the posterior PDF can be approximated by a Gaussian PDF centered at the optimal $\boldsymbol{\theta}$ based on Laplace's method of asymptotic approximation (Beck and Katafygiotis 1998). If the uncertainty is large and the posterior PDF is

distributed in the neighborhood of an extended and usually highly complex manifold of the parameter space that cannot be calculated explicitly, the asymptotic approximation is not applicable (Katafygiotis and Lam 2002). In the reference (Katafygiotis and Lam 2002), the tangential-projection algorithm is developed to approximate the manifold and the posterior PDF can then be identified. However, the computational effort required grows tremendously with an increase in the number of uncertain model parameters. A newly developed Bayesian model updating method using MCMC (Lam *et al*. 2015; Yang *et al*. 2015) can tackle this problem. The main idea of this MCMC-based Bayesian model updating method is to draw samples from the posterior PDF and the generated samples are properly weighted to approximate the posterior PDF. The high-dimension integrations involved in Bayesian inference can be efficiently evaluated using this algorithm.

The objective of this paper is to conduct SHM through robust predictive analysis (Papadimitriou et al. 2001) based on measured modal data. Firstly, Bayesian model updating using MCMC (Lam *et al*. 2015; Yang *et al*. 2015) was conducted to identify $p(\boldsymbol{\theta}|\mathbf{D},\mathbf{M})$. MCMC was performed to sample a set of models in high probability regions for the representation (or approximation) of the posterior PDF. The sampling process was divided into multiple levels. At each level, a bridge PDF, which finally converged to the target posterior PDF in the final sampling level, was constructed. Secondly, the posterior predictive response analysis was carried out under specified excitation using the MCMC samples. To assess the target structure, failure in performance was defined as the maximum displacement of the target structure under a given excitation exceeding a pre-defined threshold value. Finally, the failure probabilities of the structure were calculated under a list of threshold limits. By continuously updating the failure probabilities of the target structure by newly measured modal data, SHM could be performed in an almost real-time basis.

METHODOLOGY

Bayesian Model Updating Based on MCMC Simulation

Considering the fractional errors of natural frequency and mode shape, the posterior PDF of the uncertain parameter vector $\boldsymbol{\theta}$ conditional on measured modal parameters $\mathbf{D}$ and a given model class $\mathbf{M}$ is formulated as (Lam et al. 2015)

$$p\left(\boldsymbol{\theta}|D,M\right)=c\exp\left(-\frac{J\left(\boldsymbol{\theta}\right)}{2\kappa^2}\right) \tag{1}$$

where

$$J\left(\boldsymbol{\theta}\right)=\sum_{a=1}^{r}\left[\left(\frac{\hat{f}_a-f_a\left(\boldsymbol{\theta}\right)}{\hat{f}_a}\right)^2+\left(1-\left|\hat{\boldsymbol{\psi}}_a^T\boldsymbol{\psi}_a\left(\boldsymbol{\theta}\right)\right|^2\right)\right] \tag{2}$$

c is a normalizing constant; κ^2 is the variance of the fractional error as defined in (Lam et al. 2015); a is the mode index; r is the number of modes included for model updating; $\hat{f}_a$ is the measured natural frequency (in Hz) of the a^{th} mode; $f_a(\boldsymbol{\theta})$ is the calculated natural frequency of the a^{th} mode; $\hat{\boldsymbol{\psi}}_a$ and $\boldsymbol{\psi}_a\left(\boldsymbol{\theta}\right)$ are the measured and calculated mode shapes of the a^{th} mode. $p(\boldsymbol{\theta}|\mathbf{D},\mathbf{M})$ is usually not an easy-to-sample PDF (e.g., Gaussian PDF) in practice. MCMC is proposed in this paper to sample from $p(\boldsymbol{\theta}|\mathbf{D},\mathbf{M})$. Because the parameter space is usually very complicated in practice, directly sampling in the whole parameter space will be inefficient. Sampling is thus divided into multiple levels. In each level, a bridge PDF which will finally converge to $p(\boldsymbol{\theta}|\mathbf{D},\mathbf{M})$ is constructed as follows.

$$p_g=c_g\exp\left(-\frac{J\left(\boldsymbol{\theta}\right)}{2\kappa_g^2}\right) \tag{3}$$

where g denotes the sampling level index. The important regions of the bridge PDFs are gradually reduced level by level through changing the variance of the fractional error.

$$\kappa_g^2=\kappa_{g-1}^2/A \tag{4}$$

where A is an algorithmic parameter. In each level, Metropolis-Hastings (MH) algorithm (Metropolis et al. 1953; Hastings 1970) is applied to generate the samples. By the connection of the bridge PDF in the parameter space, the samples can then smoothly explore the parameter space and finally reach the important region of $p(\boldsymbol{\theta}|\mathbf{D},\mathbf{M})$. The sampling process continues until the bridge PDF approaches the target $p(\boldsymbol{\theta}|\mathbf{D},\mathbf{M})$. A stopping criterion is thus needed, which is crucial for model updating, especially in calculation of the posterior uncertainties. If the sampling process stops too early, the samples will be distributed in wide regions and the important region of the posterior PDF cannot be identified. If the sampling process stops too late, the samples will be concentrated in narrow regions and the size of the important region of the posterior PDF, and thus the posterior uncertainty, will

be underestimated. A novel stopping criterion is developed (Lam *et al*. 2015) by calculating the best estimate of the measure of prediction error, κ^{*2}, of the bridge PDF in the final sampling level.

$$\kappa^{*2} = \frac{J^*\left(\boldsymbol{\theta}^*\right)}{r} \tag{5}$$

where $J^*(\boldsymbol{\theta}^*)$ is the value of the goodness-of-fit function in Eq. (2) evaluated at the "optimal" point $\boldsymbol{\theta}^*$. Because $J(\boldsymbol{\theta})$ is an implicit function of $\boldsymbol{\theta}$, the optimal point $\boldsymbol{\theta}^*$ is numerically obtained by the active-set algorithm (Nocedal and Wright 2006) in this study. The value of J^* can then be evaluated numerically using $\boldsymbol{\theta}^*$. Once J^* is obtained, the κ^{*2} value of the bridge PDF in the final level can be calculated by Eq. (5). Furthermore, according to Eq. (4), the required number of sampling levels, g_r, can be calculated

$$\kappa_g^2 = \left(\frac{1}{A}\right)^{g-1} \Rightarrow g_r = \text{int}\left(1 - \frac{\ln\left(\kappa^{*2}\right)}{\ln A}\right) \tag{6}$$

where $\kappa_1^2 = 1$ is used to ensure that the bridge PDF in the first sampling level covers a wide region of parameter space. The proposed MCMC-based Bayesian model updating can efficiently evaluate the posterior marginal PDFs of the uncertain parameters without calculating high-dimension numerical integration.

Failure Probability

To assess the target structure, the structure is considered as fail when its vibration responses under a given excitation exceed the pre-defined threshold limit. The failure probability $P(x_d>x_{th}|\boldsymbol{\theta},\mathbf{M})$ can then be calculated, where x_d denotes the maximum displacement at all degrees-of-freedom (DOFs) of the target structure during the considered time period and x_{th} denotes the pre-defined displacement threshold limit. Note that $P(x_d>x_{th}|\boldsymbol{\theta},\mathbf{M})$ indicates that the failure probability is conditional on the model represented by $\boldsymbol{\theta}$ for the given model class $\mathbf{M}$. Instead of pinpointing only one model, multiple models in a model class must be considered and their relative plausibility is reflected by their posterior probabilities according to Bayesian theorem. The robust failure probability (Papadimitriou *et al*. 2001) is proposed to monitor the structure.

$$P_F = \int_\Theta P\left(x_d > x_{th}\middle|\boldsymbol{\theta}, M\right) p\left(\boldsymbol{\theta}\middle|D, M\right) d\boldsymbol{\theta} \tag{7}$$

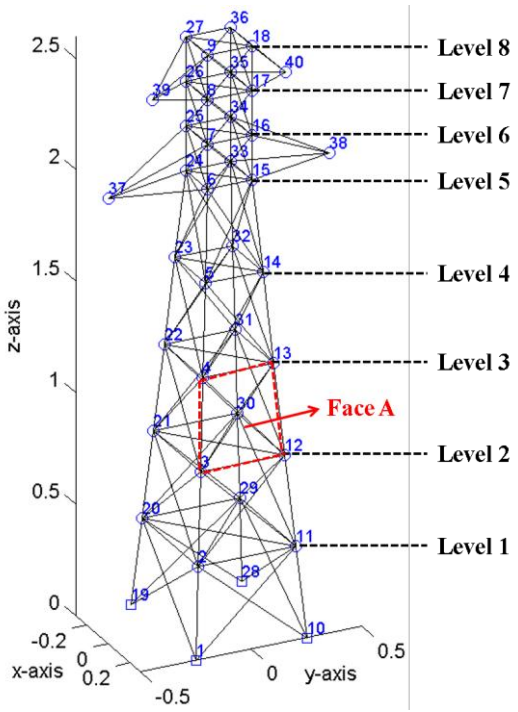
It is noted that the integral in Eq. (7) is usually in high dimension in practice. It is not analytically known and neither can it be evaluated straightforward by numerical integration. The integral in Eq. (7) can be evaluated through Monte Carlo approximation using samples of $\boldsymbol{\theta}$ generated from the MCMC-based Bayesian model updating method.

$$P_F \approx \frac{1}{N_s}\sum_{h=1}^{N_s} H\left(x_d^{(h)} > x_{th}\middle|\boldsymbol{\theta}^{(h)}\right) \tag{8}$$

$H(u)$ is an indicator function defined on a set B. If $u \in B$, $H(u)=1$. Otherwise, $H(u)=0$. N_s is the number of MCMC samples. $\boldsymbol{\theta}^{(h)}$ denotes the h^{th} MCMC sample in the final sampling level. For SHM, the sample displacement of the structure $x_d^{(h)}$ is computed under specified excitation (e.g., Gaussian-noise excitation) based on each sample $\boldsymbol{\theta}^{(h)}$. All sample displacements $\{x_d^{(h)}: h=1,2, \ldots, N_s\}$ are then included for evaluating the failure probability in Eq. (8). Following this framework, the failure probabilities of the target structure can be evaluated for various threshold limits. In the next section, a transmission tower is employed to illustrate the proposed SHM method.

CASE STUDY

The target structure, a scaled transmission tower model, is shown in Figure 1. The measured modal parameters of the tower were simulated for Bayesian model updating. For illustration purpose, the simulated natural frequencies and mode shapes of the undamaged tower, which were used as measured modal parameters, are summarized in Table 1 and Figure 2.



Unit: m.

Deterministic Model Updating of the Undamaged Transmission Tower

For model updating, uncertain parameters were assigned to monitor the stiffness of the 4 columns at different levels. For the first 5 levels, an individual parameter was assigned to monitor the stiffness of the 4 columns at each level. An additional parameter was used to monitor all columns in the upper 3 levels. Deterministic model updating was first conducted by numerically minimizing the goodness-of-fit function in Eq. (2). Finally, only a single solution $\boldsymbol{\theta}_m$ was determined by the deterministic model updating, and the results are summarized in Table 2. By following the deterministic approach, prediction analysis would be carried out using only a single identified model, which is represented by $\boldsymbol{\theta}_m$. Next section, model updating was conducted by the proposed method utilizing the same set of data and the same model class. The performance of the proposed method can be illustrated by comparing the result of deterministic method to that of the proposed method.

Table 2 Optimal solution of the deterministic model updating

$\boldsymbol{\theta}_m(1)$	$\boldsymbol{\theta}_m(2)$	$\boldsymbol{\theta}_m(3)$	$\boldsymbol{\theta}_m(4)$	$\boldsymbol{\theta}_m(5)$	$\boldsymbol{\theta}_m(6)$

MCMC-based Bayesian Model Updating of the Undamaged Transmission Tower

Instead of pinpointing a single solution, the proposed method extracts information from a given set of measured data and estimate the posterior PDF of uncertain parameters for a given class of models. In other words, the relative plausibility of multiple models is considered following Bayesian theorem conditional on the measured data. All the models are weighted by the posterior PDF and they are included for posterior prediction analysis. After Bayesian model updating using MCMC, the samples in the final sampling level are shown in Figure 3. Based on the samples, the posterior marginal PDFs are constructed by kernel density estimation (Au and Beck 1999) and they are shown in Figure 4. It is clear from the figure that in the parameter space, there are two almost equal-height peaks in the posterior marginal PDF of $\boldsymbol{\theta}(5)$ and there are multiple important regions in a wide range of the parameter space for $\boldsymbol{\theta}(2)$ and $\boldsymbol{\theta}(6)$. By comparing the deterministic solution in Table 2 to the posterior marginal PDFs in Figure 4, it is observed that the model identified by the deterministic method is only one of the models which possess relatively high plausibility. For example, at the neighborhood of $\boldsymbol{\theta}_m(2)$, there are multiple points with relatively high plausibility (see Figure 4). In fact, there is no justification for keeping only $\boldsymbol{\theta}_m(2)$ and discarding all other models. Moreover, $\boldsymbol{\theta}_m(5)$ is at one of the two peaks in the marginal-PDF of $\boldsymbol{\theta}(5)$. The posterior analysis result considers only $\boldsymbol{\theta}_m(5)$ will be very misleading (a lot of information will lose). Therefore, pinpointing a single model to represent the updated model is not appropriate in this case. A more reasonable approach is to consider all models in the important regions of the parameter space. This can be approximated by a weighted sum of important models (i.e. MCMC samples in the proposed method).

To calculate the time responses of the transmission tower, Gaussian-noise forces were applied at nodes 2 to 9 (see Figure 1) along both x and y directions. These forces were treated as i.i.d. random processes with Gaussian PDF $N(\mu, \sigma)$. The mean μ is chosen to be 1 N and the standard deviation σ is chosen to be 0.3 N. 30 seconds of forces are applied. The time responses of the tower are calculated for each sample $\boldsymbol{\theta}^{(h)}$ using Newmark's method (Chopra 2011) with time step 0.01 s. The failure probabilities of the undamaged tower are calculated for different threshold limits using Eq. (8) and they are represented by blue circular markers in the figure. Note that the tower is considered as fail if the displacement at any one of the DOFs exceeds the threshold limit.

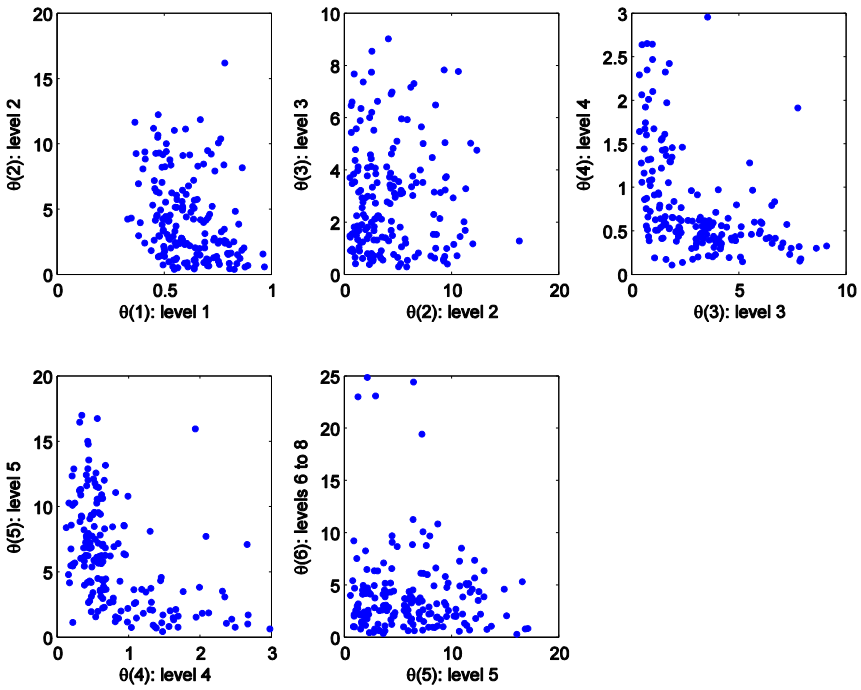

Figure 3 Samples in the final sampling level for the undamaged tower

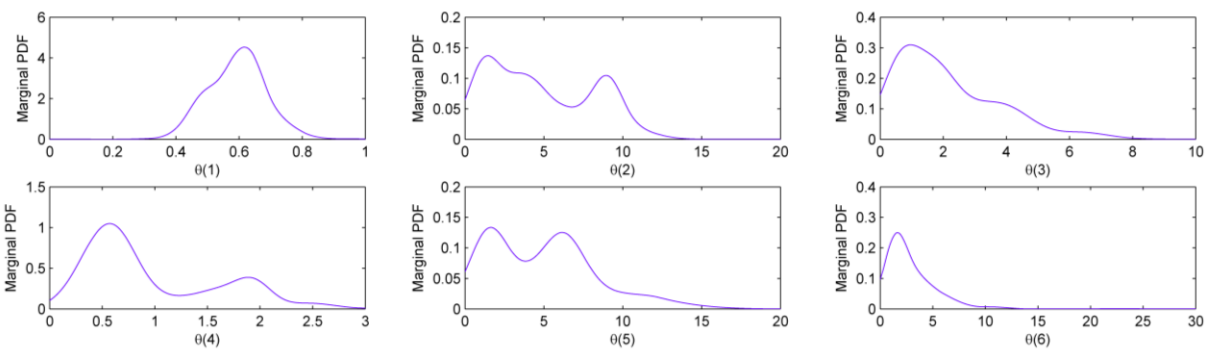

Figure 4 Posterior marginal PDFs of **θ** for the undamaged tower

MCMC-based Bayesian Model Updating of the Damaged Transmission Tower

To simulate the damage, the stiffness of the braces in face A (see Figure 1) in level 3 was reduced such that about 18% of the total brace stiffness of level 3 was lost. It must be pointed out that brace damages cannot be modeled directly by the selected model class as only the stiffness values of columns are considered as uncertain model parameters. With similar procedures, Bayesian model updating using MCMC was conducted for the damaged tower and the posterior marginal PDFs are presented in Figure 5. The failure probabilities of damaged tower were calculated (see red square markers in Figure 6) and compared to those of the undamaged tower in Figure 6. From this figure, one can read the probability, for which the displacement of the tower exceeds the threshold value. For example, for the undamaged tower in Figure 6(a) (the blue line with circular markers), the probability for the displacement exceeds 0.07 mm is 0.448. It can be observed that the curve representing the damaged tower lies above the curve representing the undamaged tower and the gap between these two curves is increasing with large threshold limits. It is clear that the failure probabilities of the damaged tower are larger than those of the undamaged tower. Following this framework, failure probabilities of the target structure can be calculated at different time instances and the results at different time instances can be compared (as in Figure 6). In this way, the target structure can be monitored in an almost real-time basis.

CONCLUSIONS

This paper carried out a feasibility study of SHM using MCMC-based Bayesian model updating and vibration prediction. Unlike the traditional damage detection methods which are sensitive to the chosen model classes, the proposed method applicable even when the level of modeling error is relatively large (as demonstrated in the numerical case study). The uncertainty from measurement noise and modeling error is explicitly addressed following the Bayesian theorem. The posterior PDF of the uncertain parameters was derived. Instead of identifying a "true" model, a set of important models (obtained by MCMC) in the parameter space of interest was considered in vibration prediction. The posterior PDF is used as a measure of the relative plausibility among various models. A newly developed MCMC-based method is applied to sample from the complicated posterior PDF. With the generated samples, the robust failure probabilities of the target structure can be computed. The health status of the target structure can be monitored on an almost real-time basis by calculating the failure probabilities at various time instances. The proposed SHM method is numerically verified by a scaled transmission tower model on undamaged and damaged status. The numerical case study showed that the failure probability obviously increased when the tower was damaged.

ABSTRACT

Elevated pipelines are commonly encountered in petro-chemical and industrial applications. Within these applications, pipelines normally span hundreds of meters and are thus analysed using beam-type one-dimensional finite elements when the global behaviour of the pipeline is sought at a reasonably low computational cost. Standard beam-type elements, while computationally economic, are based on the assumption of rigid cross-section. Thus, they are unable to capture the effects of cross-sectional localized deformations. Such effects can be captured through shell-type finite element models. For long pipelines, shell models become prohibitively expensive. Within this context, the present study formulates an efficient numerical modelling technique which effectively combines the efficiency of beam-type solutions while retaining the accuracy of shell-type solutions. An appealing feature of the model is that it is able to split the global analysis based on simple beam-type elements from the local analysis based on shell-type elements. This is achieved through a domain-decomposition procedure within the framework of the bridging multi-scale method of analysis. Solutions based on the present model are compared to those based on full shell-type analysis. The comparison demonstrates the accuracy and efficiency of the proposed method.

Finite element method, Multiscale Method, pipe, local buckling

INTRODUCTION

Thin-walled pipes are widely used in industrial applications. Usually, they are susceptible to buckling, and it is important to predict their nonlinear response accurately. Pipes usually span much larger distances in comparison to their cross-sectional dimensions. As such, beam-type elements are commonly adopted in their analysis. Standard beam-type elements, however, are based on the assumption of rigid cross-section and thus, cannot consider the deformations of the cross-section such as local buckling (Karamanos, 2002) and only allow considerations of the global behaviour such as flexural-buckling (Hobbs, 1981). In contrast, Shell-type finite elements can capture local effects. The buckling response for long pipes under combinations of bending, axial force, and external pressure using shell analyses were investigated in (Houliara & Karamanos, 2006, 2010; Karamanos & Tassoulas, 1996). On the other hand, shell elements are computationally more expensive and time-consuming, and for typical pipeline networks spanning hundreds of meters, such shell analyses become impractical.

Research on computational mechanics has been increasingly focusing on adaptive numerical analysis strategies such as mesh-free methods e.g. (Belytschko et al., 1996; E. Erkmen & Bradford, 2011), Generalized-FEM (Babuška & Melenk, 1997; Belytschko et al., 2001) and Multi-scale methods (Hughes & Sangalli, 2007; Liu et al., 2000), which improve the efficiency and accuracy of the numerical results by refining the model only where required and without changing the global simpler model of the whole structure. Common to these numerical methods is that the partition of unity concept is exploited to allow overlapping decompositions of the analysis domain so that a local enrichment can be seamlessly incorporated (Babuška et al., 2003; Li & Liu, 2002). In which naturally give rise to multiple scales in the deformation fields, such as crack propagation e.g. (Haidar et al., 2003; Mosler, 2005), or localized damage problems e.g. (Mosler, 2005) multi-scale numerical analysis techniques have been effectively used. In particular, the Bridging multi-scale method, which was originally developed to enrich the nodal values of the FEM solution with mesh-free solution (Liu et al., 1997), provides a basis to couple problems based on two different physical assumptions. The appealing feature of the Bridging

multi-scale method is that it can split the global analysis, which is based on simplified assumptions, from the local analysis which requires more sophisticated modelling. Bridging multi-scale method was previously used to incorporate nano-mechanics and atomistic behaviour into the local model e.g. (Liu et al., 2006; Qian et al., 2004; Wagner & Liu, 2003).

In pipe buckling behaviour, the interaction of local with global modes also gives rise to multiple scales in the deformation fields. In order to capture the effect of local deformations, shell formulations have been utilised in the past e.g. (Ju & Kyriakides, 1992; Ozkan & Mohareb, 2009; Song & Tassoulas, 1993; Weicker et al., 2010). Localized plasticity effects have also been incorporated into pipeline analysis through generalized plasticity models (Nowzartash & Mohareb, 2004). In order to capture ovalization in pipe elbows, efficient beam type formulations were developed in (Bathe & Almeida, 1982; Militello & Huespe, 1988). Recently, R. E. Erkmen (2013) developed an analysis procedure based on the Bridging multi-scale method of Liu et al. (2006), in order to incorporate local deformation effects in the analysis of thin-walled members. This approach allows employment of two kinematic models within the numerical analysis, and while simple beam-type elements are used for the analysis of the overall structure, more sophisticated shell-type elements are employed for the local fine-scale analysis in a relatively narrow span of the member. In the present study, we extend the procedure developed in R. E. Erkmen (2013) for the elasto-plastic analysis of pipes. Comparisons with full shell- and beam-type models are provided in order to illustrate the efficiency of the proposed analysis.

BEAM-TYPE ANALYSIS

A beam formulation based on the classical kinematic assumptions of the Euler-Bernoulli beam theory is used for the global analysis. The beam element strain vector can be written in terms of linear and second order nonlinear terms, i.e. $\bar{\boldsymbol{\varepsilon}}=\bar{\boldsymbol{\varepsilon}}_L+\bar{\boldsymbol{\varepsilon}}_N$. Orientation of the displacement components of the beam element are shown in Figure 1.

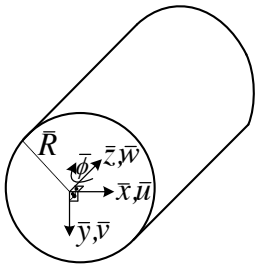

Figure 1 Deflections of the beam formulation

The linear axial and shear strains $\bar{\varepsilon}_L$ and $\bar{\gamma}_L$ can be obtained in terms of the derivatives of displacements $\bar{u},\bar{v},\bar{w}$ and the angle of twist $\bar{\phi}$ as

$$\bar{\boldsymbol{\varepsilon}}_L=\langle \bar{\varepsilon}_L \quad 0 \quad \bar{\gamma}_L \quad 0\rangle^{\mathrm{T}}=\bar{\mathbf{S}}\bar{\boldsymbol{\chi}}_L \tag{1}$$

where $\bar{\mathbf{S}}$ and $\bar{\boldsymbol{\chi}}_L$ are given explicitly as

$$\bar{\boldsymbol{\varepsilon}}_L=\langle \bar{\varepsilon}_L \quad 0 \quad \bar{\gamma}_L \quad 0\rangle^{\mathrm{T}}=\bar{\mathbf{S}}\bar{\boldsymbol{\chi}}_L \tag{2}$$

$$\bar{\boldsymbol{\chi}}_L{}^{\mathrm{T}}=\langle \bar{w}' \quad \bar{u}'' \quad \bar{v}'' \quad \bar{\phi}'\rangle \tag{3}$$

In Eq. 2 , $\bar{x}$ and $\bar{y}$ identify coordinates of a point on the cross-section, and $\bar{R}$ is the radius of the pipe. The nonlinear strains can be written as

$$\bar{\boldsymbol{\varepsilon}}_N=\langle \bar{\varepsilon}_N \quad 0 \quad \bar{\gamma}_N \quad 0\rangle^{\mathrm{T}}=\bar{\mathbf{S}}\bar{\boldsymbol{\chi}}_N \tag{4}$$

in which $\bar{\varepsilon}_N$ is the nonlinear axial strain and $\bar{\gamma}_N$ is considered to vanish. The vector of second-order displacement derivatives $\bar{\boldsymbol{\chi}}_N$ in Eq. 4 is given as

$$\bar{\boldsymbol{\chi}}_N{}^{\mathrm{T}} = \left\langle \frac{1}{2}\left(\bar{u}'^2 + \bar{v}'^2\right) \quad 0 \quad 0 \quad 0 \quad 0 \right\rangle \tag{5}$$

The element is developed by using linear interpolations for $\bar{w}$ and $\bar{\phi}$ and cubic interpolations for $\bar{u}$ and $\bar{v}$. Consequently, the equilibrium equations for static analysis can be obtained in the variational form as

$$\delta\bar{\Pi} = \int_L \int_A \delta\bar{\boldsymbol{\varepsilon}}^{\mathrm{T}} \bar{\boldsymbol{\sigma}} \mathrm{d}A\,\mathrm{d}\bar{z} - \delta\bar{\mathbf{d}}^{\mathbf{T}}\bar{\mathbf{f}} = 0 \tag{6}$$

in which A is the cross-sectional area, L is the beam span and $\bar{\mathbf{f}}$ is the external load vector. In this study, in the regions where no local deformations occur, the material behaviour is assumed elastic. Thus, in Eq. 6, the beam stresses can be obtained directly from the strains using the linear stress-strain relationship for an isotropic material. The first variation of the strain vector can be written as

$$\delta\bar{\boldsymbol{\varepsilon}} = \bar{\mathbf{S}}\bar{\mathbf{B}}\delta\bar{\mathbf{d}} \tag{7}$$

The incremental equilibrium equations can be obtained by subtracting the virtual work expressions at two neighbouring equilibrium states and then linearising the result by omitting the second- and higher-order terms, i.e.,

$$\Delta\left(\delta\bar{\Pi}\right) \approx \delta\bar{\mathbf{d}}^{\mathbf{T}}\bar{\mathbf{K}}\Delta\bar{\mathbf{d}} - \delta\bar{\mathbf{d}}^{\mathbf{T}}\Delta\bar{\mathbf{f}} = 0 \tag{8}$$

where $\bar{\mathbf{K}}$ is the stiffness matrix of the global beam model, i.e.,

$$\bar{\mathbf{K}} = \int_L \int_A \bar{\mathbf{B}}^{\mathrm{T}}\bar{\mathbf{S}}^{\mathrm{T}}\bar{\mathbf{E}}\bar{\mathbf{S}}\bar{\mathbf{B}}\mathrm{d}A\mathrm{d}\bar{z} + \int_L \bar{\mathbf{M}}_\sigma \mathrm{d}\bar{z} \tag{9}$$

in which $\bar{\mathbf{M}}_\sigma \Delta\bar{\mathbf{d}} = \delta\bar{\mathbf{B}}^{\mathrm{T}} \int_A \bar{\mathbf{S}}^{\mathrm{T}}\bar{\boldsymbol{\sigma}}\mathrm{d}A$.

SHELL-TYPE ANALYSIS

Strains of the shell-type analysis are composed of linear strains due to (a) membrane deformation $\hat{\boldsymbol{\varepsilon}}_{mm}$, (b) plate bending deformations $\hat{\boldsymbol{\varepsilon}}_b$, and (c) nonlinear components of strains due to membrane and plate bending action $\hat{\boldsymbol{\varepsilon}}_N$, i.e.,

$$\hat{\boldsymbol{\varepsilon}} = \hat{\boldsymbol{\varepsilon}}_{mm} + \hat{\boldsymbol{\varepsilon}}_b + \hat{\boldsymbol{\varepsilon}}_N = \left\langle \hat{\varepsilon}_x \quad \hat{\varepsilon}_y \quad \hat{\gamma}_{xy} \quad \hat{\gamma}_m \right\rangle^{\mathrm{T}} \tag{10}$$

Figure 2 shows the x and y axes defining a plane tangential to the mid-surface of the shell and z-axis is normal to the mid-surface.

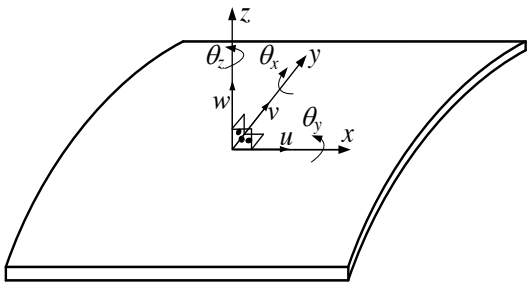

Figure 2 Local deflections of the shell element

The vector of linear components for the membrane strain $\hat{\boldsymbol{\varepsilon}}_{mm}$ can be written as

$$\hat{\boldsymbol{\varepsilon}}_{mm}^{T} = \left\langle \hat{\boldsymbol{\varepsilon}}_m{}^{T} \;\middle|\; \frac{1}{2}\left(\frac{\partial\hat{v}_0}{\partial x} - \frac{\partial\hat{u}_0}{\partial y}\right) - \hat{\theta}_z \right\rangle = \left\langle \frac{\partial\hat{u}_0}{\partial x} \quad \frac{\partial\hat{v}_0}{\partial y} + \frac{\partial f}{\partial r}\hat{\theta}_y \quad \frac{\partial\hat{u}_0}{\partial y} + \frac{\partial\hat{v}_0}{\partial x} \;\middle|\; \frac{1}{2}\left(\frac{\partial\hat{v}_0}{\partial x} - \frac{\partial\hat{u}_0}{\partial y}\right) - \hat{\theta}_z \right\rangle \tag{11}$$

in which $\hat{\theta}_x$ and $\hat{\theta}_y$ are rotations in local *x*-*z* and *y*-*z* planes respectively, $\hat{\theta}_z$ is the drilling rotation about the *z* axis, and $\hat{u}_0$ and $\hat{v}_0$ are the displacements of the mid-surface in the local *x*-*y* plane (Figure 2). In Eq. 11 the term $\left(\partial f/\partial r\right)\hat{\theta}_y$ is added according to Marguerre shallow shell theory (Robert D. Cook, 1990). As shown in Figure 3, $f = f\left(r\right)$ is the expression for the elevation of the arch in *Z*-*Y* plane in terms of coordinate *r*.

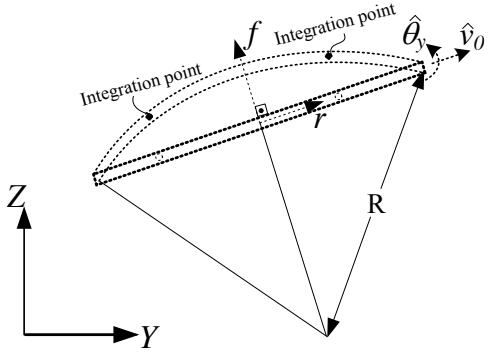

Figure 3 Arch elevation used in shell formulation

In calculating the element length and locations of the integration points, the arch length was considered. For the membrane component of the shell-type element, the finite element of Ibrahimbegovic et al. (1990) employing drilling degrees of freedom is adopted herein, so that non-coplanar elements can be easily assembled. According to Mindlin-Reissner theory (R.D. Cook et al., 2002), the plate bending strains can be written as

$$\hat{\boldsymbol{\varepsilon}}_b = -z\left\langle \hat{\boldsymbol{\chi}} \;\vdots\; 0 \right\rangle^T = -z\left\langle \frac{\partial \hat{\theta}_x}{\partial x} \quad \frac{\partial \hat{\theta}_y}{\partial y} \quad \frac{\partial \hat{\theta}_x}{\partial y}+\frac{\partial \hat{\theta}_y}{\partial x} \;\vdots\; 0 \right\rangle^T \tag{12}$$

in which $\hat{\boldsymbol{\chi}}$ is the curvature vector. It is assumed that the second order longitudinal displacement derivatives, second order lateral strains and second order shear strains are negligibly small. Thus, the nonlinear strain component can be written as

$$\hat{\boldsymbol{\varepsilon}}_N \approx \left\langle \frac{1}{2}\left(\frac{\partial \hat{w}_0}{\partial x}\right)^2+\frac{1}{2}\left(\frac{\partial \hat{v}_0}{\partial x}\right)^2 \quad 0 \quad 0 \;\vdots\; 0 \right\rangle^T \tag{13}$$

in which $\hat{w}_0$ is the out of plane deflection of the mid-surface in local z direction (Figure 2). The shell analysis is elasto-plastic, and for convenience, we apply the one step forward Euler numerical procedure as described in (Crisfield, 1991). Under plane stress plasticity conditions, i.e. $\hat{\sigma}_z = \hat{\tau}_{yz} = \hat{\tau}_{zx} = 0$, the von Mises yield criterion is used to determine whether the trial stresses are elastic. According to the forward Euler procedure in (Crisfield, 1991) since $\varepsilon_z \neq 0$, a four-dimensional yield surface is assumed. The plastic strain increment is obtained by using Prandtl-Reuss flow rule for associative plasticity. The equilibrium equation of the shell analysis can be obtained in the variational form as

$$\delta\hat{\Pi} = \int_L \int_A \delta\hat{\boldsymbol{\varepsilon}}^{\mathrm{T}} \hat{\boldsymbol{\sigma}} \mathrm{d}A\mathrm{d}z - \delta\hat{\mathbf{d}}^{\mathrm{T}}\,\hat{\mathbf{f}} = 0 \tag{14}$$

It should be noted that the virtual work functional of the shell element is modified in order to avoid numerical stability issues with Allman type interpolations of the membrane component (Ibrahimbegovic et al., 1990). Similar to the beam analysis, the variation of the strain tensor can be written as

$$\delta\hat{\boldsymbol{\varepsilon}} = \hat{\mathbf{S}}\hat{\mathbf{B}}\delta\hat{\mathbf{d}} \tag{15}$$

Similar to the beam formulation, the incremental equilibrium equations for the shell formulation can be obtained as

$$\Delta\left(\delta\hat{\Pi}\right) \approx \delta\hat{\mathbf{d}}^{\mathbf{T}}\hat{\mathbf{K}}\Delta\hat{\mathbf{d}} - \delta\hat{\mathbf{d}}^{\mathbf{T}}\Delta\hat{\mathbf{f}} = 0 \tag{16}$$

where $\hat{\mathbf{K}}$ is the tangent stiffness matrix of the shell model, i.e.,

$$\hat{\mathbf{K}}=\int_L\int_A \hat{\mathbf{B}}^{\mathrm{T}}\hat{\mathbf{S}}^{\mathrm{T}}\hat{\mathbf{E}}_{ep}\hat{\mathbf{S}}\hat{\mathbf{B}}\mathrm{d}A\mathrm{d}\bar{z}+\int_L \hat{\mathbf{M}}_{\sigma}\,\mathrm{d}\bar{z} \tag{17}$$

where $\hat{\mathbf{M}}_{\sigma}\Delta\hat{\mathbf{d}}=\int_A \delta\hat{\mathbf{B}}^{\mathrm{T}}\hat{\mathbf{S}}^{\mathrm{T}}\hat{\boldsymbol{\sigma}}\mathrm{d}A$ and $\hat{\mathbf{E}}_{ep}$ is the elasto-plastic constitutive matrix.

MULTI-SCALE ANALYSIS PROCEDURE

Proposed multi-scale analysis is performed only in a critical part of the analysis domain, in which the beam and shell models overlap. In this region, we decompose the shell nodal displacement vector $\hat{\mathbf{d}}$ into a coarse-scale component and a difference term by using a decomposition matrix **N**, which is developed based on kinematic assumptions of the classical beam theory and projects the beam solution onto the nodal points of the shell model, i.e.

$$\delta\hat{\mathbf{d}}=\mathbf{N}\delta\bar{\mathbf{d}}+\delta\mathbf{d}' \tag{18}$$

in which the first and second terms on the right-hand side represent the variation of coarse-scale model and the difference, respectively. The **N** matrix can be written as

$$\mathbf{N}=\mathbf{YZ} \tag{19}$$

where the **Y** matrix includes cross-sectional coordinates and **Z** matrix is the interpolation matrix along the beam. The above decompositions of the displacement field (Eq. 18) can be used to decompose the strain vector of the shell model, i.e.

$$\delta\hat{\boldsymbol{\varepsilon}}=\hat{\mathbf{S}}\hat{\mathbf{B}}\left(\mathbf{N}\delta\bar{\mathbf{d}}+\delta\mathbf{d}'\right)=\delta\bar{\boldsymbol{\varepsilon}}+\delta\boldsymbol{\varepsilon}' \tag{20}$$

$$\delta\bar{\boldsymbol{\varepsilon}}=\hat{\mathbf{S}}\hat{\mathbf{B}}\mathbf{N}\delta\bar{\mathbf{d}} \tag{21}$$

$$\delta\boldsymbol{\varepsilon}'=\hat{\mathbf{S}}\hat{\mathbf{B}}\delta\mathbf{d}' \tag{22}$$

Similar to the strain, the stress vector of the local shell model can be decomposed. By substituting the above relations in, the shell equilibrium equation can be decomposed into two simultaneous equations, i.e.,

$$\delta\Pi_1=\delta\bar{\mathbf{d}}^{\mathrm{T}}\mathbf{N}^{\mathrm{T}}\int_L\int_A \hat{\mathbf{B}}^{\mathrm{T}}\hat{\mathbf{S}}^{\mathrm{T}}\bar{\boldsymbol{\sigma}}\mathrm{d}A\mathrm{d}\bar{z}-\delta\bar{\mathbf{d}}^{\mathrm{T}}\mathbf{N}^{\mathrm{T}}\hat{\mathbf{f}}+\delta\bar{\mathbf{d}}^{\mathrm{T}}\mathbf{F}=0 \tag{23}$$

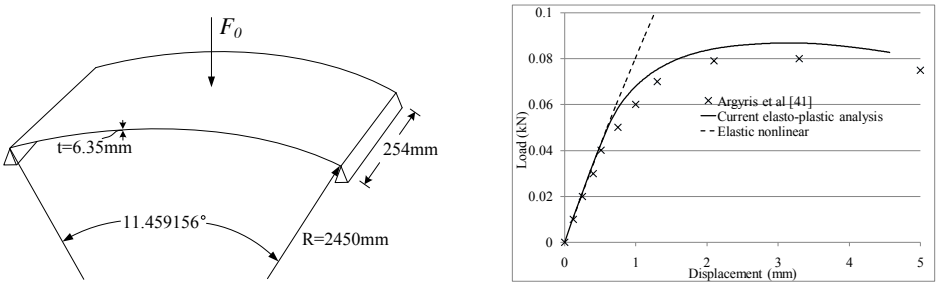
$$\delta\Pi_2=\delta\mathbf{d}'^{\mathbf{T}}\int_L\int_A \hat{\mathbf{B}}^{\mathrm{T}}\hat{\mathbf{S}}^{\mathrm{T}}\hat{\boldsymbol{\sigma}}\mathrm{d}A\mathrm{d}\bar{z}-\delta\mathbf{d}'^{\mathbf{T}}\hat{\mathbf{f}}=0 \tag{24}$$

The latter two equations are linearised to form a basis for finite element formulation. The shell solution is obtained by imposing the displacement of the beam element as an interface boundary condition for the shell element. Consequently, the algorithm of the multiscale procedure can be summarised as follows. Firstly, the global beam model is solved to obtain the initial displacement field while the local shell model (fine-scale model) is fixed. Then the displacements obtained in the previous step are applied to the local shell model in its boundaries, and the local shell model is solved to obtain the local displacement values. Two criteria are checked in each step within the framework of multiscale method. First criterion is to satisfy that the global equilibrium is achieved while the second criterion requires the vanishing of difference stress vector between the beam and the shell model to ensure that the two solutions are synchronised. Until the second criterion is satisfied, the difference stress vector is applied to the model as a complementary force until this force becomes smaller than a predefined tolerance.

VERIFICATION OF THE SHELL ANALYSIS

Before using multi-scale developments in the present model, the elasto-plastic shell model implemented in Section 3 was verified. Towards this goal, a cylinder panel under point load was considered. As shown in Figure 4.a, the curve edge nodes of the panel are assumed to be free in all directions while the side nodes are fixed against translation in all three directions. The modulus of elasticity, the Poisson ratio and the yield stress is taken

as 3.103kN/mm2, 0.3, and .001kN/mm2, respectively. The results are obtained by using 20x10 elements, i.e., 20 elements along the curved direction and 10 elements along the fixed edge direction, and compared with those obtained by the TRIC continuum formulation of Argyris et al. (2002) as shown in Figure 4.b and excellent agreement is observed.

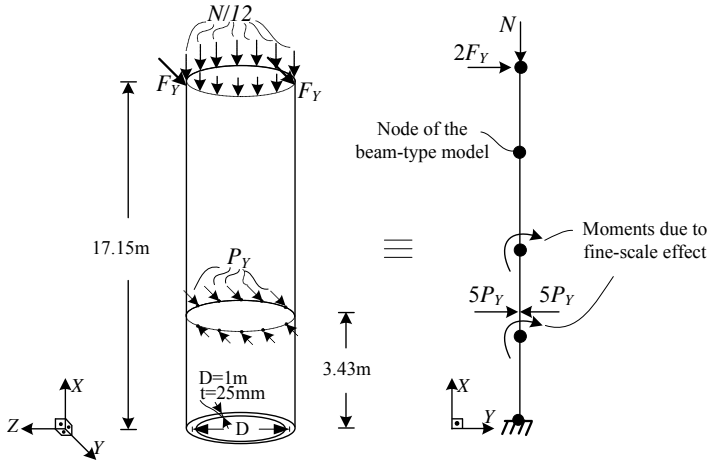


(a) Dimensions and loading (b) Load-deflection relations in the middle

Figure 4 Description of the arch and load-deflection relations

NUMERICAL EXAMPLES

As shown in **Figure 5**.a, the pipe analysed has a 17.15m span, a 1m diameter and a 25mm wall thickness. The pipe is fixed at the bottom end and is subject to a compressive force up to 15000 kN acting at the top and a total lateral load up to 15 kN (F_y=*7.5* kN).



(a) Dimensions and loading of the pipe in the shell model (b) Equivalent multi-scale model

Figure 5 Description of the modelling of the pipe

The pipe is pinched at height *z=3430mm* through two equal and opposite sets of five forces 5Py as shown in **Figure 5** (up to a value of P_y=*1800* kN), such that it induces distortion within the cross-section as well as plastic deformations. Modulus of elasticity and the Poisson's ratio used in this example *E=300* GPA and *v=0.3*, respectively. The yield stress was taken as 300MPa and no hardening was assumed.

For the beam-type and multi-scale analyses four equal-span elements are used. In the shell analysis, the circumference was divided into 12 shell elements and the pipe height was sub-divided into 30 elements. The axial load is applied as distributed load acting at the nodes of the top cross-section of the shell model. In the multi-scale analysis, the cross-section is again divided into 12 shell elements and span was sub-divided into 14 elements. In order to verify the validity of the beam-type analyses, we also present a comparison against the constrained shell solution which is obtained by applying multiple-point constraints on the nodal displacements of the shell model based on the decomposition matrix **N** and adopting the beam constitutive matrix **E**.

Firstly, a linearly elastic analysis was conducted. The applied loads were a compressive force (i.e., *N=15000* kN) and a small lateral force, (F_y=*7.5* kN). The load versus tip horizontal deflection and tip rotation curves are plotted as shown in Figure 6.a, and b respectively.

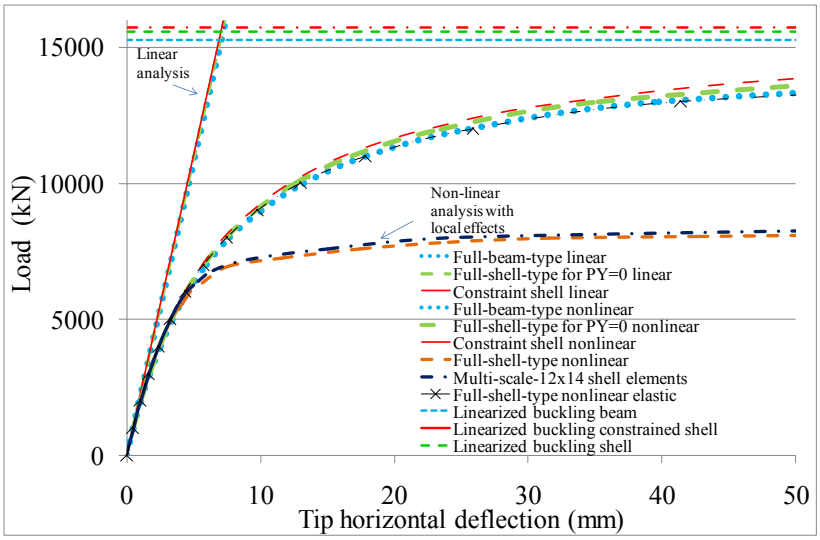


Figure 6 Description of the arch and load-deflection relations

Secondly, buckling loads based on a linearized buckling analysis corresponding to beam-type, constraint-shell-type and full-shell-type analysis are found as P_A=715,277kN, P_A=15,740kN and P_A=15,587kN, respectively, thus verifying the validity of beam analysis model, and suggesting that ovalization in this case have a negligible effect on the results. In the shell analysis, it was verified that no plastic deformations have taken place.

Thirdly, a nonlinear analysis was conducted, in which the loads were incremented from N=0, F_y=0 to a maximum of N=*15000* kN, F_y=*7.5* kN without pinching loads (i.e., P_Y=0). As shown in Figure 6.a-b, excellent agreement is observed between the beam analysis and the shell analysis.

Fourthly, in addition to the applied compressive loads, pinching loads were incrementally applied from zero to P_Y=*1800* kN in order to induce additional distortional deformations as well as plastic deformation. The corresponding load versus deflection curves are also shown in Figure 6.a and b. It should be noted that the comparison with fully elastic solution under local loads shows that plastic deformations are attained. The load versus deflection curves for the constrained shell and beam-type solutions are observed to be identical to those of the case where P_Y=0. On the other hand, when local deformations are introduced, the plastic deformations cause softening effect and increase the overall deflections of the full shell-type solution, which are not captured using the beam-type analysis given the rigid cross-section and elastic material response assumptions. In contrast, the multi-scale solution is very efficient in capturing the same behaviour as that predicted by the full shell-type analysis. In the multi-scale analysis, an overlapping region was considered between z=*0* and z=8003.33mm. The results are in very good agreement as can be verified from Figure 6.

CONCLUSIONS

In this paper, an analysis method based on the multi-scale domain decomposition approach was developed for the elasto-plastic analysis of pipes. The multi-scale domain decomposition allows the method to incorporate the effects of local deformations on the overall behaviour of the pipe by using a shell model only within the region of local deformations. A pipe buckling case was analysed and the results of the multi-scale analysis procedure proposed herein were compared with those of the full shell- and beam-type analyses. It was shown that very accurate results are obtained using the proposed analysis procedure.

Performance of Bridge Structures

SURVEY AND INVESTIGATION OF PERFORMANCE OF SUPERSTRUCTURE OF LONG SPAN BRIDGES IN CHINA

*Email: jinxingong@163.com & gong_jx.vip@eyou.com

ABSTRACT

With the rapid development of China's economy in the past three decades, requirements for construction of infrastructure for transportation have been enhanced and a great many long-span bridges have been built. Internationally, it can be boasted that China is one of the countries with the most long-span bridges. However, inadequate performance in long span bridges is often observed in field investigations, such as, excessive deflection in the mid-span, cracking of the concrete, cable corrosion in cable-stayed bridges, suspender cable corrosion in suspension bridges, and the corrosion of reinforced steel in the concrete resulting in the scaling and spalling of the concrete cover. This arouses the concern for the safety, serviceability, durability, service life, life cycle cost of maintenance and rehabilitation of long span bridges. A survey was made on the working condition of long span bridges in China. The causes resulting in deterioration of long span bridges are examined and measures for prolonging the service life of long span bridges in view of design, construction and maintenance are proposed.

KEYWORDS

Long-span bridges, survey, typical damage, deflection, crack, corrosion, durability, service life.

INTRODUCTION

With the rapid development of the economy in China in the past three decades, it has necessitated an increase in the construction of transportation infrastructure and a great many long-span bridges have been built. According to the statistics, by the end of 2013, the number of highway bridges reached 735,300 and the total length up to 39,778,000 m, in which 3,075 are large span bridges with a total length greater than 1,000 m of multi-span and total length greater than 150 m of single-span, and the total length 5,461,400 m. By July 2014, the top ten bridges with the greatest main span in the world, China make up six for cable-stayed bridge, five for suspension bridge, six for arch bridge and seven for prestressed concrete girder bridge. We can say indescribably that great achievement has been made in the design and construction of long span bridges in China.

However, it is another scenario for the long span bridges after years of operation. Survey and investigation reveals that more than 70% of the bridges show various degrees of deterioration (Lu 2011), including excessive deflection in mid-span, cracking in the box girder, corrosion of cables and so on. This unexpected poor performance raises the concern of the safety, serviceability, and the life cycle maintenance cost of bridges. Therefore, it is important to identify and analyze the causes of the deterioration of long-span bridges, so as to recheck and revise the design and construction code, and provide a range of precautionary and measures to mitigate the degrading process, ensuring the safety and prolonging the service life of bridges.

This paper summarizes the typical damage and defects in the superstructures of long-span bridges in China, and analyzes the causes resulting in the deterioration of bridges and briefs the precautionary measures to avoid and mitigate the degradation.

TYPICAL DEFICIENCY OF LONG-SPAN BRIDGE

Excessive Midspan Deflections of Main Girder

As reported in the literature, there is a worldwide problem with the excessive deflection of the main girder of long span bridges. This phenomenon is more remarkable for the long span bridges in China concerning such features as:

- deflection with an accelerating, decreasing or constant growth rate over time,
- long-time deflections much larger than the design value (Xie *et al*. 2007; Bao and Zhou 2009).

Table 1 shows 11 examples of excessive long-time deflection of long-span prestressed concrete bridges which

represent the typical deformation performance of long-span bridges in China. All the bridges surveyed in table 1, except Yuanshan Bridge which is hinged rigid frame bridge with T type section, are continuous rigid frame bridges with girder section of single-cell box. The construction methods of these bridges include three-dimensional prestress, cast-in-situ, cantilever casting construction, internal prestress and post-tensioned. Sugute Bridge used both internal prestress and external prestress in mid-span.

Table 1 Deflection of several long-span prestressed concrete bridges in China

No.	Bridge	Location	Completion	Span/m	Maximum Deflection/cm	Served time/year
1	Secondary channel of Humen Bridge	Guangdong	1997	150+270+150	22.2	7
2	Huangshi Yangtze River Bridge	Hubei	1995	162.5+3×245+162.5	30.5	7
3	Sanmenxia Yellow River Highway Bridge	Shanxi to Henan	1992	105+4×140+105	22	10
4	Jinsha Bridge	Guangdong	1994	66+120+66	22	6
5	Dongming Yellow River Bridge	Shandong	1993	75+7×120+75	14.6	—
6	Fenglingdu Yellow River Bridge	Shanxi	1994	87+7×114+87	29	14
7	Yajisha Bridge	Guangdong	2000	86+160+86	23	3
8	Jiangjin Yangtze River Bridge	Chongqing	1997	140+240+140	31.7	10
9	Sugute Bridge	Yunnan	2007	65+110+65	28	—
10	Luoxi Bridge	Guangdong	1988	65+125+180+110	6.4	3
11	Yuanshan Bridge	Taiwan	1977	75+150+2×142.5+118	63	—

Note: "—" means it is not mentioned in the literature.

Numerous aspects are responsible for the excessive deflection of long-span bridges, and the main causes are as follows:

Shrinkage and creep of concrete

The uncertainties associated with the creep and shrinkage of concrete are the main obstacle for the prediction of long time deformation (Xie *et al*. 2007). Much research has been devoted to concrete creep and shrinkage and many prediction models, including CEB-FIP, ACI, JSCE, GL and B3, have been proposed. Although great progress has been made and various improved theoretical models have been developed, in the best situation, the coefficient of variation is 20% for the creep compliance and 35% for the shrinkage strain, which is far from expectation (Takács 2002). A linear concrete creep theory is adopted for the long-term deflection prediction in the bridge design. With this hypothesis, the concrete creep tends to be constant after several years of completion. But the fact is that the long-term deflection caused by concrete creep is far greater than the design values, which implies that inappropriate model may be employed or nonlinear creep occurred, at least in local position. At this point of view, concrete creep prediction is still a great challenge we have to be faced.

In recent years, on the other hand, with the utilization of high strength concrete and reinforcing steel and optimization for the concrete box girder, the plate member becomes thinner and thinner, leading to the effects of shrinkage and creep of the structure becoming more and more obvious (Wang and Shi 2006). Besides, pumping concrete is now widely used for fabricating the large prestressed concrete columns, for the purpose of ensuring the flowability of concrete with superplasticizer as a commonly used additive. If the vibration is not sufficient in intensity and time, the formation of voids will result in significant shrinkage and creep of concrete (Wang *et al*. 2010).

Cracks in girders

Various cracks in girders contribute significantly also to the long-time deflection of the long-span bridges, which may be exhibited in the following aspects (Qiao 2011):

- reducing the stiffness of the girders,
- resulting in internal force redistribution in the cracked section and decrease of the depth in compression, which in turn increase the stress of concrete in compression and tendon, leading to further creep and

prestress loss,
- expanding the cracks by overloaded vehicles, eventually increasing deflection.

Decrease of Longitudinal Effectiveness of Prestressing in the Girder

It is the third reason which contributes to the excessive long-time deflection of long-span bridges that the decrease of longitudinal effective prestressing of bottom slab in the sagging moment region and top slab in the negative moment region (Zhan and Chen 2005). In the operation of a bridge, prestressing in the tendon of girder lost with time, decompressing the concrete gradually. It is equivalent to applying an additional bending moment in the girder, which intensifies the deflection of midspan (Bai 2007). Furthermore, the interaction among shrinkage, creep, cracking and prestressing loss exacerbates the long-time deflection of the bridges (Wang *et al*. 2010). Much research has been devoted to prestressing loss. Calculation method of prestressing loss is different from country to country. Up to date, however, no simple, accurate and unified approach has been found.

Shear lag

In a box girder, shear flow transmits from vertical webs to the horizontal flanges. This phenomenon is called shear lag which causes in-plane shear deformation of the flanges and results in unpredicted extra longitudinal displacement at the web-flange junction. The shear lag produces out-of-plane warping of an initially planar cross section and a significant non-uniformity of the distribution of the longitudinal normal stress across the flange width. Despite considerable research on shear lag has been made (Kristek *et al*. 1987; Luo and Li 2000; Luo and Li 2002), long-term deflection caused by shear lag is considered insufficiently in design. Nowadays, 'Wide Single Cell Box' is a commonly used format in the design of bridge girder, which possesses greater span to width ratio and always generates a lager lateral force, leading to a difficulty of structural analysis.

Apart from the aforementioned aspects, the excessive long-time deflection is also associated with thermal effect, overload vehicle, corrosion of reinforcing steel, deficiencies in design and construction method, especially the adverse stress state of the bridge due to the inadequate construction way in the formation of the profile of a bridge (Xie *et al*. 2007).

Cracks in Box Girder

Beyond the excessive deflection, cracking in box girder is another typical deficiency of long-span prestressed concrete box girder bridges, which is always dubbed a 'complication' of excessive deflection and initiates the 'cracking-deflection-cracking' cycle in bridges. As a matter of fact, cracks of the concrete lower the stiffness of the girder resulting in an increase of deflection as well as a redistribution of the internal force on the bridge, which in turn expedite the generation of new cracks. Furthermore, the crack forms the routine to transport the outside harmful aggressor to the surface of the reinforcing steels or prestressing tendons, resulting in reinforcing steels or prestressing tendons corrosion and threating the safety of the bridge.

In 2012, a survey was made on 180 prestressed concrete box girder bridges with a main span greater than 60m (196.85 ft) bridges by the Research Institute of the Highway Ministry of Transport in China and the cracks were divided into five categories depending on their position. The ratios of the number of bridges with cracks to the total number of bridges under investigation are shown in table 2 (Zhang 2012). The details of the five kinds of cracks are summarized for the seven investigated long-span prestressed concrete bridges in Table 3. All the bridges in Table 3 are continuous rigid frame categories with single-cell box section. Except for the Second Bridge of Xiangtan Xiangjiang for which two construction methods, cantilever assembling and casting, are adopted, all the others use one construction method cantilever casting.

Table 2 Percentige of cracks in diferent position of the box girder of bridges

Position	Web	Top slab	Bottom slab	Diaphragm plate	Dental plate
Percentige	86.4%	90.9%	54.5%	86.4%	36.4%

Table 3 Cracks description of seven selected long-span prestressed concrete bridges investigated

No.	Bridge	Location	Completion	Span/m	Cracks description	Served time/year
1	The Second Bridge of	Hunan	1993	50+5×90+50	The maximum length of single crack in web and top, bottom slab is	7

	Xiangtan Xiangjiang				2.2m and 8.5m. The maximum wedth of crack is 0.4mm.	
2	Huangshi Yangtze River Bridge	Hubei	1995	162.5+3×245 +162.5	There is a plenty of diagonal cracks in webs near the ends. The number of cracks inside the box gider more than the outside.	7
3	Sanmenxia Yellow River Highway Bridge	Shanxi to Henan	1992	105+4×140 +105	Diagonal cracks in webs distributes in the ends of the side span and range of L / 4.	10
4	Jinsha Bridge	Guangdong	1994	66+120+66	A large number of inclined cracks in webs.	6
5	Dongming Yellow River Bridge	Shandong	1993	75+7×120+75	The maximum wedth of crack is 0.69mm.	10
6	Fenglingdu Yellow River Bridge	Shanxi	1994	87+7×114+87	The maximum wedth of crack is 0.75mm.	14
7	Luoxi Bridge	Guangdong	1988	65+125+180 +110	The maximum wedth of cracks in web, top slab and bottom slab are 0.8mm, 1.8mm and 0.11mm.	17

Extensive site investigation reveals that, in general, seven kinds of typical cracks in a box girder can occur in the box girder based on the position, stress state and so on, that are (Zhan and Chen 2005; Zhong 2006; Liu 2009; Feng 2009):

- cracks in web,
- cracks in top slab,
- cracks in bottom slab,
- cracks in diaphragm plate and radial cracks at the edge of manhole,
- cracks in dental plate,
- splitting cracks under the anchorage,
- cracks along the longitudinal duct of prestressing tendon.

Of the above type of cracks, the most dangerous one is the diagonal crack in webs for the long-span prestressed concrete box girder bridges (Song and Zhu 2008; Pan 2013).

Cracks in box girder web

The diagonal cracks in the web occur in the region around 1 / 4 span to the ends or pivot of the pier, with an angle of 25-50 degree with the axial line of the girder (Gu and Peng 2004; Peng 2011), as shown in figure 1. This kind of crack is perpendicular to the direction of the principal tensile stress, reflecting an insufficiency in the shear resistance of the girder.

a) Outside of box cell b) Inside of box cell

Figure 1 Diagonal cracks in web of girder

One of the main causes of cracks in the web may attribute to the loss of vertical effective prestressing (Jia and Peng 2006; Deng *et al*. 2007). The principal tensile stress of girder is sensitive to the existence of vertical prestressing force and the stress level (Yuan 2006; Li 2003; Zhu *et al*. 2006). However, during construction, the

actual vertical effective prestressing may not reach the expected design value as it is affected by a variety of factors, such as anchorage deformation, retraction of tendons, deviation of anchorage plate, not attaining the anticipated stress level, insufficient strength of concrete during prestressing and corrosion of prestressing tendons, coupling with the action of temperature, shrinkage and creep and so on. In addition, insufficient consideration of the torsional shear stress caused by the vehicle load, as well as the combined action of the longitudinal and the transverse stress, insufficient structural fatigue strength, uneven force in the two side of the web of the box girder, improper construction procedure and overload in the operation are also important aspects affecting the cracking of the web box girder (Song and Zhu 2008; Wang and Fang 2006).

Cracks in top slab and bottom slab

The cracks, including longitudinal and transverse cracks, in the top and bottom slab of prestressed box girders are more common (Wang *et al*. 2008; Yuan 2006). Both the longitudinal and transverse cracks reflect the insufficient capability of crack resistance of each slab. Longitudinal cracks in the top slab and transverse cracks in the bottom slab are shown in figures 2 and 3 respectively.

The causes responsible for the formation of longitudinal cracks include:

- insufficient transverse effective prestress or excessive transverse prestressing loss,
- deviation of transverse prestressing tendons,
- insufficient consideration for the radial force resulting from the longitudinal prestress,
- thermal stress caused by cement hydration during construction.

The causes resulting in transverse crack include:

- insufficient longitudinal effective prestress or excessive longitudinal prestressing loss,
- underestimation of shrinkage and creep by theoretical prediction,
- insufficient consideration on shear lag effect, leading to a higher section stress peak than the average (Qiao 2011).

Wires Corrosion

Stay cable, main cable and suspenders are some of the main elements for cable-stayed bridge and suspension bridge respectively. They are usually exposed to the adverse environment and sensitive to corrosion because of high working stress. Albeit intensive and protective measures and steps are taken, damage and defects are found in routine and specific inspections. In the 1970s and 1980s, two-barrier corrosion protective system, prestressing strand inside polyethylene (PE) sheath injects with cement slurry and polymer-modified cement slurry, had been widely used. For this system, the anchoring zone is a deficiency-prone region, and many other problems may occur in the cement slurry grouting process, for instance, cracking in PE sheath due to higher grouting pressure and shrinkage of PE sheath with the decrease in ambient temperature, defects resulting from cement slurry grouting in separate stages and damping after solidification, insufficient grouting, cement paste segregation, all of which may induce the corrosion of the wire or strand, stress corrosion, corrosion fatigue and so on. Corrosion cases of stay cables and suspenders are listed in tables 4 and 5 respectively.

Table 4 Cable corrosion of several cable-stayed bridges in China

No.	Name	Comp-letion	Span/m	Corrosion situation	Desciption	Served time/year

1	Jiujiang Bridge	1988	13×16+40+6×50+2×160+13×50+40+7×16	About 70% of sheaths were damaged and over 30% of wires corroded and broken. Both ends of the anchor heads corroded seriously.	Single pylon cable stayed bridge with double inclined cable, ordinary prestrssing wire and hot extruded LDPE sheath.	11
2	Haiyin Bridge	1988	85.5+175+85.5	Cable 15 fallen off, cable 9 relaxed. Insufficient grouting of cement slurry in the range of 3m to the end of the cable. Wires corroded seriously.	Double pylon cable stayed bridge with single inclined cable, 3-cell box section, high strength galvanized steel wires and prestressing strand inside PE sheath injected with cement slurry and polymer-modified cement slurry.	7
3	Yellow River Bridge	1982	40+94+220+94+40	In the inspection of 1986, aluminum sheaths splitting and rusty spots on wires were detected and then treated. In 1990, cable wires corroded severely with a depth of 42mm on occasion. Some wires relaxed.	Double pylon cable stayed bridge with double inclined cable, galvanized steel wires and prestressing strand inside PE sheath injected with cement slurry and polymer-modified cement slurry.	14
4	Sanshui Bridge	1996	180+110	Cracks occurred in 27 inner sheaths. The original protective material in ducts aged. 34% of ducts were in ponding.	Single pylon cable stayed bridge with dissymmetrical double inclined cable and hot extruded PE sheath covered with orange PU protection layer.	8
5	Jianwei Minjiang Bridge	1990	52+66+240+66+52	PE sheath was fractured. Profile of the bridge was somewhat changed. 56.2% of wires corroded and 17.2% broken.	Double H-type pylon cable stayed bridge with double inclined cable, 3-cell box section and hot extrusion PE sheath.	9
6	Bayi Great Bridge	1997	50+2×160+3×50+3×50+2×160+50	Microcracks could be found in all the cable coating, and 15 cables severely cracked. Corrosion, spalling of concrete and ponding occurred in some anchor heads.	Double pylon cable stayed bridge with double fan-type cable plan and PE sheath.	10
7	BaiSha-Zhou Yangtze River Bridge	2000	50+180+618+180+50	Severe damage of cable sheaths occurred, and several high strength steel wires exposed to air and rusted. Ponding and rust could be found in anchors and embedded pipes.	Double pylon cable stayed bridge with double cable, high strength galvanized steel wires and HDPE sheath.	6
8	Panora-mio Bridge	2001	40.5+136+320+136+40.5	Sheath cracking could be found in 127 cables out of 192. Corrosion occurred in cable wires and anchorages. Stress in some cables exceeded the limits.	Double pylon cable stayed bridge with single inclined cable, wrapped with glass and polyester filament at the inner layer and hot extrusion PE sheath in the outer layer.	7
9	Fuling Yangtze River Bridge	1997	149+330+149	Various degrees of damage occurred in 73% cables and 84% cable sheaths, and 94% anchor heads. For the anchor heads, 399 were suffering from 8 kinds of	Double pylon cable stayed bridge with double cable, Π-type section of girder, suspension system with sperated pylon and girder.	9

				damage, including rust in sealing cover and penetration of water.		
10	Linjiang-men Bridge	1994	9×30+2×132.5+6.52	Cracking, breakage and aging occurred in sheaths. Some anchor heads and wires in anchorage zone corroded.	Single pylon cable stayed bridge with double fan-type cable plan, galvanized steel strands covered with glass fiber cloth and hot extrusion HDPE sheath.	—

Table 5 Cable corrosion of several suspension bridges in China

No.	Name	Compl-etion	Span/m	Description of corrosion	Description of bridge	Served time/year
1	Nanpan-jiang Bridge	1998	18.5+24.1+3×20.5+240+4×20.5	Spalling of paint and corrosion occured in most anchorage zone of suspenders. The steel plate for fixing the main cable saddle corroded and bolts thereof missing on occasion.	The main cable are 19×97 ϕ5 parallel high-strength galvanized steel wire tendons, 39 pairs of suspenders (61 ϕ 7 steel wires) in total, rise-span ratio is 1/11.	5
2	Xiling Yangtze River Bridge	1996	255+900+225	The entire protective coating system of the main cable deteriorated, including peeling and spalling, resulting in water entering the cable sleeve.	110 × 91 ϕ 5 high-strength galvanized steel wire tendons for main cable, polyisobutylene putty and polyisobutylene putty wrapped with round wires, rise-span ratio is 1/10.465.	—
3	Fengdu Yangtze River Bridge	1997	164.5+450+130	No corrosion prevention measures were taken inside the cable saddle and the external coating aged and spalled. Anchor rods seriously corroded. The depth of water in anchor chamber was over 1m and the relative humidity was more than 70%.	61 × 91 high-strength galvanized steel wire tendons for main cable, rise-span ratio is 1/11.	16
4	Wujiang Bridge	1997	66+60+168+60+66	Isabelline rust stain on the surface of main cable in midspan was clear, and water vapor could be found inside the sleeve and corrosion products deposited on steel wires. Almost all the screws and nuts on the lower end of suspender were corroded.	Each suspension cable consists of 85 parallel steel wires with PE sheath.	—
5	Jiangyin Yangtze River Bridge	1999	336.5+1385+309	Various degrees of corrosion occurred in cable wires and many wires broken.	Steel wire rope for suspender with hot extrusion PE sheath.	10

PRECAUTIONARY AND TREATMENT MEASURES

Excessive Deflections of Main Girder and Cracks in Girder

Design

Further research should be made to improve the design of long-span prestressed concrete box girder bridges, including a calculation method considering spatial effects and long-time deflection, enhancement of rigidity of superstructure. Particularly, reasonable arrangement of prestressing tendons is an important aspect need to investigated further (Xie *et al*. 2007).

It is crucial to adopt a proper shrinkage and creep model for predicting the long-time deflection of prestressed box girder bridges in design. Bažant (2012) concluded by studying the Koror-Babeldaob Bridge that poor material model for creep and shrinkage is one of the main causes of underestimation of deflection and prestress

loss. Besides, it is important to select appropriate parameters relating to the prediction of prestressing loss. Enlarging frictional coefficient appropriately, setting reasonable camber and reserving tendons for remediation are other measures.

Environmental temperature change plays an important role for the long-time deflection and cracking of prestressed box girder of bridge. So, refined analysis of thermal effect is important in design. In addition, the inclined crack resistance can be improved by providing transverse prestressing tendons in the cell box and bend-up reinforcements in the web (Ren 2007).

It is effective to reduce long-time deflection by increasing the depth-span ratio appropriately (Qi *et al*. 2007). This is because, firstly, the stiffness of the main girder is enhanced and the stress state in the section is improved, secondly, the efficiency of prestressing is raised owing to the increase of the eccentricity of longitudinal prestressing tendons in the case of tendons percentage keeping constant (Pan 2013; Song and Zhu 2008). Increasing the number of the cells in the box girder, reducing the span to width ratio of the bridge and the height of the pylon are benefit to minimize the shear lag effect.

Construction

The following are some tips for reducing the long-time deflection and cracking of prestressed box girders of a bridge associated with construction:
1. Guarantee sufficient vibration of concrete and the construction quality.
2. Pay attention to the treatment of joints, ensuring the roughness of the interface.
3. Load concrete as late as possible. Don't stack too many construction materials on deck.
4. Position the corrugated pipe accurately and smoothly.
5. Ensure the prestressing force reaching preset control value, especially the vertical prestressing tendons.
6. Control the accuracy of bridge deck camber.
7. Drag the prestressing tendons as late as possible in permission of construction time to avoid excessive prestressing loss caused by creep of early-age concrete (Zhou 2013). Grout in time after prestressing tendons dragging.

Operation management

Overspeed and overload of vehicles on the bridge should be strictly prohibited. Periodic inspection mechanism should be established and regular maintenance should be strengthened. Once a deficiency is found, the causes should be clarified and the severity should be assessed. In some situation, the damage should be repaired on time, for example, cracks in concrete.

Cable Protection

The type of cable, suspender and anchorage should be selected and reliable measures of protection and vibration absorbing system should be adopted appropriately. Protection of the PE sheath should be taken and repaired timely in case of damage. In order to prevent the anchorage from corrosion, the exposed parts of anchorage ends should be coated with special rust cement and stainless steel waterproof covers should be installed (Liang 2008; Guo *et al*. 2009; Tao 2010). Steel duct should be sealed up by filling with special materials such as polyurethane foamed plastic. To isolate anchorages from water vapor and corrosive elements, sealing collars should be installed and sealed with water stopping silica gel (He 2002; Ye and Zhong 2005). Regular inspection and maintenance strategy should be made and carried out.

CONCLUTION

On basis of a great amount of literature and survey reports, a clarification is made on typical damage and deficiencies observed in the superstructures of long-span bridges in China, and the causes are identified. It is manifested that the prestressing loss, shrinkage and creep of concrete, cracking of concrete and corrosion of reinforcing steel in concrete are all accountable for the excessive long-time deflection of girders. A decrease in effective prestressing is one of the major agents that cause typical cracks in box girders, while the damage to the PE sheath in transportation, installation and ageing in operation are responsible for the corrosion of stay cables and suspenders. As a matter of fact, numerous factors are related to the deterioration of performance of long-span bridges and more challenges lie ahead for tackling the related problems. Thus, great effort should be made on in-depth research, refined designs and construction, as well as maintenance and rehabilitation.

ABSTRACT

A large amount of resources has been invested in building and maintaining existing infrastructure. Several of these structures are now becoming old and do not meet the requirements of today and/or are reaching the end of their technical lifespan. It is not possible to replace all of these structures, that are deemed or are about to be deemed obsolete, due to high cost and environmental impacts. An approach to keep these structures in use for a longer time is through an innovative and intelligent assessment of the actual state of stress and behavior. In such cases, using structural health monitoring to assess the structure might be an efficient way to extend the life of the structure.
This paper describes a unique monitoring program for two similar 33 m long steel truss bridges situated in Sweden. One of these bridges, Aby River Bridge, had a regulated axle load of 25 tons and was tested to failure in 2013. The other bridge, Rautasjokk Bridge, has a regulated axle load of 30 tons which will be upgraded to 32.5 tons and will be in use for the coming years. The monitoring program was performed as; monitoring of the bridge over Aby River when it was still in service. After replacement the old bridge was moved and tested under static loads to assess boundary conditions and state of stress. Structural parts from this bridge were then disassembled and tested for material properties and fatigue capacity. A theoretical assessment of the Rautasjokk Bridge was performed based on the conclusions from the measurements on the Aby Bridge. Finally, the plan is to verify findings by performing measurements on live loading for the Rautasjokk Bridge in service limit state, to be performed during autumn 2015. The aim of this project is to verify the continuous safety for the Rautasjokk Bridge by using input from tests performed at both bridges.

Structural Health Monitoring, Steel truss bridge, Fatigue, Model updating, Assessment.

INTRODUCTION

Bridges have often been replaced on theoretical assumptions that they have reached the end of their lifespan. Beside the safety aspects, the economy is the single most important factor when it comes to exchanging bridges. In later years the environmental burden has also gained influence in becoming a concern in decision-making. The Swedish Traffic Administration has declared intentions to increase their work with Life Cycle Analysis (LCA), (Trafikverket 2012). For bridges, this will lead to that a greater amount will be assessed for their actual capacity before necessary actions are taken, whether it is repairs, upgrading or replacing the entire structure.

The assessment of an existing bridge can be performed with different levels of accuracy and effort. Generalized load-models might often be sufficient in order to verify if the load capacity is good enough or at least serve as an initial estimation. Conservative assumptions may, however, lead to an exaggerated safety level. Together with increased loads, the simple solution is often to replace the structure. The opposite, overestimating the capacity can however be catastrophic. Failure of a bridge may result in major delays and possible human casualties.

Up to 2012, the Swedish authorities own 3842 railway bridges and 145 tunnels and over 13,642 km railway tracks, (Du and Karoum 2014). A substantial part of the bridge stock in Sweden and Europe is older than 50 years, as shown in Figure 1, at the same time; loading and traffic intensity on our existing bridges are increasing as time goes by.

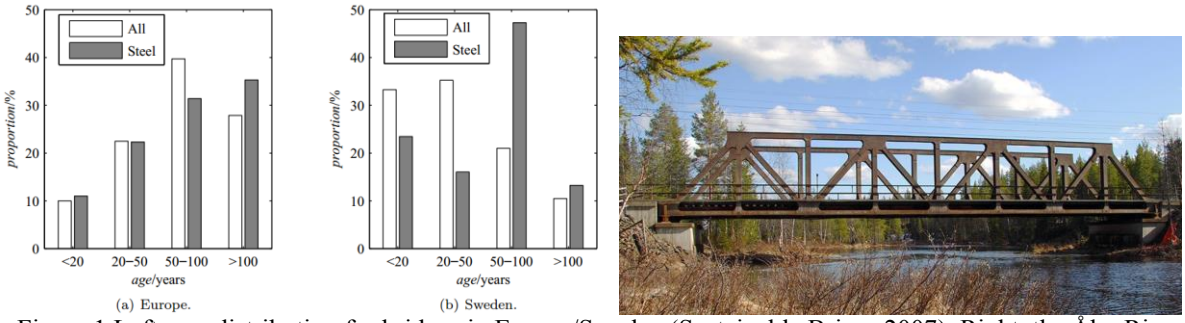

Figure 1 Left, age distribution for bridges in Europe/Sweden (Sustainable Briges 2007). Right, the Åby River Bridge in its original position.

An increase in traffic, both in regard of weight and intensity significantly reduces the lifespan of steel bridges due to Fatigue. The load models and estimation of the fatigue capacity is not as straight forward as for the ultimate limit state, which makes it more difficult verify the proper safety levels due to uncertainties.

Even if several old bridges theoretically have served their lifespan concerning fatigue or insufficient load capacity due to increased loads and increased traffic they are not necessarily in need of being exchanged. With the help of new knowledge together with refined calculations and inspections it might be possible to prolong the lifespan of these bridges. In order to ensure continued safety of the bridge it is often required to monitor the structure by preforming measurements.
The bridge over Aby River is one of these brides that theoretically had reached the end of its lifespan, when it was replaced in 2012. In order to gain knowledge of its structural behavior, the old bridge was moved to temporary supports close to its original position in order to be tested for both static and dynamic loading

The overall aim of this study was to identify critical hotspots for the Aby River-bridge and to develop a method for assessing these. Another objective is to identify measurements that characterize the structural behavior, in order to create a method for non-destructive assessment of similar bridges. The reason for the particular interest of this bridge is that there is an identical bridge over the Rautasjokk River, located on the iron ore line in the northern parts of Sweden. If the measurements from the Aby River-bridge can provide information that the bridge over Rautasjokk doesn't need to be replaced, great savings can be made.

PREVIOUS WORK

Before the Aby-River Bridge was taken out of service in the autumn of 2012, measurements were performed while it was still in use. Since the live measurements was less comprehensive than the final tests, it served as a step towards planning the full scale tests. Train loads were known and therefore it was possible to calibrate models to measured data (Blanksvärd 2012a; Blanksvärd 2012b; Moreno 2013).

Simulations of the intended load case were performed prior to the test by a Finite Element Model created in ABAQUS. The model was made as a shell model with the limitations of not assigning any constraints at the joints; therefore all connections are fully rigid. Strain hardening is not considered either.

Digital image correlation (DIC) measurements were performed at the joint between the longitudinal stringer beams and the crossbeams, in order to evaluate the degree of constraint in the connection between the stringers and the crossbeams which according to calculations were the critical detail which led to the exchange of the structure. The evaluation of these results (Elhag 2012) can be found in the master thesis by Elhag.

GEOMETRY AND MATERIAL

The Bridge consisted of a 33 meter long steel truss railway bridge that was located along the Swedish mainline. Since it was built in 1951, it was designed according to the present trainloads type F46 which corresponds to 25 tons axle load which also is the present load on the railway. The location for the bridge is in a rural environment and approximately 50 km from the coast. Girders and connections in the bridge are partially riveted and partially welded. The steel used in the superstructure is described in Table 1 with material properties according to (Trafikverket 2005).Compared with the steel materials used today the variation of material properties from the time of construction are far greater (Larsson and Lagerqvist 2009). The yield strength used in the modelling of the bridge are higher than the measured values. The modelling in this paper were done based on a priori knowledge, data from similar structures, the actual properties were tested after destruction of the bridge.

Table 1 Material properties used for analysis

Part	Material	F_{yk}	F_{uk}	F_y Used for modelling	F_y Measured	F_u Measured
Stringer beams, verticals, diagonals	S1311	240 MPa	360 MPa	345MPa	308MPa	460MPa
Main truss, Cross girders,	S1411	270 MPa	430 MPa	345MPa	333MPa	475MPa

EXPERIMENTAL WORK

Test Set Up

After the bridge was taken out of service it was transported and mounted on temporary supports close to the tracks. When in place, a vast number of sensors were mounted. The load on the bridge is induced by two jacks where the jack is attached to a girder that distributes the load to four equally distributed point loads. In order to be able to archive the force needed to load the bridge to failure the jacks were anchored to the bed rock. During the phase of drilling the intended precision was not possible which is the reason to why the loads aren't symmetrical around the center of the bridge.

Monitoring Program

This project is a unique opportunity to gain knowledge of the structural behavior of this kind of bridges. Since the full scale testing was performed under a limited amount of time which will finally resulted in failure of the bridge, the program for measurement was made as comprehensive as possible. The limitations for the test equipment were 145 channels and 141 were used during the tests. In addition to this, DIC measurements were made. The different sensors were divided between 72 strain gauges, 46 LVDT's, 8 temperature gauges and the DIC measurements (Aramis-system, from GOM). This paper will be limited to the measurements for the global analysis of the main truss. The measurements consist of 18 different predefined load series where three last ones are done with the rail removed and the last one to failure. Figure 3 show how the load was varied over the different series of measurement. The sensors placed on the main truss for the global analysis are illustrated in Figure 2 and Figure 4 and further described in Table 2.

Table 2 Sensors for measuring global effects

Sensor	Units	Description	Sensor	Units	Description
LFRS1	mm	Rotation at support	RFD1	µm/m	Three directional strain gauge
LFRS2	mm	Rotation at support	RFV1_3	µm/m	Three directional strain gauge
LFS1	mm	Settlements at support	RFV1_4	µm/m	Three directional strain gauge
LFS2	mm	Settlements at support	TFV1_2	µm/m	Strain gauge in main direction
LM1	mm	Deflection at mid span	TUF1	µm/m	Strain gauge in main direction
LM2	mm	Deflection at mid span	TUF1_4	µm/m	Strain gauge in main direction
LRFV1	mm	Horizontal deflection	TUF2	µm/m	Opposite side of TUF1
LRMV1	mm	Horizontal deflection	TUM1	µm/m	Strain gauge at both top and lower flange
LRS1	mm	Settlements at support	TUM1_4	µm/m	Strain gauge at mid span
LRS2	mm	Settlements at support	TUM1_4s	µm/m	Strain gauge in main direction
LRST1	mm	Rotation at support	TUM2	µm/m	Strain gauge at both top and lower flange
LRST2	mm	Rotation at support	TUM3	µm/m	Strain gauge on the vertical at mid span

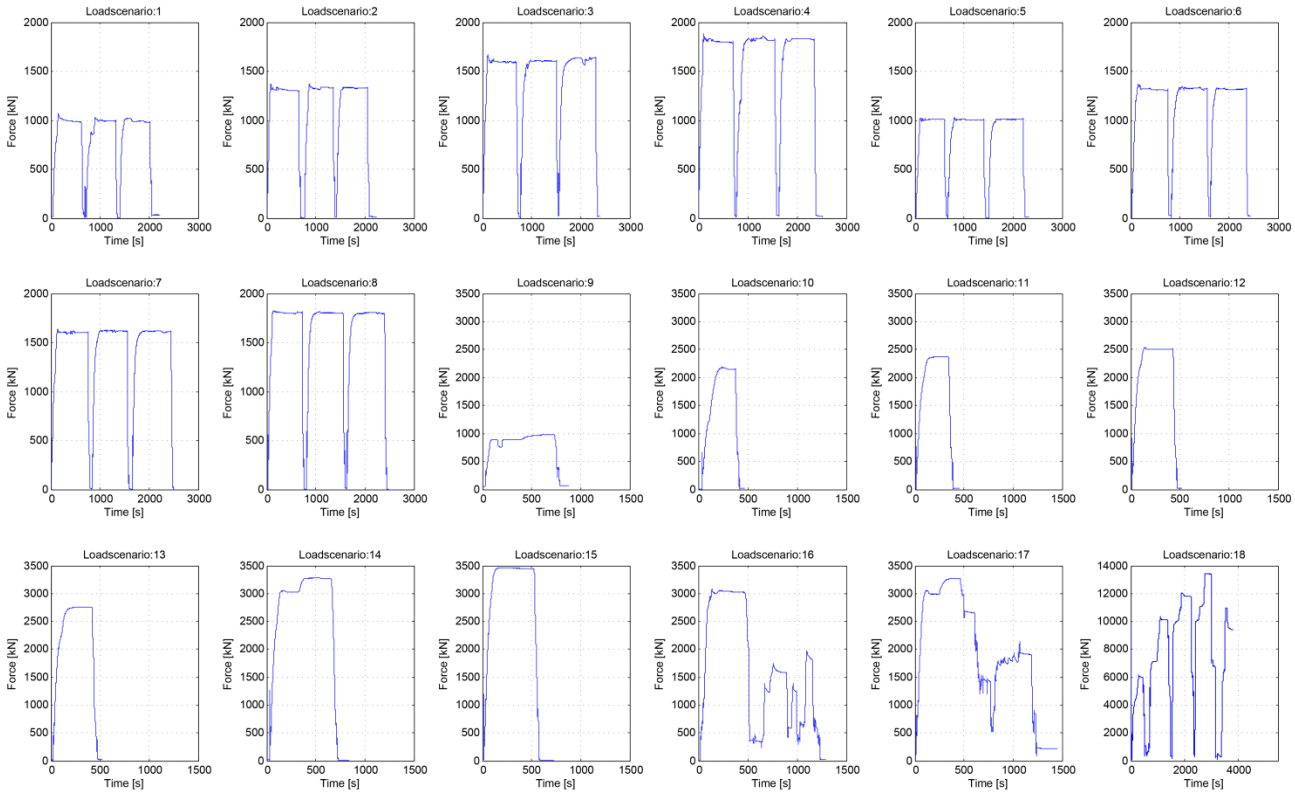

Figure 3 Load scenario (units are loading force in kN on the y-axis and elapsed time in seconds on the x-axis)

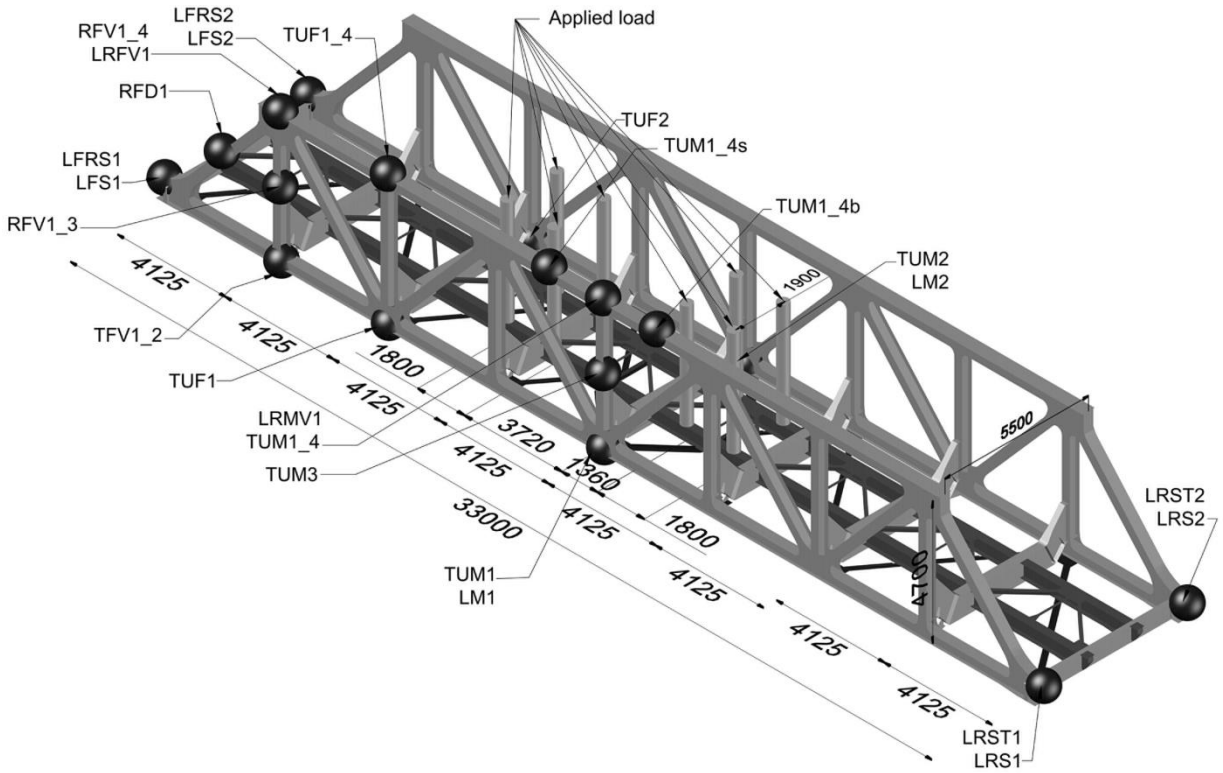

Figure 4 Position of sensors for global measurements, with the description in Table 2

Since the FEM-simulation indicated that buckling of the top frame would be the limiting failure mode, the horizontal displacement was monitored; the sensor is shown in Figure 6b. The positions of the both sensors for measuring the horizontal displacement are shown in Figure 4. Figure 6b illustrates the sensor measuring the global deflection at mid span. At the same point the strains were measured for the lower frame for both the upper and lower flange. By measuring the strain of two or more points on a cross section it is possible to calculate the section forces that are caused by a specific load. Since the bridge was placed on temporary supports and loaded to failure, settlements were likely to occur. In order to be able to adjust and get correct results for deflection it was necessary to measure the settlements at the supporting points which are shown in Figure 4 together with the sensors for measuring rotation at the support.

RESULTS AND DISCUSSION

Estimations made before testing by the Finite Element Software Abaqus indicated that the global failure would occur at approximately at 9MN and that it would be buckling of the top frame in the main truss. Before buckling of the frame there would be some yielding and redistribution of forces in the structure. The results in Figure 6 show both the static non-destructive testing and the final test to failure. For the static load scenarios one point is taken for each terrace point, which means that for load scenario 1-8 three points of measurement were taken and for 9-17 it is just one whereas the failure test are shown in its whole. Values from the sensors are given as a function of the total force induced by both of the hydraulic jacks. The jacks are manually controlled, but kept at an equal load level. The force is calculated as a function of the oil pressure and the area of the cylinder. In Figure 5 the expected results from the simulation are displayed together with the measured results. Looking at the diagram, one can conclude that the simulation corresponds well to the measured results regarding global deformation within the linear elastic range. However, once it starts yield the results differs to some extent. The reason for the difference in FEA results compared to the measured response beyond the elastic range is that redistribution of stresses close to the load (patch loading failure) was conservative in the FEA. Figure 5 also show the magnitude of what live load that the tested load corresponds to.

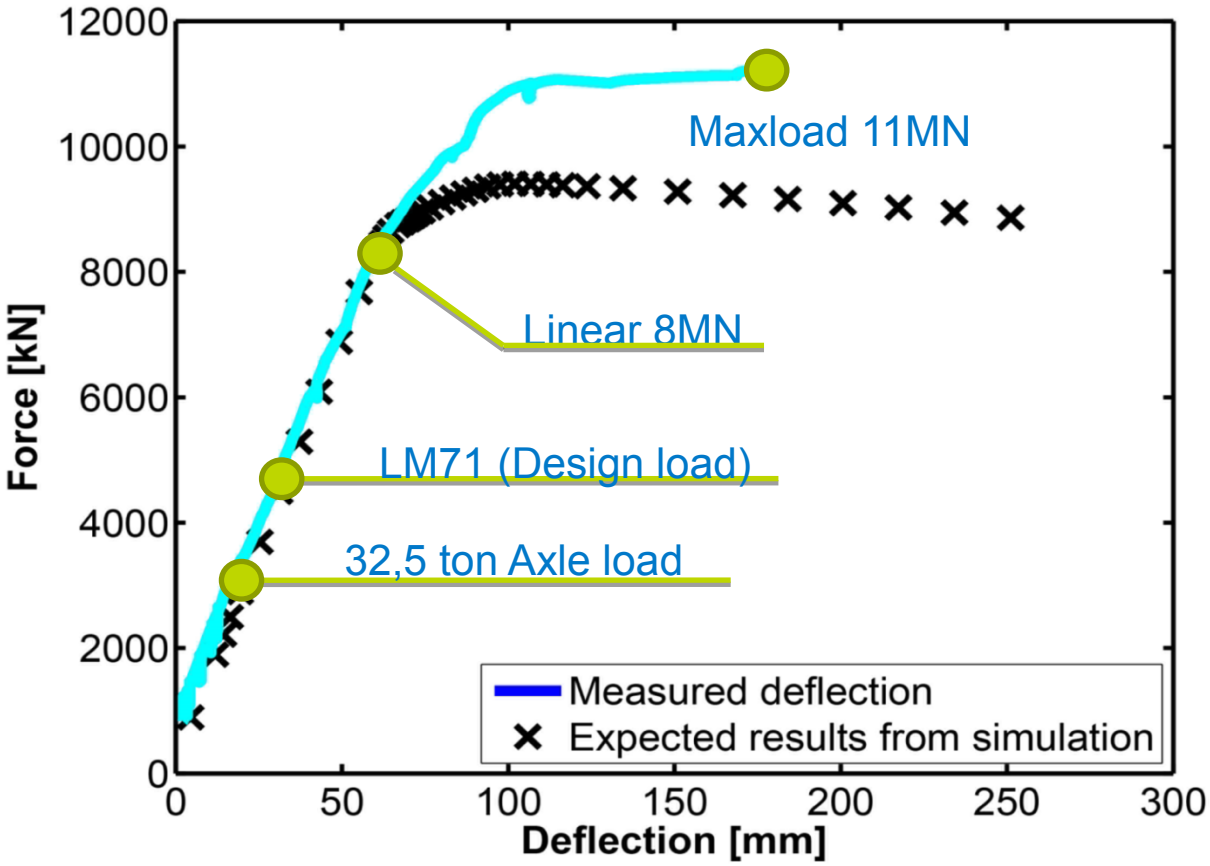

Figure 5 Deflection at mid span (sensor LM2). The figure also show the expected outcome based on the simulation and the parts that are cut out because of repositioning of the jacks.

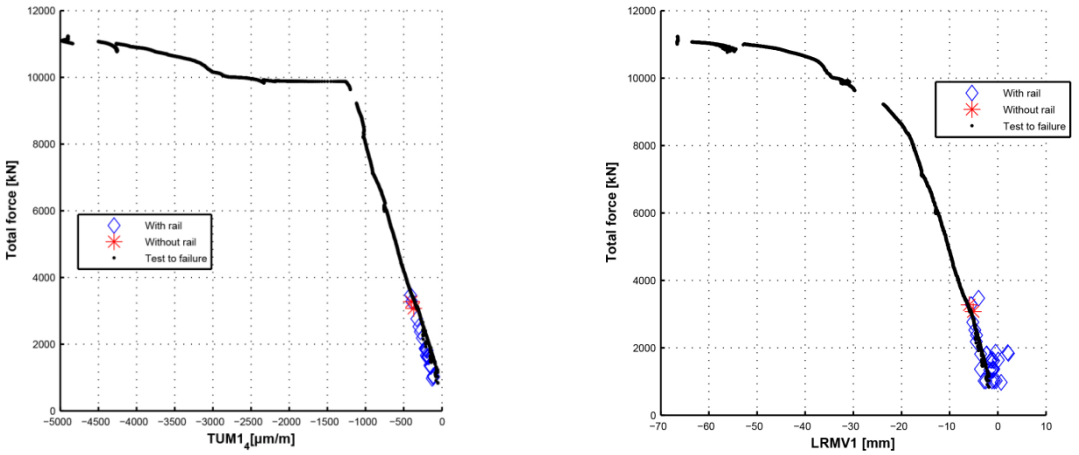

A B

Figure 6 A) Strain as a function of total force, B) Horizontal deflection for the top frame in the upper frame at mid span

As the load increases, the top frame eventually starts to yield. By observing Figure 6a it appears that the yielding starts at approximately 10MN, since the member is compressed without constraints in the horizontal direction buckling will occur as a consequence, as seen in Figure 6b and 7b.

Besides the global buckling mode of the top frame there were local failures underneath one of the load distributing beams Figure 7a. The web could not withstand the high concentrated force which resulted in local shear buckling as well as local buckling due to patch loading.

A B

Figure 7 Left, the local failure of the longitudinal stringer beams. Right, the global failure mode, buckling of the top frame in the truss

An often discussed matter regarding these kinds of bridges are the consideration if the longitudinal stringers should be considered as simply supported or continuous. This is an issue that is of great interest, especially with regard to fatigue. Due to this; the curvature in the joint between the longitudinal stringers and the crossbeam was measured, as can be seen in Figure 8. From the measurements showed in Figure 8c, it is clear that the rail has a significant effect for the continuity of the longitudinal stringers, which could be used when assessing the Rautasjokk Bridge.

CONCLUSION

The failure that eventually prevented the bridge from taking more load was buckling of the top frame, which was an estimated outcome according to the simulation performed on the bridge. Besides buckling of the top frame, there were local failures in the web in the area where the load was applied. The local failure might be interesting to study from a scientific point of view, but is not relevant with respect to the capacity of the bridge since the trainloads will be more distributed. The assessment calculations performed according to the Swedish assessment code for railway bridges proves that the bridge can carry the higher load with regard to ultimate limit state, however, fatigue proved to be the governing problem for the technical lifespan. For the assessment of fatigue, reduction of real stresses through measurement is likely to prove even more fruitful than for ultimate limit state since measurements can be performed on hotspots and a small reduction of the stresses influence fatigue more due to the slope of the Wöhler curve.

FUTURE WORK

The measurements for the Aby bridge has, to date, only been roughly investigated, and will be evaluated further in combination with future work. The steel material has been subjected to tensile testing, toughness tests and fracture mechanical testing, which remains to be evaluated. This involves updating both analytical calculations and numerical modelling.
During the autumn of 2015 a monitoring program for the Bridge over Rautasjokk is going to be performed. The purpose of this monitoring program is to verify assumptions and conclusions made on the Aby Bridge, evaluation of dynamic response as well as measuring hot spots for fatigue under live loading.

FRP STRENGTHENING OF 60 YEAR OLD PRE-STRESSED CONCRETE BRIDGE DECK UNITS

Ryan Cork, Jack Foote, Leo de Waal, Van Thuan Nguyen, Dilum Fernando
School of Civil Engineering, The University of Queensland, Australia
*Email: dilum.fernando@uq.edu.au

ABSTRACT

Over the past few decades Fibre reinforced polymers (FRPs) have gradually gained recognition as an effective material for the strengthening of reinforced concrete (RC) structures. When compared to traditional strengthening methods, FRP has many advantages that make it an attractive alternative. Some of these advantages include FRP's high strength-to-weight ratio and excellent corrosion resistance. This study presents an experimental study investigating the effectiveness of a novel FRP strengthening scheme, which involves glass FRP I beam profiles and carbon FRP pultruded plates, for strengthening existing pre-stressed concrete deck unit bridges in Queensland, Australia. Two 9.05m long pre-stressed concrete bridge deck units taken from a decommissioned bridge in Queensland, Australia were tested under 4-point bending until failure: one as a control and the other strengthened with the proposed strengthening system. FRP strengthening using the proposed system was found to increase the ultimate capacity of the bridge deck unit by 105%. In addition, FRP strengthening was also found to increase the flexural stiffness.
